

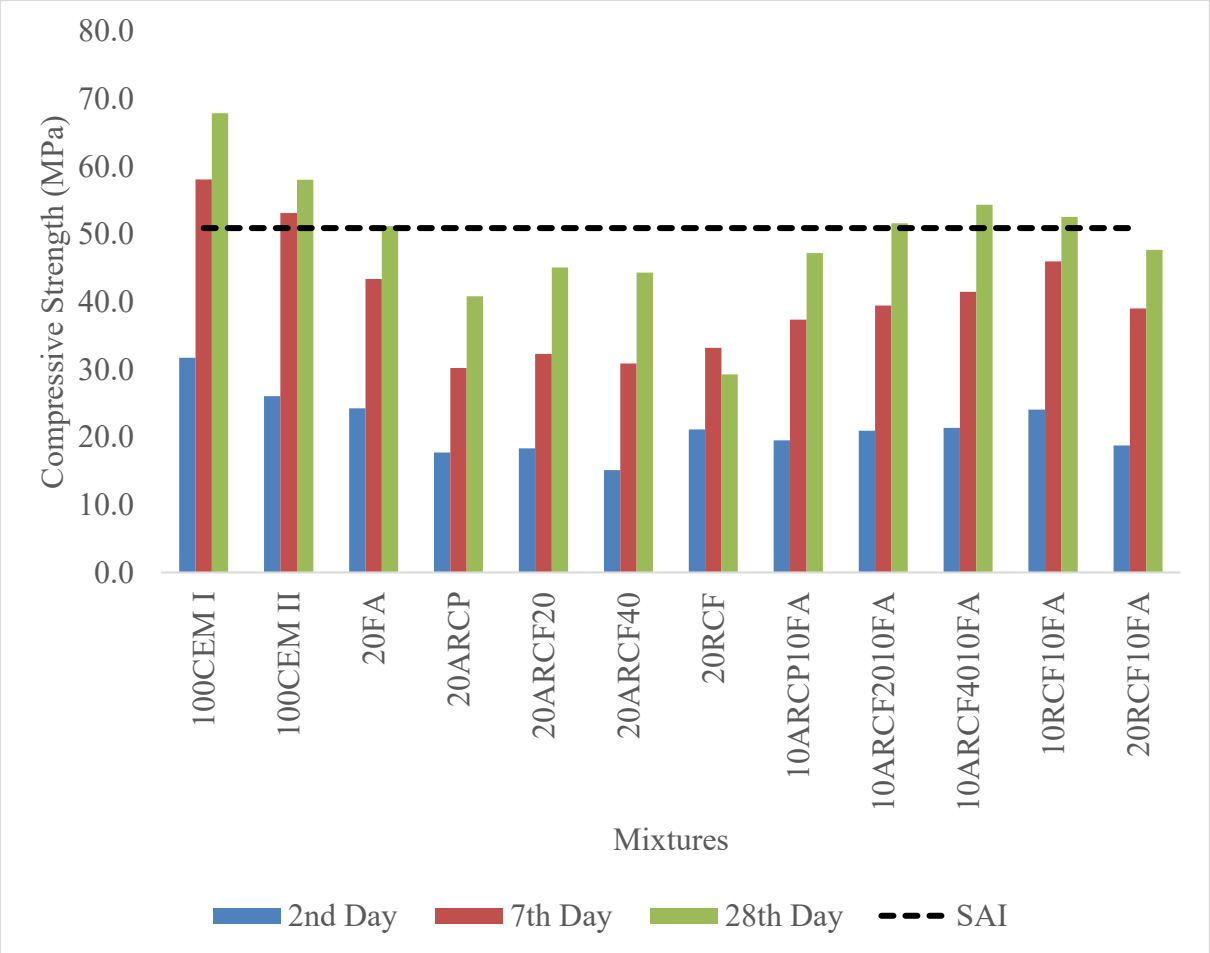

Fig. 2. Compressive strength results.

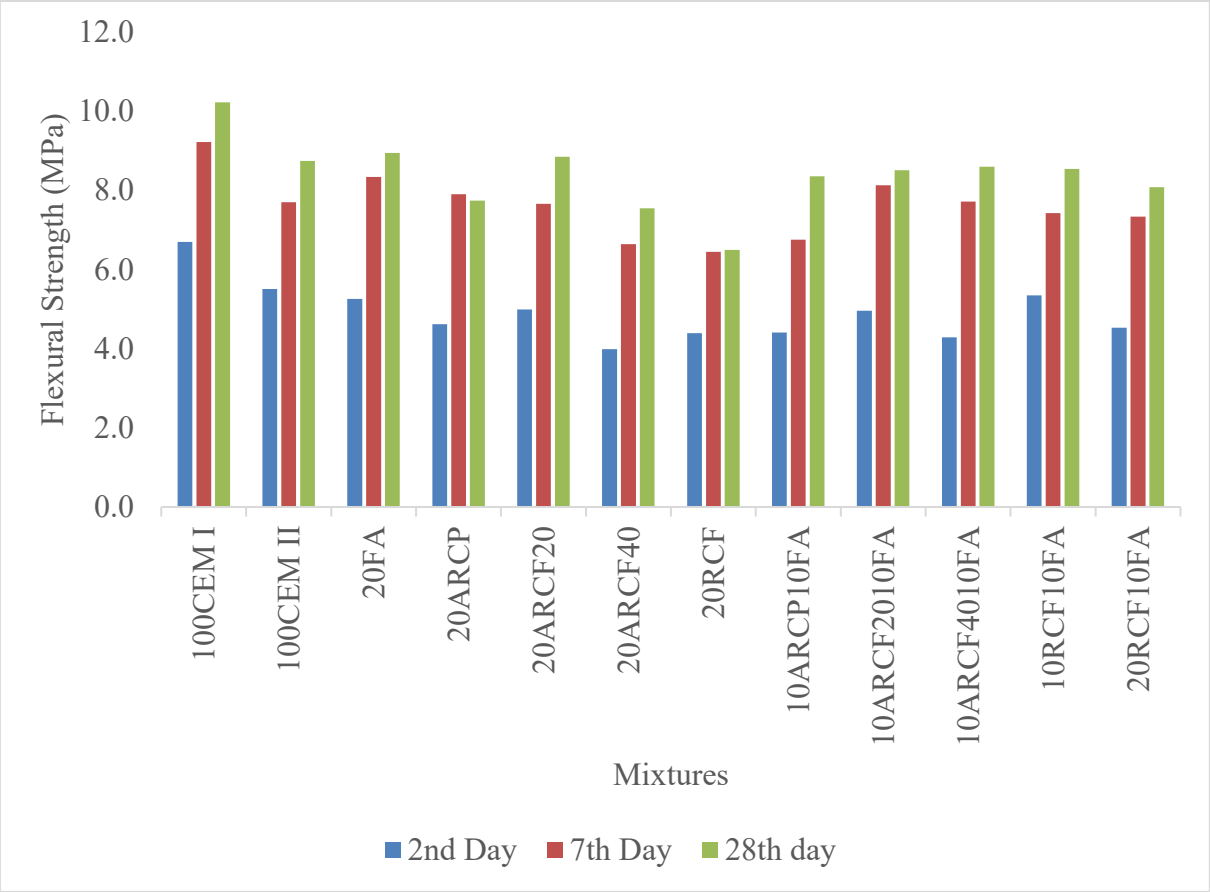

Fig. 3. Flexural strength results.

4 Conclusion

Overall, the results suggest that recycled concrete powder can be used partially in place of cement but its mechanical performance depends significantly on the properties of the recycled concrete powder used and the water demand in the mix. Direct 20% RCP substitution resulted in a significant decrease in 28 days strength. However, hybrid mixes using 10% RCP and 10% FA together provided a more balanced mechanical performance. It can be said that it compensated to some extent for the strength losses that occurred in some mixes using only RCP. The mix that best achieved fly ash recovery was the one using RCP; fly ash recovery was limited in the mix using ARCP. Therefore, based on the results RCP alone should not be considered a supplementary cementitious material. The compressive strength activity of the 20FA, 10ARCF2010FA, 10ARCF4010FA, and 10RCF10FA mixtures provided 75% of the reference mixture and can be used as pozzolans in concrete applications according to the ASTM C311 standard. Optimization within the mix should consider the type of RCP used, the w/b ratio and the use of other materials. Finally, the hybrid RCP-FA combination approach allows for acceptable mechanical performance using recycled materials.

Abstract. Concrete sludge waste generated during the ready-mixed concrete production process contains hydrated cementitious phases and fine aggregate. Due to the heterogeneous content of concrete sludge, its direct reuse in concrete is limited. This study investigated the use of two different types of concrete sludge, obtained directly from the bottom of a pool and processed through a filter press, and obtained through carbonation as a substitute for cement. In the carbonation process, the materials were first moistened by adding water at 25% of their dry mass. The materials were carbonated for an hour in an environment of 75 ºC and 100% CO_2. Physical, chemical and mineralogical properties were determined both before and after carbonation. The sieve residues, blaine fineness, water demand and setting times of the binder phases of mixtures with 6% and 15% cement substitution were examined. The compressive strengths of the produced mortars were determined and their mechanical performance was analyzed. The results indicate that substitution levels such as 6%, are suitable for the evaluation of materials like concrete sludge. However, higher levels of substitution indicate that the mineralogical composition, particle size and carbonation process of the concrete sludge need to be optimized together.

Keywords: Alternative supplementary cementitious materials; CO_2 sequestration and mineralization; recycled materials.

1 Introduction

A large portion of the carbon emissions released in cement production originates from clinker production and fuel. Therefore, reducing the clinker ratio in cement production and developing alternative binder materials remains important. This is the first step towards the cement and concrete industry becoming carbon neutral [1,2]. With the circular economy, not only additives such as fly ash and blast furnace slag but also the use of powders obtained from concrete waste as alternative complementary cementitious materials in cement production has gained importance [3,4].

Concrete sludge, which is formed after washing mixers in ready-mix concrete plants or after the return of unpoured concrete from the construction site, may contain components such as hydrated or partially hydrated cement particles, calcium hydroxide, calcium carbonate, and fine aggregate. Direct storage of this material poses an environmental risk due to both the need for

storage space and the high alkalinity of the material. In contrast, appropriate dewatering, drying, and grinding processes can allow concrete sludge to be pulverized and used as a substitute for cement or fine aggregate. However, the variable internal structure, low reactivity and water-increasing effect of this material may limit its usage rate [3-5].

Carbonation of concrete waste is an approach that allows calcium-containing hydrated phases, which are the hydration products of cement, and calcium silica hydrate to react with CO_2 to form stable calcium carbonate phases. Carbonation efficiency can vary depending on the particle and surface properties, void ratio, water absorption properties, and mineralogical structure of the material [4,6,7]. It can be said that carbonated reclaimed fine materials can accelerate hydration, fill pore structures and contribute to mechanical strength when used up to a certain percentage [5-8]. Carbonation efficiency depends on parameters such as CO_2 concentration, temperature, relative humidity, processing time, particle size, and initial moisture content. Water is required in the medium for the reaction. Excess water in the medium can prevent the gas from penetrating into the particles; low water content can limit the dissolution and penetration of ions [6].

Many studies exist in the literature on the carbonation of recycled concrete powders. However, studies on the use of fine fractions obtained from ready-mixed concrete plants after several processing flows as cement substitutes are limited. Furthermore, there is a lack of research on the carbonation of this material. Therefore, chemical, mineralogical and mechanical investigations related to the carbonation of concrete sludge are important.

The aim of this study was to compare two different types of concrete sludge obtained from the bottom of sedimentation pool (WCS) or filter presses (FCS), in their carbonated and non-carbonated forms (cWCS and cFCS) by substituting 6% and 15% cement in the mortar phase. X-ray fluorescence (XRF) and X-ray diffraction (XRD) analyses were performed to understand the effect of carbonation. Specific gravity, blaine fineness, sieve analysis, water demand, and setting time tests were conducted on the binder phase mixtures in the mortar. The compressive strengths of the produced mortars were evaluated at 1, 2, 7, and 28 days.

2 Materials and Methods

In the experiments, ordinary portland cement (PC) was used as the reference binder. Two different types of concrete sludge were selected. These were wet concrete sludge (WCS) taken from the bottom of the settling pool and concrete sludge (FCS) that passed through the filter press process after the settling pool. The carbonated versions of these concrete sludges were coded as cWCS and cFCS, respectively.

Two different concrete sludges (WCS and FCS) were moistened with water at a rate of 25% of their dry weight prior to carbonation. The moistened materials were then carbonated in a controlled environment with a 100% carbon dioxide (CO_2) concentration and a temperature of 75 °C for one hour. The high CO_2 concentration and temperature enabled the acceleration of the mineralogical transformation in such a short time as one hour.

The main oxide components in PC, WCS, FCS, cWCS, and cFCS samples were determined using X-ray fluorescence spectrometry (XRF) in Table 1. The CaO content of concrete sludges varies between 29.8% and 33.9%. SiO_2 content ranges from 23.3% to 33.2%, and Al_2O_3 content from 6.2% to 7.6% (Table 1). The lower CaO/SiO_2 content of concrete sludges compared to PC does not necessarily mean that these materials will not exhibit PC like hydration behavior. However, the remaining hydrated phases with their fine particles, filling, and nucleating effects can contribute to mechanical performance. After carbonation of the concrete sludges, the ignition loss value of WCS increased from 20.9% to 28% (Table 1). This increase in ignition loss is consistent with the increase in the XRD results (Table 2). The same behavior was observed in the FCS sample. The ignition loss value of FCS also increased from 23.2% to 25.2%

(Table 1). The greater change in ignition loss of WCS suggests that the material has a higher carbonable phase content and is more susceptible to carbonation. The specific gravities of WCS, FCS, cWCS, and cFCS are 2.47, 2.70, 2.40, and 2.60, respectively. Decreases in specific gravities were observed after carbonation of the materials. Therefore, when concrete sludge is substituted for cement, the volume of the binder phase may increase slightly. This increase in volume can cause changes in water demand.

The mineralogical phase structure of the concrete sludges was determined by X-ray diffraction (XRD). XRD analysis revealed the presence of calcite, quartz, alite, portlandite, tobermorite, and silica phases in the materials using the Rietveld method (Table 2). According to XRD results, the dominant phase structure in the concrete sludges is calcite. Calcite, which was 60.1% in WCS, increased to 93.9% in cWCS (Table 2). Furthermore, while portlandite and tobermorite phases were present in WCS, these phases could not be detected in cWCS. This result suggests that carbonation converts portlandite to calcium carbonate and then also degrades tobermorite, converting its calcium content to calcium carbonate. The dissolution and carbonation of calcium-containing hydrated phases are consistent with the mechanisms described in the literature for recycled concrete powders [5-7]. No carbonation effect was observed in the FCS sample as in the WCS sample. The limited increase in calcium carbonate suggests that FCS may have already carbonated before carbonation or that the reactive calcium phases were lower (Table 2).

Table 1. Chemical analysis.

Component (%)	WCS	FCS	cWCS	cFCS	PC

Materials derived from concrete sludge were used in mixtures at 6% and 15% by weight as replacements for portland cement. The reference mixture used 450 grams of PC, 1350 grams of standard sand and 225 grams of water, according to European standards. In the 6% concrete sludge replacement series, 423 grams of PC and 27 grams of substitute material were used; in the 15% concrete sludge replacement series, 382.5 grams of PC and 67.5 grams of substitute material were used. The water/binder (w/b) ratio was kept constant at 0.5 in all mixtures. No additional chemical additives were used in the mixtures (Table 3).

The 32, 45, and 90 µm sieve values, blaine specific surface area and specific gravity of the prepared binder phase mixtures containing carbonated and non-carbonated concrete sludges were determined in Table 4. The specific surface areas of the binder mixtures varied between 4500-4550 cm^2/g, but efforts were made to keep them close to each other. In addition, the sieve oversize values increased with increasing carbonated or non-carbonated concrete sludges substitution ratio (Table 4). The standard consistency water demand and setting initial and final times of these binder mixtures were measured. The 1, 2, 7, and 28-day compressive strengths of the mortar samples were measured.

Table 4. Physical properties of the binder phases in the mortar mixtures.

Mixture	32 µm (%)	45 µm (%)	90 µm (%)	Specific Gravity (g/cm^3)	Fineness (cm^2/g)
Reference	22.4	11.1	1.4	3.14	4500

15cWCS	29.4	16.4	2.0	3.09	4510

3 Findings

In the consistency test, water demands varied within a narrow range of 23.8%-25.6% in all mixtures. The 6WCS mixture had the lowest water requirement at 23.8%, while the 15cWCS mixture had the highest at 25.6%. The initial and final setting times of the reference mixture were 129 and 201 minutes, respectively (Fig. 1). The 6WCS mixture showed an earlier setting time compared to the reference mixture, with a setting start time of 116 minutes and a setting final time of 186 minutes. In contrast, the initial setting time of the 6cWCS mixture increased to 160 minutes, and the final setting time increased to 250 minutes. In mixtures using FCS, the 15cFCS mixture showed initial setting time of 195 minutes and final setting time of 283 minutes. The literature does not provide consistent interpretations regarding the behavior of carbonated materials in relation to setting time. Since it will vary depending on the physical, chemical and mineralogical properties of the carbonated material, it may also have positive or negative effects on the hydration mechanism [5,8]. According to this study, it can be said that carbonated materials generally extend the setting time (Fig. 1).

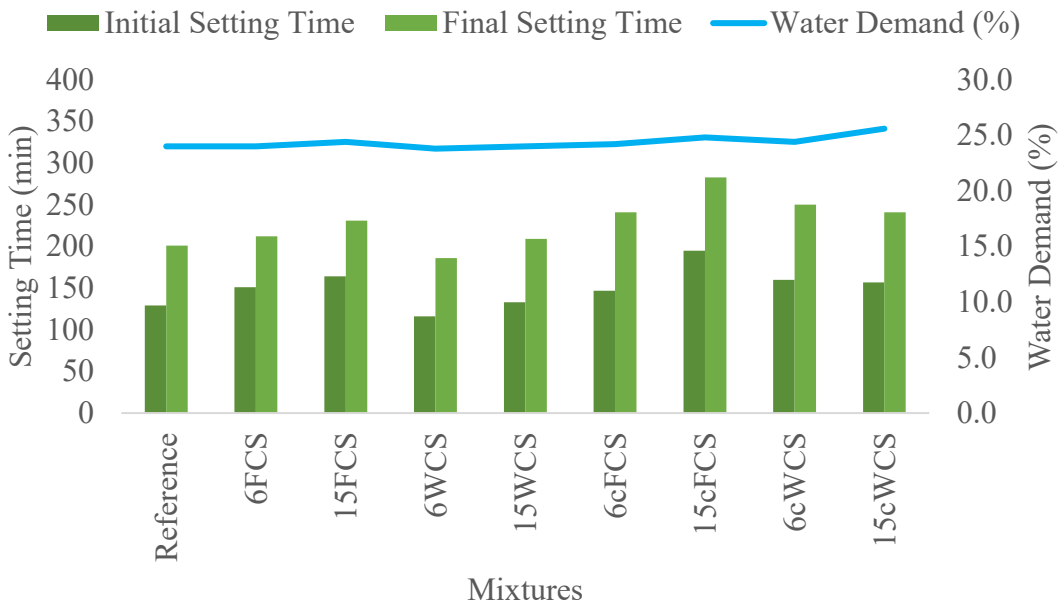

Fig. 1. Setting time results of all mixtures.

The 1, 2, 7, and 28-day strengths of the reference mortar were 21.2, 33.1, 49.2, and 59.2 MPa, respectively in Figure 2. All sludge substituted mixtures performed below the strength of the reference mixture at all days. The main reasons for this are the reduced clinker content and the low early reactivity of the sludge-based material. Despite this, the strength difference decreased in some substituted mixtures at higher ages. The 6FCS mixture exhibited the best performance among the sludge substituted mixtures. 6FCS showed a compressive strength of 48.4 MPa at 7 days and 58.2 MPa at 28 days. These values correspond to approximately 95% of the compressive strength of the reference mixture. The 6cFCS mixture also reached approximately 95% of the reference at 28 days with 56.4 MPa. The 6WCS and 6cWCS mixtures yielded strengths of 53.6 and 54.0 MPa, respectively. These results indicate that a 6% substitution rate was able to maintain mechanical performance. At a 15% substitution rate, a significant loss of strength was observed across all series. The 28-day strengths of the 15FCS, 15WCS, 15cFCS, and 15cWCS mixtures were 45.3, 44.3, 46.8, and 44.9 MPa, respectively. As the substitution

rate increased, the carbonated series showed better improvements compared to the non-carbonated series. cFCS provided 1.5 MPa higher 28-day strength than FCS, while cWCS provided 0.6 MPa higher 28-day strength than WCS. Nevertheless, the improvement in the carbonated mixtures was not sufficient to compensate for the loss of strength (Fig. 2).
The effect of carbonation on strength can vary depending on the material type and the percentage of substitution. Carbonation of FCS at 6% reduced the 28-day strength by 1.8 MPa, while carbonation of WCS increased it by 0.5 MPa. At a 15% substitution level, carbonated mixtures yielded higher strength than non-carbonated mixtures. Based on these results, it can be said that optimum carbonation should not be attributed solely to calcium carbonate formation. Advanced carbonation can reduce reactivity by consuming hydrated phases and improve carbonation nucleation behavior [6-9]. When comparing WCS-cWCS, although the increase in calcite after carbonation was high, the strength gain was limited. In other words, it can be said that the effect on mechanical performance is not limited only to mineralogical change. In conclusion, a linear relationship between CO_2 sequestration capacity and cement substitution performance should not always be expected (Fig. 2).

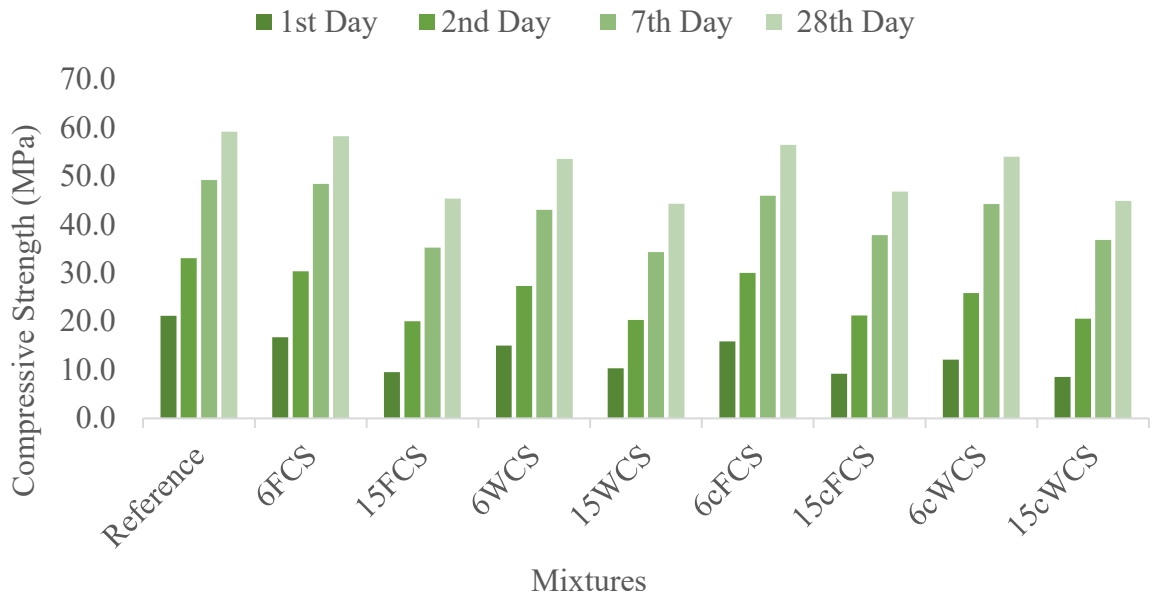

Fig. 2. Compressive strength results of all mixtures.

4 Conclusion

In this study, carbonated derivatives of concrete sludges processed in two different ways (WCS and FCS) were investigated under conditions of 100% CO_2 concentration, 75 °C temperature, 25% humidification and 1 hour by substituting 6% and 15% portland cement. The results obtained are:
-Carbonation caused a mineralogical change in WCS, increasing the calcite content from 60.1% to 93.9%. Portlandite and tobermorite structures were not detected.
-Loss on ignition values increased from 20.9% to 28% in WCS and from 23.2% to 25.2% in FCS. This behavior indicates calcium carbonate formation.
-Water demands varied between 23.8% and 25.6%, and the setting times of carbonated materials were generally longer.
-6FCS mixture gave the best compressive strength result in concrete sludge substitute mixtures.

-Increasing the substitution ratio to 15% resulted in a loss of strength in all series. In mixtures containing carbonated materials, an increase in strength was observed but it did not reach the strength of the reference mixture.
-The results indicate that using 6% concrete sludge is a promising study in terms of recovery and sustainability. For higher concrete sludge substitution ratios, particle size distribution, degree of carbonation, reactivity, and other factors should be considered together.

Early-age strength development in slag-fly ash geopolymers: effect of varying ohmic heating curing durations

Mazem Yılmaz[1] and Mucteba Uysal[2]
[1] 0000-0003-3616-9396, Istanbul Aydin University, Civil Engineering Department, Istanbul, Türkiye, mazembalaban@aydin.edu.tr

Abstract. In this study the effects of ohmic heating curing duration on the physical and mechanical properties of slag-fly ash-based geopolymers were investigated. Specimens were subjected to electrical curing under constant voltage for 3, 6, 12, and 24 hours, and the development of UPV, compressive strength, and flexural strength was evaluated. In addition, the 3-day strength values of specimens cured for 24 hours were compared with those cured at room temperature in terms of setting time, unit weight, porosity, and water absorption. The results show that increasing the ohmic heating duration accelerates geopolymerization kinetics, shortens the setting time, and significantly enhances early-age mechanical strength. In addition, ohmic heating curing method reduced the final setting time by 82% compared with ambient curing condition and under ohmic heating curing while the geopolymer achieved a compressive strength of 24.63 MPa after only 3 hours. Furthermore, the effects of different ohmic heating durations on strength development were clearly identified, providing valuable insights for optimizing the curing period. Overall, the results demonstrate that ohmic heating curing is an effective and practical method for achieving rapid strength gain and process optimization in geopolimer production.

Keywords: Ohmic heating curing; early-age strength; geopolymer; potassium activator.

1 Introduction

Due to sustainability-oriented approaches, research on geopolymer materials has increased significantly. Geopolymers are amorphous binder materials formed by the activation of aluminosilicate-based raw materials, such as ground granulated blast furnace slag (GGBS) and fly ash (FA), using potassium-based, sodium-based, or combined hydroxide-silicate alkaline solutions [1]. In geopolymer systems, thermal curing is generally required to achieve high early-age strength [2] [3]. FA with low calcium content exhibit slow strength development at ambient temperature. The curing method plays a decisive role in determining the physical and mechanical properties of geopolymer systems in the hardened state [4]. Various curing techniques can be applied to these materials, including ambient curing, thermal curing, steam curing, and ohmic heating [5].

Ohmic heating is a rapid curing technique based on the application of alternating current (AC) to the specimens and has emerged as a more environmentally friendly alternative compared to conventional dry steam curing methods [6]. Also referred to as electrical curing, this method converts electrical energy directly into thermal energy by passing an electric current through a medium with limited electrical conductivity [7]. As a result, the specimen is heated volumetrically and uniformly, significantly reducing the temperature gradient between the interior and the surface [8]. Consequently, crack formation caused by thermal gradients is more limited compared to other thermal curing methods. Moreover, curing techniques involving

external heating, such as autoclaving or steam curing, are difficult to implement under construction site conditions, whereas the application of AC to fresh concrete through ohmic heating enables early-age strength development in situ. In addition, ohmic heating significantly shortens the setting time by accelerating the early-age reaction kinetics [9]. This approach may help overcome major barriers to the widespread use of geopolymer materials. Kovtun et al. [10] reported that the 28-day compressive strength of alkali-activated FA concrete produced using electrical curing reached 48.5 MPa, whereas the same mixture cured under ambient conditions exhibited a compressive strength of only 10.9 MPa. Aygun et al. [11] reported that, in GGBS-FA-based geopolymers, replacing 80 °C thermal curing with electrical curing resulted in an increase in compressive strength of up to %148.

In this study, the effect of ohmic heating curing on the early-age mechanical and physical properties of GGBS-FA-based geopolymer mortars activated with potassium-based activators was investigated. Within this scope, the strength development of geopolymer mortars up to 3 days was examined. In addition, the setting times of specimens produced under ambient and ohmic curing conditions were compared, and their unit weight, porosity, and water absorption values at the age of 3 days were determined in accordance with ASTM C642 standard.

2 Materials and Experimental Methods

Ground granulated blast furnace slag (GGBS) and fly ash (FA), whose chemical composition are given in Table 1, were used as cementitious materials. Natural sand with a particle size range of 0-5 mm was selected as the fine aggregate. Potassium hydroxide (KOH) with molarity of 12 M and potassium silicate (K_2SiO_3) were used as alkaline activators.

Table 1. The chemical composition of the binders (%).

	SiO_3	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	K_2O	Na_2O	SO_3	LOI
S	40.80	12.82	1.13	0.77	34.56	6.57	0.63	0.81	0.22	0.03
FA	59.67	25.22	4.61	-	0.47	2.27	1.36	0.61	0.55	0.013

GGBS and FA were used as binders as a 1:1 ratio by weight. The binder-to-sand ratio was 1:2.5, the activator-to-binder ratio was 0.60, and the KOH-to-K_2SiO_3 ratio was 1:2. The specimen preparation was carried out in the following stages. First, the dry materials were mixed for 2 minutes to ensure homogeneity. The alkaline activators were mixed for 2 minutes after which they added to the dry mixture. The resulting mixture was then mixed for an additional 2 minutes. The freshly prepared geopolymer mortar was cast into prismatic molds with dimension of 40 x 40 x 160 mm^3 in two layers, and each layer was compacted using a vibration table. The prepared specimens were then subjected to the curing conditions specified in Table 2.

Table 2. Curing conditions.

Curing Type	**Curing conditions**	**Curing procedure**
Ambient curing	22±1 °C and %65 relative humidity	After casting, the specimens were kept in the molds for 24 h and then demolded.
Ohmic heating	Constant 25±1 V voltage	Immediately after casting, the specimens were subjected to electric curing at the specified voltage for 3, 6, 12, or 24 h, and then demolded.

Under ohmic heating conditions, copper plates were attached to the 40 x 40 mm cross-sectional faces of the wooden molds (40 x 40 x 160 mm), and a constant voltage applied to the specimens

through these plates using and AC power supply. The variation of the current and specimen temperature as a function of time during 24 h of ohmic heating is presented in Fig. 1.

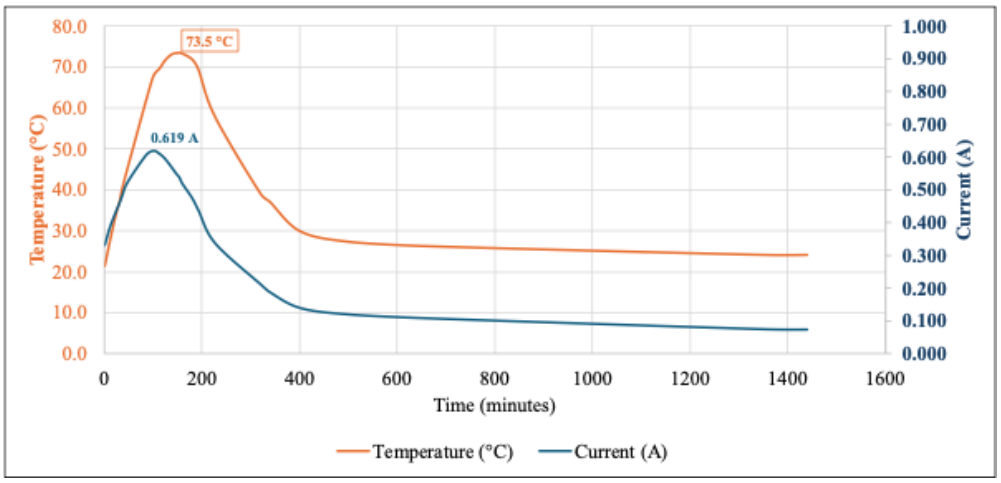

Fig. 1. Variation of current and specimen temperature as a function of time during 24 h of ohmic heating.

To evaluate the strength development of specimens subjected to ohmic heating curing, ultrasonic pulse velocity (UPV) measurements, as well as compressive and flexural strength test, were conducted at curing ages of 3, 6, 12, and 24 hours, and at 3 days, in accordance with TS EN 196-1. The specimens were exposed to ohmic heating curing for a maximum duration of 24 hours. Specimens tested at 3 days were stored under ambient conditions after first day. For comparison, specimens cured under ambient conditions were also tested for UPV, flexural and compressive strength at 1 and 3 days, the results were compared with those of the ohmic heating cured specimens. In addition, setting times were measured for both curing methods. Furthermore, the bulk density, water absorption, and porosity of the 3-day-old specimens were determined using the wire basket method.

3 Result and Discussion

3.1 Setting Time

The setting time result are presented in Table 3, and it is observed that ohmic heating has a pronounced shortening effect on the setting time. While specimens cured under ambient conditions completed their setting in approximately 245 minutes, the final setting time of the specimens subjected to ohmic curing was reduced to about 45 minutes, indicating an acceleration of the setting process by approximately 82%.

Table 3. Setting time results.

Curing condition	Initial setting time (min)	Final setting time (min)
Ambient curing	200	245
Ohmic heating curing	35	45

3.2 Unit Weight, Porosity, and Water Absorption Results

The results presented in Table 4 indicate that ambient curing and ohmic curing have limited effects on the unit weight, porosity, and water absorption properties of the specimens. While

the unit weight of the specimens cured under ambient conditions was determined to be 2.06 g/cm³, a slight decrease to 2.04 g/cm³ was observed for the specimens subjected to ohmic curing. An examination of the porosity values reveals that the porosity of the ohmic curing specimens was slightly higher (15.5%) compared to that of the ambient curing specimens (14.9%). Similarly, the water absorption ratio of the ohmic curing specimens was measured as 7.54%, showing a marginal increase relative to the ambient-cured specimens (7.13%). These increases suggest that the rapid reaction development induced by ohmic heating at early ages may lead to the formation of a relatively more open pore structure, particularly during the initial stages.

Table 4. Setting time results.

Curing type	Unit weight (%)	Porosity (%)	Water absorption (%)
Ambient curing	2.06	14.9	7.13
Ohmic curing	2.04	15.5	7.54

3.3 Compressive Strength, Flexural Strength and UPV

The results presented in Fig. 2 and Fig. 3 clearly demonstrate that ohmic heating curing significantly accelerates early-age compressive strength development. Specimens subjected to ohmic curing achieved a compressive strength of 24.63 MPa after only 3 hours, which increased to 31.43 MPa after 12 hours, corresponding to an increase of approximately 27.6%. The rate of strength gain was notably high during the first 12 hours, after which the rate of increase gradually decreased. This rapid early strength development can be attributed to the homogeneous internal temperature rise induced by ohmic heating, which accelerates reaction kinetics within the binder system. The internally generated ohmic heating enhances ion mobility and promotes faster formation of the binding gel phase, leading to early matrix densification. As the reactions progress and the availability of reactive phases decreases, the strength gain rate diminishes at later ages. In contrast, specimens cured under ambient conditions exhibited a compressive strength of 8.10 MPa at 1 day, which is approximately 74.3% lower than that of the ohmic-cured specimens (31.48 MPa). Although the compressive strength under ambient curing increased by 116.3% from 1 to 3 days, reaching 17.52 MPa, this value still corresponded to only 44.9% of the strength achieved with ohmic curing. These findings indicate that ohmic heating curing provides a substantially more effective approach for enhancing early-age compressive strength compared to ambient curing.

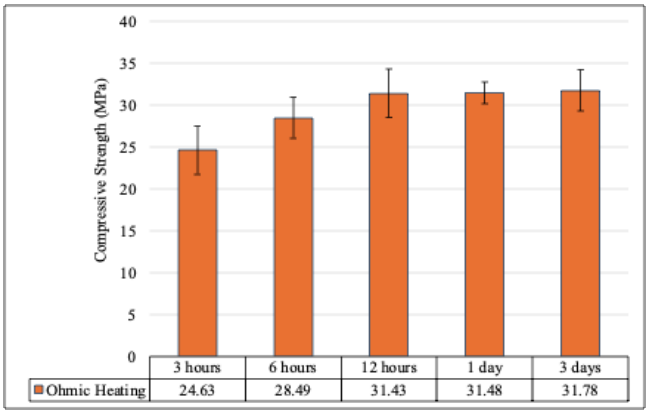

Fig. 2. Compressive strength development of the specimens during the first 3 days under ohmic curing.

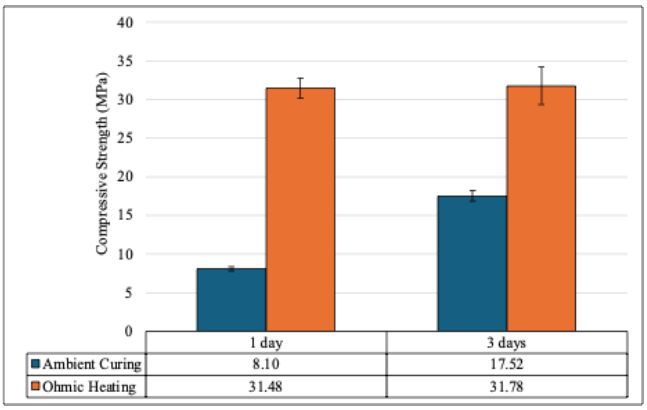

Fig. 3. Compressive strength results under ambient and ohmic curing.

The development of flexural strength under ohmic heating curing during the first 3 days is presented in Fig. 4, while the comparative results with ambient curing are given in Fig. 5. The findings clearly indicate that the application of ohmic heating significantly accelerates the development of early-age flexural strength. For the specimens subjected to ohmic curing, the flexural strength reached 4.706 MPa after only 3 hours and increased to 6.189 MPa at 1 day, corresponding to an increase of approximately 31.5%. In contrast, the specimens cured under ambient conditions exhibited a flexural strength of only 2.160 MPa at 1 day, which is considerably lower than that of the ohmic-cured specimens.

After 3 days of curing, the flexural strength values reached 3.769 MPa and 6.275 MPa for the ambient-cured and ohmic-cured specimens, respectively. Despite the gradual strength gain observed under ambient curing, the flexural strength achieved at 3 days remained lower than that obtained with ohmic curing. These results demonstrate that ohmic heating curing promotes a faster development of the microstructure at early ages, leading to a pronounced improvement in flexural strength.

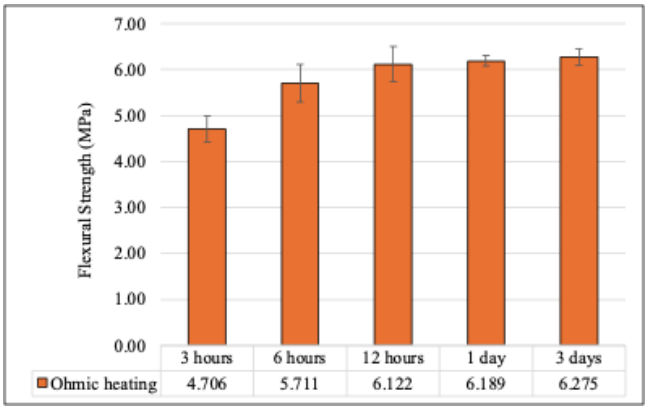

Fig. 4. Flexural strength development of the specimens during the first 3 days under ohmic curing.

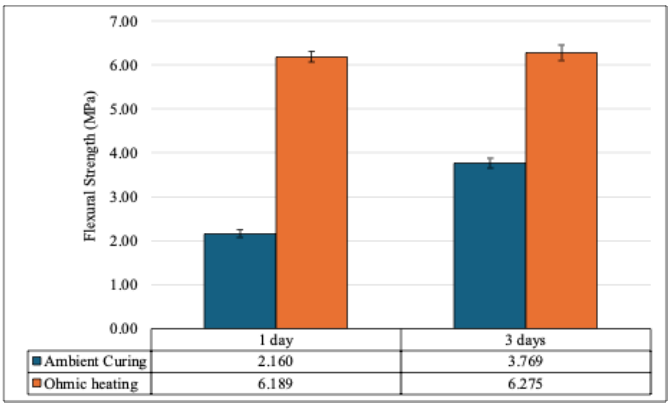

Fig. 5. Flexural strength results under ambient and ohmic curing.

UPV is non-destructive testing method used to evaluate internal voids, cracks, and discontinuities in concrete. An increase in ultrasonic wave velocity generally indicates improved homogeneity, and overall quality of the concrete. The development of UPV under ohmic heating curing during the first 3 days is presented in Fig. 6, while the comparative result with ambient curing is provided in Table 5. The result show that the UPV value of the specimens subjected to ohmic heating reached 3226 m/s after only 3 hours and increased by approximately 12.2% to 3618 m/s at. 3 days. In contrast, the UPV value of the specimens cured under ambient conditions was measured as 3504 m/s at 3 days. These findings are consistent with the compressive strength results and suggest that ohmic heating curing contributed to a more compact matrix structure, which was reflected in the higher early-age UPV values.

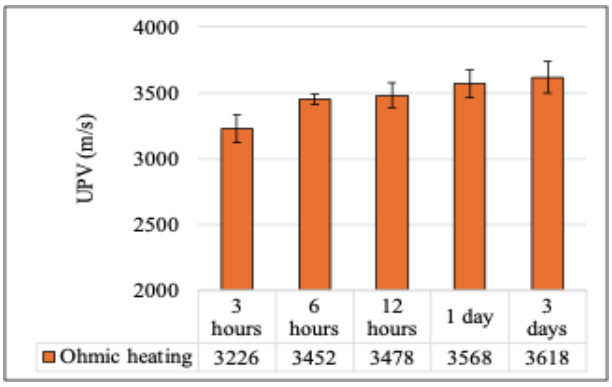

Fig. 6. UPV development of the specimens during the first 3 days under ohmic curing.

Table 5. UPV results.

Curing condition	**UPV (m/s)**	
	1 day	**3 days**
Ambient curing	3319	3504
Ohmic curing	3568	3618

4 Conclusion

The main conclusion obtained from this study are presented below.

- Ohmic heating resulted in an approximately 82% shorter final setting time compared to ambient curing.
- Ohmic heating curing achieved a compressive strength of 24.63 MPa after only 3 hours.

- Ambient-cured specimens exhibited a 44.9% lower compressive strength (17.52 MPa) lower than the 3-day compressive strength of those subjected to ohmic curing (31.78 MPa).
- Ambient-cured specimens exhibited a 39.9% lower flexural strength (3.769 MPa) lower than the 3-day flexural strength of those subjected to ohmic curing (6.275 MPa).
- Ambient curing and ohmic curing have limited effects on the unit weight, porosity, and water absorption properties of the specimens.

Abstract. One of the most popular methods for reducing the carbon footprint of cement-based materials is to incorporate mineral admixtures capable of carbonation, such as reactive magnesia, into the systems. However, studies on their use in construction materials are very limited. In this research, two distinct magnesia sources—magnesite and dolomite—were calcined at different temperatures and exposure times in laboratory conditions to produce magnesias with varying reactivities. Their reactivities were compared using the citric acid reactivity test, the corrected hydration conversion ratio and the change in mass during calcination. Based on the results, the most reactive magnesia was selected and added to Portland cement containing fly ash and GGBFS, at 15% and 30% of the total powder content by mass. The specimens were exposed to three different CO_2 concentrations: 0.04% (for 28 days), 20% (for 2 days), and 50% (for 2 days) under similar temperature and humidity conditions. Their mechanical performance on the 1st, 3rd, 7th, and 28th days was compared. The most reactive magnesia samples were obtained from calcining dolomite at 800 °C for 3 hours and from magnesite at 600 °C for 2 hours. The mortars containing reactive magnesia showed low strength regardless of the curing regime. However, the presence of reactive magnesia modified the strength gain in CO_2 curing regimes.

Keywords: Carbonation; Reactive magnesia; Curing; Portland cement.

1 Introduction

Nowadays, in order to reduce the carbon footprint of cement-based construction materials, a very common method is to incorporate mineral admixtures, which can be inert or have hydraulic and/or pozzolanic properties, into Portland cement clinker [1]. Few of them, however, can enhance mechanical properties by binding the CO_2 in the air to their structure. In other words, they have the ability to react with CO_2 in air and form carbonates, increasing strength by carbonation [2]. One of the most popular admixtures for enhancing strength of cementitious composite with such a mechanism is reactive magnesia.

The reactive magnesia is generally obtained through a calcination process of magnesium carbonates, which leads to the decomposition of the carbonate structure and removal of the CO_2 [2, 3]. The calcination temperature causes microstructure modifications and differences in the reactivity of the magnesia produced [2, 4, 5]. Therefore, the magnesias obtained are usually divided into groups according to their calcination temperature and, hence, their reactivity [3, 4, 6, 7, 8]. These, from the highest to the lowest reactivity, can be classified as reactive, dead-burned and fused magnesia. It is determined that the reactivity of the reactive magnesia produced at low temperatures such as 600 °C, is higher than that of the dead-burned magnesia obtained from the calcination at high temperatures such as 1500 °C since the latter has a denser crystalline structure than the former. On the other hand, the magnesia reactivity

depends not only on calcination temperature but also other factors such as residence (exposure) time and impurities [4, 7].

The magnesium carbonate, present as an impurity of limestone in raw meal of Portland cement clinker is burned at temperatures of about 1500 °C where the clinker is produced in rotary kilns of cement plants. Due to its exposure to these temperatures, its structure decomposes, forming dead-burned magnesia. Since its reactivity rate is lower than that of the Portland cement, the reactions of magnesia take place later than those of the Portland cement. Since the volume of the hydration products is higher, expansion cracks develop and they undermine the mechanical performance of the whole system [9]. As a result of this, standards regarding the specification of Portland cement, limit the maximum amount of magnesia present in the clinker to 5% or 6%, by weight [10, 11]. Unlike dead-burned magnesia, the reactive magnesia does not cause to crack due to expansion in the matrix. The reactions of reactive magnesia occur at the same time as or before the hydration of the Portland cement, so the hydration/carbonation products requiring higher space to form, do not lead to the expansion cracks in the fresh state of Portland cement fraction [2]. This allows reactive magnesia to be used safely in Portland cement systems [2].

Blends of Portland cement and reactive magnesia are defined as reactive magnesia cements [6]. In order to avoid undesirable consequences, it is important to determine the reactivity of magnesia before its use in the cement since that it can create unintentionally expansions or not is depending on its reactivity [4, 9]. To measure its reactivity, methods such as the citric acid coloration time or the magnesia hydration conversion ratio tests have been proposed by researchers [2, 8, 9, 12].

The reactive magnesia cements are reported to reduce the overall CO_2 emissions due to not only a reduction in the amount of Portland cement clinker but also its ability to absorb CO_2 in air to its structure [2]. In addition, it is considered that if stack gas of a typical cement plant is used for the curing environment of the reactive magnesia-incorporated cementitious composites, the overall emissions can be reduced further [5, 13, 14].

The largest mineral reserve of Türkiye is dolomite, the volume of which is estimated to be 15.8 billion tons [15]. Turkish magnesite production in 2016 reached 3.2 million tons, which positioned Türkiye as the world's leading magnesite producer after China [16 ,17]. It is therefore important to find possible ways to utilize them in cement industry in regarding to proposing a solution to reduce CO_2 emissions resulted from cement plants. Incorporating the reactive magnesias produced from two different Turkish magnesium carbonate sources into Portland-composite cements can both decrease the overall carbon footprint for the production and increase the mechanical performance of the end products through their ability to be carbonated.

In the literature, numerous studies were conducted on the microstructure, mechanical performance and durability of reactive magnesia cements, preferring not producing by calcining magnesium carbonates to obtain reactive magnesia, but utilizing commercially-available MgO having almost no impurity, as the reactive magnesia [2, 8]. However, in this study, the reactive magnesia was selected among the magnesias produced by calcining two different magnesium carbonate sources with different burning regimes under laboratory conditions. This paper aims to achieve the following: (1) to obtain reactive magnesia, by calcining naturally obtained magnesium carbonate sources, namely dolomite and magnesite, mined in Türkiye, under different burning regimes and determine the most reactive one with respect to its reactivity; (2) to investigate its mechanical performance in different CO_2 levels for Portland-composite cements in the short term; (3) for reactive magnesia cements, to assess the suitability of the mineral admixtures, namely fly ash and ground granulated blast furnace slag frequently used for producing Portland-composite cements. In this study, naturally-obtained sources, namely dolomite and magnesite, were burned under different burning

regimes and the obtained magnesias were compared by means of the change in mass during calcination, the corrected hydration conversion ratio and the citric acid coloration time. After determining the most reactive magnesia sample, it was included to Portland-fly ash and Portland-slag cements at 15% and 30% by mass of total binder. The mortars based on these cements were exposed to different CO_2 curing regimes. The effect of reactive magnesia on the compressive strength was determined under low-, medium- and high-level CO_2 curing regimes and compared with the control samples.

2 Materials and Methodology

2.1 Materials

As the magnesium carbonate sources to produce reactive magnesias, dolomite (D) and magnesite (M) were obtained from Antalya and Kütahya regions of Türkiye, in crushed form, respectively. After grinding them using a laboratory – scale ball mill, their chemical properties were determined as shown in Table 1. Fig. **1** shows the XRD profile of the magnesium carbonate sources used.

Table 1. Chemical analysis results and physical properties.

		Dolomite (D)	**Magnesite (M)**	**Portland Cement (P)**	**Fly Ash (F)**	**Ground granulated blast furnace slag (S)**
Oxide Analyses (%)	LOI	46.1	49.5	4.8	-	-
	CaO	33.1	0.9	60.1	3.7	38.2
	MgO	18.5	43.3	1.7	1.4	5.7
	SiO_2	0.3	0.7	18.9	55.6	37.8
	Fe_2O_3	0.2	0.5	2.7	9.1	0.8
	Al_2O_3	0.1	0.1	4.0	23.1	12.9
	SO_3	0.1	0.03	5.7	0.5	1.3
Physical Properties	Density (g/cm^3)	2.83	2.95	3.07	2.24	2.85
	Fineness (cm^2/g)	~4000	~4000	~4000	~2850	~4800

The Portland-composite cements were produced by incorporating the mineral admixtures to Portland cement (P). As the main binder, the Portland cement (P) used in this study and obtained from Baştaş Cement Factory, was classified CEM I 42.5 R according to TS EN 197-1. The mineral admixtures used were F-type fly ash (F) from Sugözü Thermal Power Plant and ground granulated blast furnace slag (S) from İskenderun Demir Çelik A.Ş. Their oxide composition and XRD profiles are depicted in Table 1 and Fig. **2**, respectively.

2.2 Methodology

The magnesium carbonate sources, namely magnesite and dolomite, were burned under different burning regimes based on TGA results. Various preliminary tests were applied to the magnesias produced to determine the most reactive magnesia sample. The selection considered not only the reactivity of the magnesia, but also the required temperature and exposure time to produce it for environmental considerations. Using the selected reactive magnesia and three curing regimes having different CO_2 levels, mortars were produced to investigate their compressive strength performance.

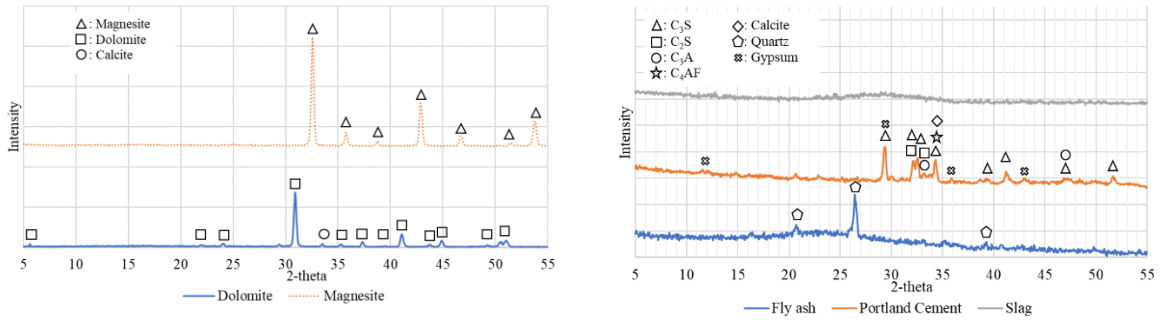

Fig. 1. XRD profiles of the materials utilized.

The calcination process was applied by a furnace and the rate of interior temperature increase was kept constant at about 100 °C/hour. The material was allowed to cool down in the furnace after burning. The magnesias were subjected to various preliminary tests proposed in the literature [8] in order to determine their reactivity:

Citric acid coloration time: This was defined as the required time for 1 g calcined magnesium carbonate sample in 200 mL of 0.0175 M citric acid solution containing a phenolphthalein indicator to change the color of the solution from white to pink during being stirred at a constant rate of 600 rpm. After 30 minutes (1800 seconds), the experiment was terminated for the samples not showing any color change. This method is based on the procedure proposed by Zhu et al. [12].

Change in mass during calcination: The oven-dried magnesium carbonate source, the weight of which was already recorded, was exposed to the burning regime and the mass decrease due to the removal of its CO_2, occurred in the specimen was measured. Even if the loss cannot give any insight into the crystallinity or reactivity, showed whether the temperature was sufficient to calcine the material completely, or not.

Corrected magnesia hydration conversion ratio: A 2 g of dried magnesia sample was mixed with 100 g of distilled water, and in the following day, the solution was filtered to obtain particles in solution with a vacuum pump. The change of mass in dry condition (w_1) shows the mass of water reacted with magnesia to form magnesium hydroxide. Based on stoichiometric calculations and chemical reaction, the magnesia hydration conversion ratio can be written in Eqn. 1. However, due to impurities present in magnesium carbonate sources (which can not be calcined), a factor indicating the purity of the sample (Mass ratio of MgO in calcined sample) should be introduced as presented in Eqn. 2. This method is based on the procedure proposed by Zhu et al. [12].

$$X\,(\%) = \frac{40.30(w_1 - 2)}{18.02 w_0} \cdot 100 \qquad \textbf{Eqn. 1}$$

$$X_{corrected}\,(\%) = X\,(\%) \cdot \frac{1}{\text{Mass ratio of MgO in calcined sample}} \qquad \textbf{Eqn. 2}$$

According to the experimental findings, the most reactive magnesia (RM) was mixed with P, S and F to produce reactive magnesia cements according to the mixture proportions stated in Table 2. The amount of the pozzolanic mineral admixtures (S and F) was adjusted to be 30% of the Portland cement fraction, representing CEM II/B-S and CEM II/B-V types, frequently produced in Türkiye. The amount of reactive magnesia was set relative to the total weight of the Portland cement and mineral admixtures at 15% and 30%. The content of the calcareous sand was fixed at 2.75 times the total binder content (P + S + F + RM) to produce mortars. The mixing process for the mortars was carried out in accordance with ASTM C 109. The reactive magnesia and mineral admixtures were added to the portland cement at the very beginning. The water content of the mortars was adjusted based on mass loss during the calcination process, the details of which are explained in subsequent sections.

Table 2. Mix proportions of reactive magnesia cements.

Reactive Magnesia Cements	Portland Cement (%)	Ground Granulated Blast Furnace Slag (%)	Fly Ash (%)	Reactive Magnesia (%)
	P	**S**	**F**	**RM**
C	100	0	0	0
CS	77.0	23.0	0	0
CF	77.0	0	23.0	0
15CM	87.0	0	0	13.0
15CMS	67.0	20.0	0	13.0
15CMF	67.0	0	13.0	13.0
30CM	77.0	0	0	23.0
30CMS	59.3	17.7	0	23.0
30CMF	59.3	0	17.7	23.0

It was determined that three CO_2 curing regimes would be applied to the specimens in a carbonation chamber. For these, the CO_2 levels were determined to be 0.04% (low level – ambient), 20% (medium level) and 50% (high level). These concentration levels represented the ambient conditions, typical stack gas obtained from a cement factory and CO_2 enriched stack gas of a cement factory, respectively [13, 14]. The curing relative humidity (RH) and temperature were kept constant at 90% and 25 °C, respectively for all curing regimes. To see the effect of CO_2 curing regimes in the short term, the mortars were cured in three regimes having different CO_2 concentrations for just two days. In labelling the specimens, the number represents the amount of reactive magnesia. The suffixes after the name are put to indicate the curing regime. The specimens marked with '-', '+' and '++' were cured in the low-, medium- and high-level CO_2 curing regimes, respectively. In the 2nd day, all samples cured in medium- and high-level CO_2 regimes were moved to low-level CO_2 regime.

5 cm-cubic molds were filled with the mortars and immediately after casting, the materials were moved to curing regime. For 1st-, 3rd-, 7th- and 28th- day compressive strength, at least 3 specimens were failed according to the standard ASTM C109.

The thermogravimetric analyses were performed with Perkin Elmer Pyris 1 TGA Instrument. The temperature range was arranged 35 – 1050 °C and the burning rate was adjusted to be 20 °C/min. The XRD profiles were obtained with BTX III Benchtop XRD Analyzer having 5–55 2-theta XRD range. The curing of the specimens was performed in a carbonation chamber, capable of controlling CO_2 concentration, temperature and humidity.

3 Results and Discussion

The higher loss on ignition results seen in Table 1 showed the content of CO_2 removed from the carbonates present in dolomite and magnesite due to ignition process. All the CO_2 was resulted from the calcination of the carbonates present in the sources during burning. The contents of the magnesium carbonates are about 39% and 90% in dolomite and magnesite, respectively. As the amount of the calcium carbonate present in dolomite is 59%, its amount in magnesite is negligible. In order to get a clue about their calcination temperatures, the thermogravimetric analyses conducted to the magnesite and dolomite were investigated and their results (Fig. **2**) showed that the maximum mass losses occurred at the temperatures slightly higher than 600 °C and 750 °C, respectively. In addition, the ultimate mass losses of the dolomite and magnesite were determined to be approximately 52% and 48%, respectively. Considering that the mass losses were resulted from the decomposition of carbonates, these results are consistent with the CO_2 content shown in their chemical analysis results.

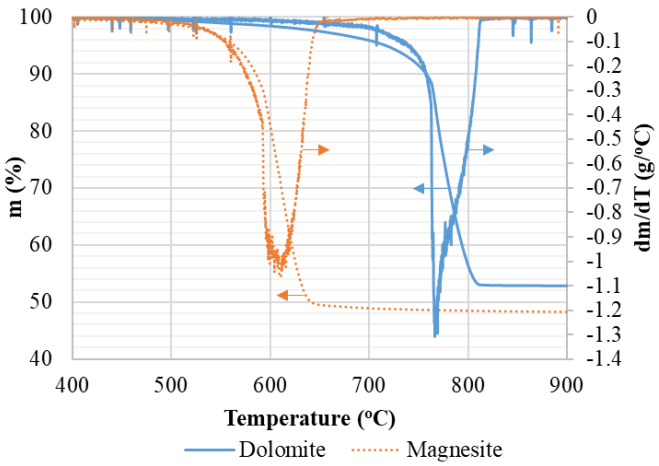

Fig. 2. The TGA results for the magnesium carbonate sources.

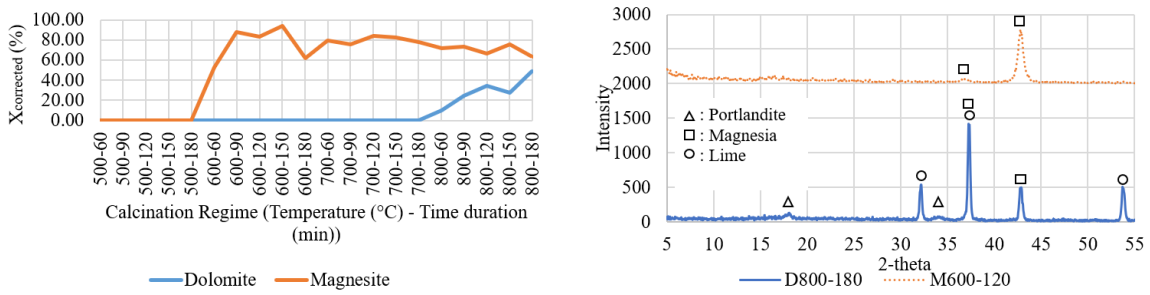
Based on the results of the thermogravimetric analyses, the oven-dried magnesite and dolomite were calcined with the maximum temperatures varying from 500 °C to 800 °C with the intervals of 100 °C. The residence times were ranged from 60 minutes to 180 minutes with the periods of 30 minutes. The specimens obtained were named according to their burning regimes and the former and latter numbers represented the burning temperatures in °C and residence time in minutes, respectively, in the names of the reactive magnesia candidates. The first letter, 'D' or 'M' stood for the magnesium carbonate source type, dolomite and magnesite, respectively.



The results of the preliminary experiments to determine the reactivity of the magnesias produced are shown in Table 3 and Fig. **3**(a). The mass changes during calcination did not change significantly until the temperature 800 °C and 600 °C, for dolomite and magnesite, respectively. This shows that the calcination started at about these temperatures. The higher calcination temperature of dolomite than that of magnesite was undoubtfully resulted from the higher calcium carbonate content of the dolomite. The citric acid coloration time determined also supported these findings. The coloration times measured for the magnesia produced at below these temperatures were so long (higher than 1800 s) that these magnesias could be assumed to be unreactive. When considering hydration conversion ratios, the samples produced from magnesite in the calcination temperature of 600 °C had the highest reactivity. However, for the samples produced from dolomite in higher temperatures of 700°C showed a slight reactivity. The samples yielding lower citric acid coloration time had higher conversion ratio, indicating the higher reactivity of magnesia with water. It is clear that the increase in temperature resulted in the decrease of the coloration time, and correspondingly, increase in the reactivity. Considering the results, for the most reactive magnesia should be chosen among the magnesia candidates burned at temperatures of 800 and 600 °C for the magnesite and dolomite, respectively. In addition, for these, best results were obtained at the exposure times of 180 and 120 minutes. The results show the production of the ‘D800-180’ magnesia was more energy-intensity process than that of the ‘M600-120’ magnesia. To obtain a more ‘green’ reactive magnesia produced with lower CO_2 emission, the source should not be burned at higher temperatures (The higher the calcination temperature, the more energy consumed and the higher the CO_2 emission due to burning process).

Table 3. Results of preliminary experiments.

Magnesia	Mass change during	Citric acid coloration	Magnesia	Mass change during	Citric acid coloration

	calcination (%)	time (s)		calcination (%)	time (s)

D800-180	46.50	10	**M800-180**	50.95	32

The reactive magnesias were investigated with their XRD profiles as shown Fig. **3**(b). It was determined that since the 'D800-180' magnesia had free lime, the probability of occurrence of soundness problem due to its presence was higher. So, for oncoming experiments, as the reactive magnesia (RM), the 'M600-120' magnesia was preferred to use to produce cement mortars, instead of the 'D800-180' magnesia.

(a) (b)

Fig. 3. (a) $X_{corrected}$ results for magnesias produced. **(b)** XRD results for M600-120 and D800-180.

For preparation of mortars, the mix design stated for ordinary Portland cement in ASTM C 109 standards, was based; however, it was seen that RM reacted with water in the very first minutes vigorously, resulting higher amount of heat evolved. Since it caused loss of consistency, extra water was added to the mixtures to compensate the loss of water. Therefore, the total water content was calculated by Eqn. 3:

$$w_t = 0.484\,x(RM + P + F + S) + 0.43\,x\,RM \qquad \textbf{Eqn. 3}$$

where, 0.484 is the water / cement ratio specified in ASTM C 109 standard. The water content to hydrate 1 g of reactive magnesia with no impurities can be calculated by the molar

masses of the chemical compounds in following the chemical reaction, $MgO + H_2O \rightarrow Mg(OH)_2$. Accordingly, the content of the water consumed in that reaction is just the proportion of the molar mass of water (18) to the molar mass of magnesia (40), which is 0.45 g (=18/40). However, the M600-120 cannot be obtained purely due to the impurity present. Assuming that magnesite lost its all CO_2 during calcination, approximately 95 % of the material is MgO. Therefore, it can be concluded that 1 g of RM (with its impurities) reacted with 0.43 (=0.45 x 0.95) g of water.

The compressive strength results can be seen in Fig. **4**. It is obvious that F and S were effective in contributing especially early and late age, respectively. This was due to the higher pozzolanic effect of F and latent hydraulic properties of S [1]. The RM in cements decreased the strength because of M – S – H gels or brucite produced from its hydration reaction (It was stated that the CO_2 concentration in ambient conditions was not sufficiently high to yield carbonation products of the RM [2]). It was reported that since the RM hydration products had higher porosity and lower binding property than the hydration products of P [2, 6, 8]. It is recognized that the 2d- CO_2 curing regime modified the effect of mineral admixtures on the strength. The F caused the formation of C – S – H gels because of the pozzolanic reaction of SiO_2 with portlandite produced from hydration of P [1]. The CO_2 in medium- and high-level curing regimes led to the consumption of portlandite to from calcite (having lower binding properties than C – S – H gels) [18]. This can reduce the effect of F. The strength contribution of slag was dependent on the pH of the pore solution. According literature, the activation of slag was possible only in higher alkaline solutions, and because of higher CO_2, the portlandite, mainly responsible for high pH, was consumed by possible carbonation reactions [1, 18]. When considering 15CM in different curing regimes, it is obvious that the higher CO_2 concentration led to a slight decrease in strength. However, among all the specimens 30CM, the highest strength was obtained for medium-level CO_2 curing regime. High-level curing regime caused a lower strength even than the low-level one. Although the strength obtained for the specimen 30CM+ (~23 MPa) was slightly lower than the specimen 15CM+ (~24 MPa), it can be concluded that 30% RM addition is the most appropriate one considering the reduction in the amount of P. In addition, it was seen that the decreases in strengths due to addition of RM differed for different curing regimes. Therefore, the 28^{th} day-strength reductions for reactive magnesia cement mortars with respect to the cement mortars containing none cured in the same curing regime were calculated. Fig. **4**(d) shows the results for all curing regimes. As expected, the cement mortars containing 30% RM showed higher strength reductions than the ones containing 15% due possibly to the dilution effect for all curing regimes. On the other hand, for medium-level curing regime, the strength reduction had a tendency to decrease. This was due to the reaction of CO_2 with the RM incorporated to cement mortars. As a result, the carbonation products formed partially compensate the strength reduction detected. However, in high-level curing regime, it was seen that the decrease in strength to increase unlike medium-level CO_2 curing regime. Initially, the carbonation started at the surfaces of the specimens and it was considered that the carbonation products have lower permeability for gas ingress into specimen. So, the impermeable shell formed, as a result of the carbonation of P as well as RM, at the surface prevented further carbonation reactions and strength gain for the interior sections of the specimens [18]. Thus, it can be concluded that for reactive magnesia cements, the concentration of CO_2 was a crucial parameter and it was important to find out optimum CO_2 concentration for RM to be carbonated effectively.

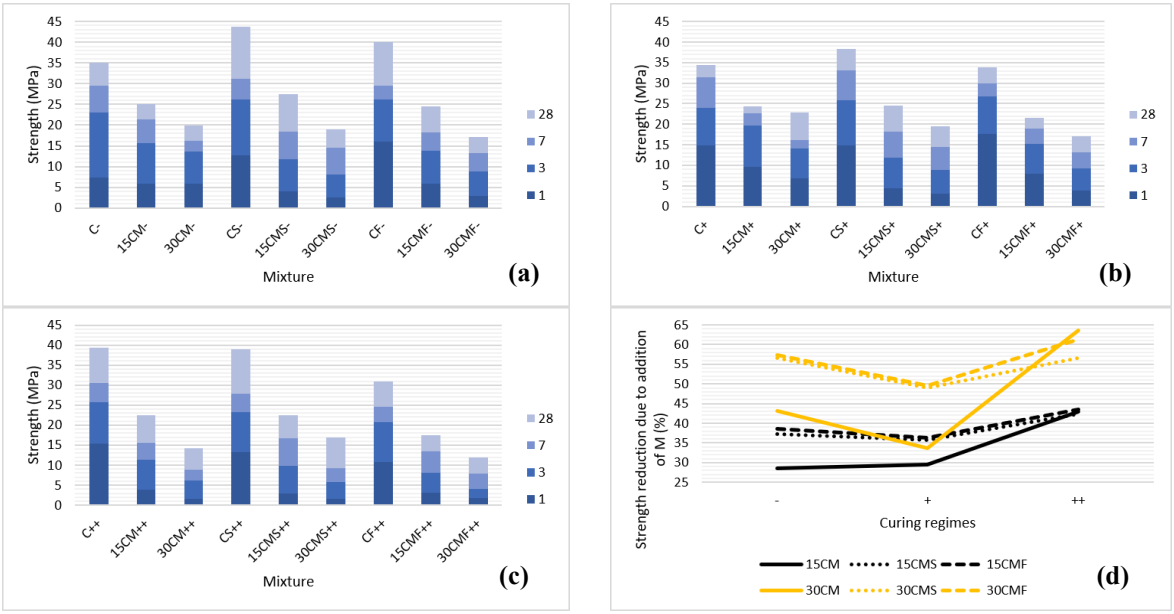

Fig. 4. (a, b, c) Compressive strength results for the specimens cured in low-, medium- and high-level CO_2 regimes. **(d)** Strength reduction due to addition of reactive magnesia.

4 Conclusion

In this study, the following conclusions were reached:

- It was possible to produce reactive magnesias by calcining magnesite and dolomite at the temperatures of 600°C and 800°C, respectively. However, since calcined dolomite had free lime and its calcination temperature was higher, the reactive magnesia obtained from magnesite was selected to produce reactive magnesia cements with Portland cements.
- At low-level CO_2 curing regime, it was seen that the increase in reactive magnesia of the cements caused strength to be lower, because of the dilution effect. The hydration products of the reactive magnesia fraction could not contribute the strength sufficiently.
- It was concluded that the CO_2 concentration was a key parameter for the carbonation of reactive magnesia. The strength decrease at medium-level CO_2 regime due to the addition of reactive magnesia was not so high as that observed in the high-level one. This was resulted from the impermeable carbonate barrier, preventing CO_2 ingress and hence the carbonation further at high-level CO_2 regime. In medium-level CO_2 regime, the concentration was not so high for this type of shell formation. However, the carbonation products compensated the decrease.
- The effect CO_2 level differed on the reactions of fly ash and GGFBS. Since the CO_2 reacted with the portlandite present in pore solution, CO_2 effect was much more pronounced. The activation of GGFBS was directly related with the pH of the pore solution, and in the case of medium- or high-level CO_2 curing regimes, the pH was lowered. But, this effect was detected to be limited due to latent hydraulic properties of GGFBS. In addition, the portlandite necessary for the pozzolanic reaction of fly ash was consumed by CO_2, its effects were limited in medium- and high-CO_2 curing regimes.

Abstract. A large portion of carbon emissions in cement production originates from clinker production. Therefore, reducing the clinker ratio is a cornerstone of carbon neutrality strategies for the cement and ready-mixed concrete sectors, both in the short and long term. In this study, eight different clays with varying chemical and mineralogical properties were calcined and their pozzolanic properties were measured. The characterization of the eight different calcined clays was determined using XRF and XRD. The samples were calcined in a static kiln for 120 minutes at the particle size of less than 3 mm. The pozzolanic activity of the calcined products was determined using the Chapelle test. The mixtures were substituted into Portland cement at 20, 25 and 30% alone, or in combination of limestone at 10, 12.5, and 15%. The chemical composition, specific gravity, fineness, specific surface area, sulfate content, setting time, water requirements, and compressive strength of the produced cement mixtures were investigated. The amorphous phase ratios of the clays ranged from 16 to 50%. In general, limestone-free mixtures containing 20-25% metakaolin showed good performance in terms of strength. In mixtures containing limestone, low limestone ratios were effective. However, as the proportion of calcined clay in the mixtures increased, the water requirement increased and generally shortened the setting time. The findings showed that low-carbon, environmentally friendly cements can be produced when appropriate clay selection, degree of calcination, sulfate balance, and limestone ratio are ensured.

Keywords: Green cement; metakaolin; clinker substitute; pozzolanic activity.

1 Introduction

The cement industry is responsible for approximately 8% of global carbon dioxide emissions. A large portion of these emissions occur during the clinker production phase of cement manufacturing. A significant portion of the emissions in clinker originates from the calcination of limestone and fuels. Therefore, issues such as alternative fuels, raw material carbon capture

and storage, energy efficiency, and alternative pozzolanic materials are becoming increasingly important in cement production [1,2].
By-products such as fly ash and ground blast furnace slag have been used as clinker reducers in cement for many years. It is predicted that the use of these products will decrease over the years due to the green transformation in the energy and iron and steel sectors [2-4]. Calcined clay, being a widely available raw material worldwide, requiring a lower calcination time and temperature compared to clinker production, and exhibiting pozzolanic activity after firing, has significant potential as an alternative pozzolanic raw material [5].
In kaolinite containing clays, after undergoing dehydroxylation during heat treatment and losing a significant amount of water, they transform into amorphous and reactive metakaolin. If the calcination temperature is insufficient, the amorphous phase may not form; if heated excessively, it may sinter, causing the resulting amorphous structure to revert back to a crystalline structure. The pozzolanic reactivity formed after calcination depends not only on the chemical composition of the clay but also on the degree of crystallization, grain size, and mineralogical structure [3-6]. When metakaolin is substituted for cement in a specific portion of the matrix, it reacts with calcium hydroxide, a hydration product of cement, to form a CASH structure. When limestone is also added, the reactive phase in metakaolin combines with limestone to form carboaluminate. Carboaluminate can improve the pore structure in the matrix and compensate for the strength loss in mixtures with low clinker content [4-7].
Studies in the literature mention that water requirements increase and workability decreases with increasing metakaolin content. However, it can be said that when used up to a certain ratio, it improves strength and resistance to external influences [8]. Therefore, in the substitution of metakaolin, it is not only the pozzolanic activity of the material that should be used, but also the fineness, chemical properties, specific surface area of the material to be substituted for cement, and its performance in conjunction with the chemical additives to be used should be considered [9-10]. The aim of this study is to compare the fresh state and strength performance of kaolinitic clays obtained from different regions, either directly as a replacement for cement or in combination with limestone, after calcination.

2 Materials and Methods

2.1 Raw Materials and Metakaolin Production

Eight different clay samples obtained from various sources were used in this study. The chemical composition using XRF (Table 1). Mineralogical analysis of the samples were determined using XRD testing (Table 2). The samples were calcined in a static electric furnace for 120 minutes each, to a particle size of less than 3 mm. Calcination temperatures were determined using the TGA test method applied to the clays. The appropriate calcination temperature was determined by identifying the dehydroxylation range of the clay from the TGA results. Clays K1 and K2 were calcined at 800°C, clays K3, K4 and K5 at 850°C, and clays K6, K7 and K8 at 900°C.

2.2 Pozzolanic Activity and Cement Mixtures Activators

The pozzolanic activity of calcined clays obtained from eight different sources was measured using the Chapelle method (Table 3). The results are presented as mg $Ca(OH)_2$/g. The substitution rates of calcined clays for cement were 20, 25, and 30%. In addition, series with 10, 12.5, and 15% limestone were prepared. Accordingly, the non-limestone series contain 70-80% clinker, while the limestone systems contain 55-70% clinker.

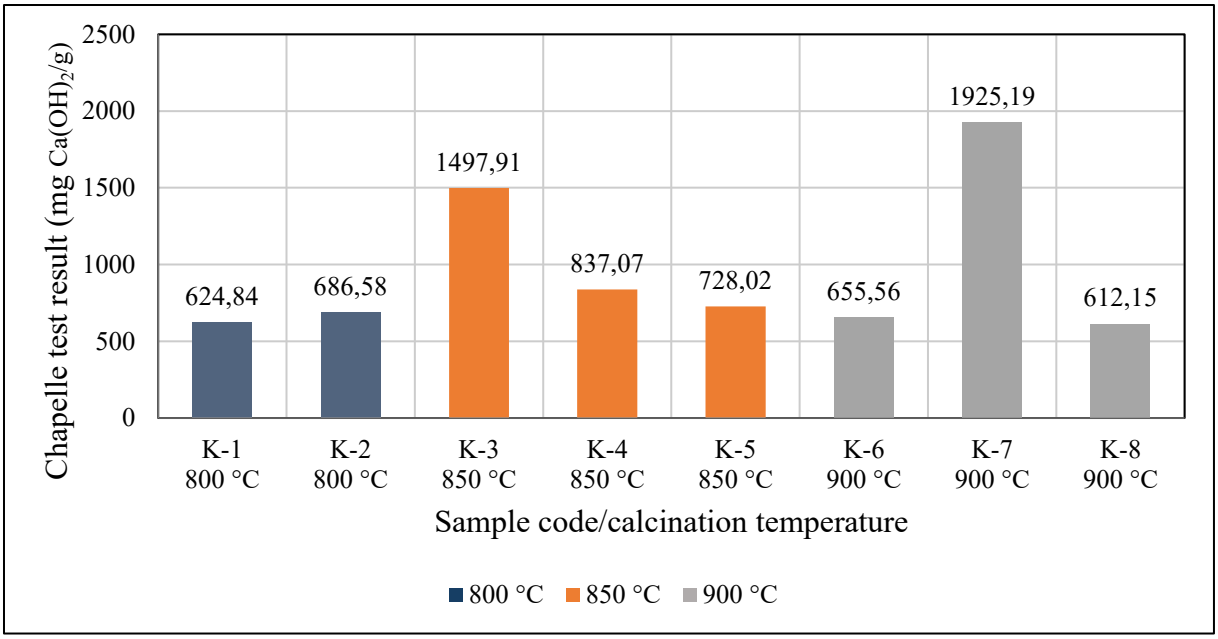

Fig. 1. Pozzolanic properties results.

2.3 Mix Design

The chemical composition, SO_3 content, sieve analysis, Blaine specific surface area, water requirements, setting initial and final times, and compressive strengths of the prepared binder mixtures were determined. The results were compared with a standard Portland cement reference.

The mixtures contain cement, metakaolin, limestone, sand and water according to their composition. Each mixture is produced according to EN 197-1, and the binder phase of the mixtures contains 450 g of binder phase, 1350 g of sand, and 225 g of water. The water/binder ratio of all mixtures is 0.5 and is kept constant (Table 3).

Table 3. Mix proportions.

Mix (x = 1 to 8)	Cement (g)	Metakaolin (g)	Limestone (g)
K-x/1	360.0	90.0	-
K-x/2	337.5	112.5	-
K-x/3	315.0	135.0	-
K-x/4	315.0	90.0	45
K-x/5	281.25	112.5	56.25
K-x/6	247.5	135.0	67.5

3 Findings

The Blaine specific surface areas of the series ranged from 3750-7150 cm^2/g, with an average of 5400 cm^2/g. The average percentage above a 45 µm sieve was 6.2%. When the metakaolin ratios in the mixtures were high, the Blaine value also increased. However, while a positive relationship with strength was expected due to the filler effect when this value increased, fineness alone could not be established as an indicator of its effect on strength.

Water demands generally ranged between 28.6 and 31.0% in the K1-K5 series. In the K6-K8 series, it ranged between 31.6 and 32.0%. In the scenario where the metakaolin ratio increased from 20 to 30%, the water demand increased by an average of 1.5-2.5%. The lowest water demand values were observed in mixtures using 20% metakaolin and 10% limestone

powder. The highest water demand was observed in mixtures combining 30% metakaolin and 15% limestone powder.

The SiO_2 content of the calcined clays ranges from 66.6-77.4%, and the Al_2O_3 content from 15.3-26.9%. The highest Al_2O_3 content was found in clay K4, and the highest SiO_2 content in clay K5. The higher Fe_2O_3 values in clay samples K6, K7, and K8 compared to other samples necessitate further evaluation of these materials in terms of color and chemical equilibrium with the clinker. In addition, the total SiO_2, Al_2O_3, and Fe_2O_3 ratios of all samples are suitable according to the required chemical composition properties of pozzolanic materials. No consistent trend was found between the amorphous phase content and the Chapelle test values. For example, K8 has the highest amorphous phase ratio, but its Chapelle value of 612.2 mg/g places it in the lower ranks of the clay group. K7 clay, with an amorphous phase ratio of 41.8%, gave the highest activity value of 1925.2 mg/g. K3 clay showed the highest pozzolanic activity with a value of 1497.9 mg/g. K1, K2, K6, and K8 clays exhibited results around 700 mg/g. Chapelle results alone cannot provide insight into the performance of the cement matrix. Besides pozzolanic activity, the filling effect needs to be evaluated the particle size of the material, and the sulfate balance formed by the system.

SO_3 content was approximately 2.8-3.0% in batches without limestone and around 2.6% in batches with limestone. As the proportion of limestone and calcined clay increases, the amount of clinker decreases. Therefore, since the sulfate/aluminate ratio in the system also changes, the optimum gypsum requirements of mixtures containing limestone and calcined clay may be compared to the reference Portland cement.

In mixtures containing limestone powder, strength generally performed worse than in mixture series containing only 20-25% metakaolin. The best balance was given by mixtures containing 25% metakaolin and 12.5% limestone. According to studies in the literature, it is emphasized that reactive aluminates in calcined clay form monocarboaluminates together with the clays, and this resulting phase binds the aluminate, increasing the volume and structural density of the hydration products [4-7]. For this synergy to occur, the purity and fineness of the reactive alumina limestone in metakaolin must be controlled.

Setting generally started between 150-190 minutes and setting ended between 230-260 minutes. The use of metakaolin shortened the setting time by 15-25 minutes. Limestone addition reduced the setting time in some batches, while in others it had no noticeable effect.
The 28-day compressive strength results for all K1, K2, K3, K4, and K5 series exceeded the reference mixture's strength of 59.2 MPa. The K1 series yielded approximately 61-62 MPa, the K2 and K5 series approximately 62-63 MPa, the K4 series approximately 63-64 MPa, and the K3 series approximately 64-65 MPa. The K6 series yielded approximately 58-59 MPa, and the K8 series approximately 59-60 MPa, yielding results equal to or exceeding the reference mixture. Based on these results, it can be said that mixtures containing 20-25% metakaolin alone produce results superior to the reference due to pozzolanic reaction and filler effect (Figure 2).It is expected that K3, which gives the highest chapelle test result, will provide the highest strength. However, the fact that metakaolins with lower pozzolanic reactivity, such as K1, K2, and K8, perform better than the reference mixture demonstrates that this is not solely related to their free lime consumption capacity. The fact that K7 has a very high chapelle value but is limited in cement performance is consistent with and supports this connection. Variables such as the high iron content, particle size distribution, or sulfate ratio of K7 may be the reasons why it does not fully reflect its pozzolanic activity in the mortar strength (Figure 2).

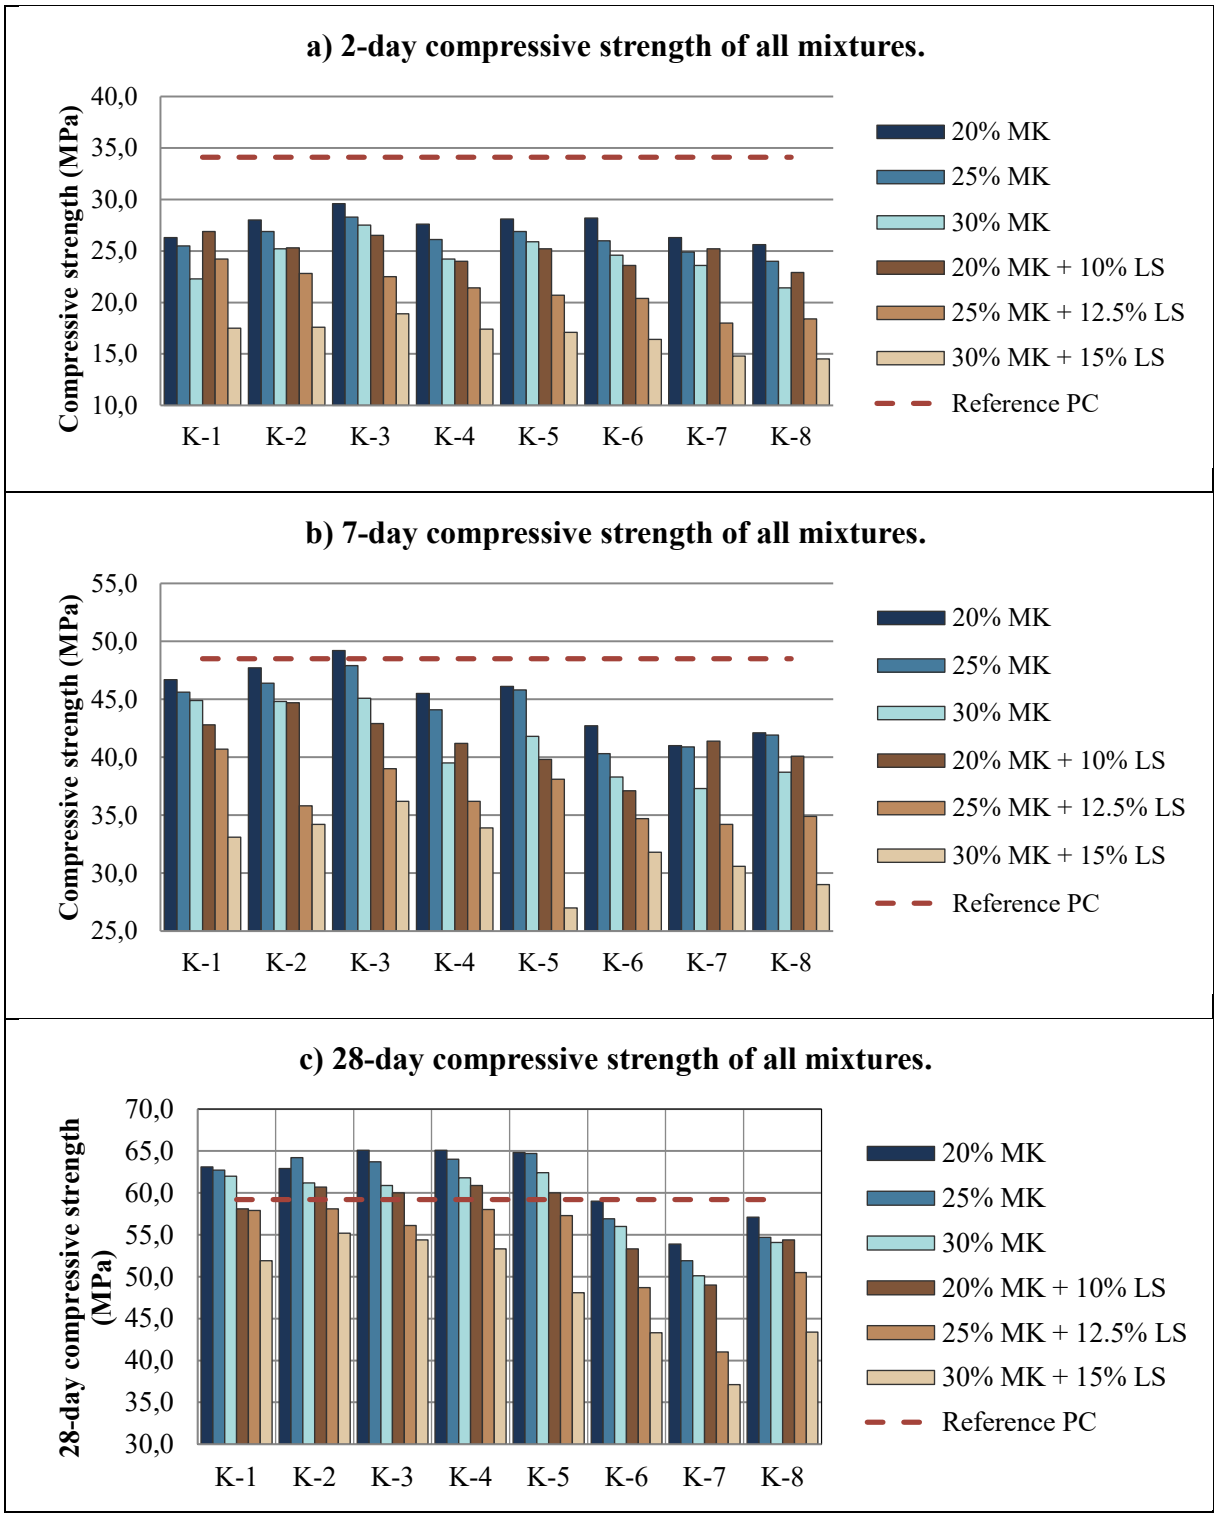

Fig. 2. Compressive strength of all mixtures.

4 Conclusion

Metakaolins, obtained by calcining kaolin-containing raw materials coded K1 to K8 at 800-900°C for 120 minutes, showed variations according to the phase structures formed after calcination. Amorphous phase ratios ranged from 16-52%, and Chapelle activity values ranged from 612-1925 mg $Ca(OH)_2$/g. Raw material selection and calcination conditions were influential in determining metakaolin quality. Metakaolins K3 and K7 yielded the highest pozzolanic activity values. However, the effect on cement strength performance does not

directly correlate with pozzolanic activity performance. Pozzolanic activity is related to phase structure, particle properties, sulfate ratios, and other components of the mixture.

In the experiments, it can be concluded that all series between K1-K5 exceeded the reference mixture values. K3 was the series that gave the best value with 65 MPa. In general, limestone-free mixtures containing 20-25% metakaolin have yielded the most stable strength performance. In low-clinker mixtures with limestone, a content of 20% metakaolin and 12.5% limestone can be considered feasible (Figure 2). Increasing the metakaolin ratio increases the water requirement but it can also shorten the setting time. Optimizing the SO_3 levels with component properties is an important aspect.

In conclusion, kaolinitic clays can enable the production of green cement containing calcined clay by achieving a controlled particle size distribution and calcination parameters.

Abstract. One cannot have a design of any merit that will stand up to quality control without a precise estimate of the concrete's compressive strength. Nor can one optimize materials in a sustainable fashion without it. The problem with conventional methods, whether they be empirical correlations or the physical testing of cylinders, is that they are resource intensive and do not cope well with the intricate chemistry of today's multi-component binders. Our solution is a robust feedforward artificial neural network (ANN). We have evaluated the ANN's predictive capacity against 1,030 experimental records for eight design parameters; the proposed ANN significantly outperforms XGBoost, Random Forest, Support Vector Regression, and Multiple Linear Regression, while achieving performance highly competitive with the top-performing CatBoost model. Over the whole of the multi-age dataset the model yields an R^2 of 0.9280 and an RMSE of 4.4500 MPa; for the 28-day subset these come in at 0.8250 and 4.9100 MPa respectively, comparable to the 0.8303 R^2 from the CatBoost model. An examination of the correlation and parametric sensitivity shows that cement content and curing age are the primary drivers of strength, while water content is the principal limiting factor. In short, the ANN is a computational, non-destructive means of appraising strength which makes for a simpler mix design and obviates the need for excessive physical trial batches, thereby reducing the infrastructure's embodied carbon.

Keywords: Concrete Compressive Strength, Artificial Neural Networks, CatBoost, Machine Learning, Mix Design Optimization, Predictive Modeling.

1 Introduction

It is hardly necessary to make the case for concrete as the foundation of modern civil engineering. Our essential infrastructure is built on it, from a highway bridge to the underpinnings of a commercial high-rise or any heavy industry. The safety and structural integrity of such systems are only as good as the uniaxial compressive strength of the concrete employed. To be sure of quality one must have cylinders or cubes of concrete cast and allowed to cure in a moist environment for 28 days before subjecting them to mechanical testing [1, 2]. While a 28-day figure will satisfy the design code, there is a logistical and scheduling cost to waiting four weeks on the lab numbers at the site of construction [3].

Portland cement, water, and mineral aggregate are no longer the only ingredients one will find in the field. High-performance concretes of the present day are of a different order of sophistication, with chemical superplasticizers and industrial SCMs in the form of fly ash or GGBFS being employed [4, 5]. A multi-component binder is the outcome, its non-linear hydration

kinetics a product of both pozzolanic and hydraulic reactions; a complexity defying the standard linear or polynomial regression [3, 6]. Machine learning is an appealing solution in this respect as it can extract the physical and chemical patterns from the empirical data [4–6]. For tabular regression, there is room for ensemble methods such as CatBoost or XGBoost, but when it comes to mapping the continuous non-linearities and high-dimensional feature interactions at hand, deep feedforward Artificial Neural Networks (ANNs) are more fitting [1, 7–9].

An experimental dataset of 1,030 records of concrete mixtures has been the basis for a rigorous evaluation of the feedforward artificial neural network in our work. To see how it stacks up, the proposed architecture is pitted against five top machine learning algorithms [10, 11]; testing has been carried out under both 28-day fixed and multi-age curing conditions. The aim is to provide a computational framework with real heft to the engineer, something robust and practical that will allow a swift assessment of mix performance and do away with the necessity of too many laboratory batch trials. In this way, we can further the cause of sustainable concrete production.

2 Dataset Description and Exploratory Data Analysis

2.1 Concrete Mixture Dataset

The 1,030 laboratory concrete mixture records that form the basis of this study were taken from the empirical data of some of the more highly regarded experimental testing programs [1]. Together, they constitute a dataset with eight continuous inputs, namely the cement content, blast furnace slag and fly ash, water, superplasticizer, coarse and fine aggregate, as well as curing age. One also has the uniaxial compressive strength (measured in megapascals). Of the total, 425 have been set aside to assess how the model performs in accordance with standard design code; these are all specimens cured for 28 days. Prior to training, we normalized the input features in order to be free of any bias arising from scale and to ensure a uniform convergence of the gradient descent across the various parameter ranges.

2.2 Exploratory Data Analysis and Feature Correlations

To determine the material mechanisms in play, we have put the two dataset partitions through an assessment of their Pearson correlation coefficients. The 1,030 samples in their entirety reveal cement content to be most positively correlated with compressive strength ($r = +0.50$), a result one would anticipate given that reactive binder is readily available for the formation of hydration products.

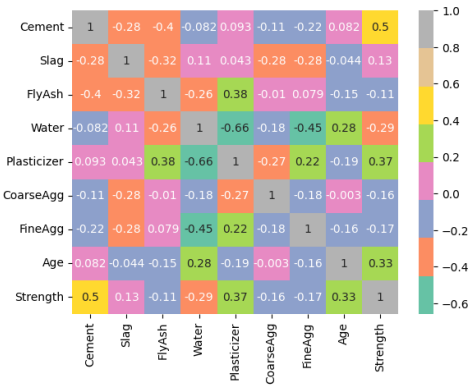

Fig. 1. Pearson correlation matrix for full concrete dataset (N = 1030) across 8 input variables and compressive strength.

Curing age has exhibited a positive trend (r = +0.33), indicative of the microstructure's increased density over time. One can attribute the superplasticizer dosage to a correlation of r = +0.37 as well, given its role in dispersing the cement grains and reducing the need for water. Then there is the water content, which, in accordance with Abrams' law on the water-to-cement ratio, is negatively correlated in a significant way (r = -0.29).

When one looks at the 28-day fixed-curing subset, the influence of mix proportions is much more pronounced. The cement content registers a positive correlation coefficient of r = +0.67 while that of the water content is a negative r = -0.40. These are results that bear out what the water-to-binder ratio will allow in terms of compressive strength, curing time being a given.

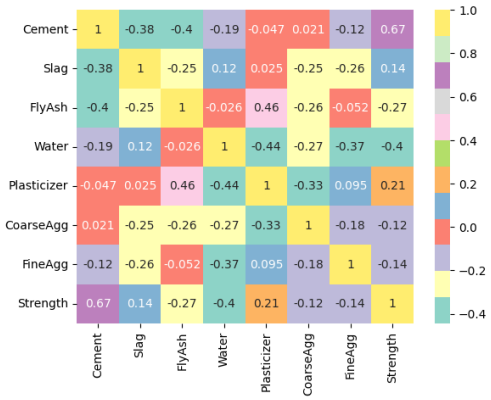

Fig. 2. Pearson correlation matrix for 28-day concrete dataset (N = 425) with fixed curing age.

3 Methodology

3.1 Neural Network Model Architecture

The present study employs a multi-layer feedforward ANN. In the way the network is designed, one finds an input layer of eight neurons and a linear output made up of a single neuron with a number of dense hidden layers in between, all running on ReLU activation functions. We have opted for Adam stochastic gradient optimization as it is both numerically stable and does not tax computational resources. To prevent any overfitting [5], a dropout regularization of 0.15 is in place.

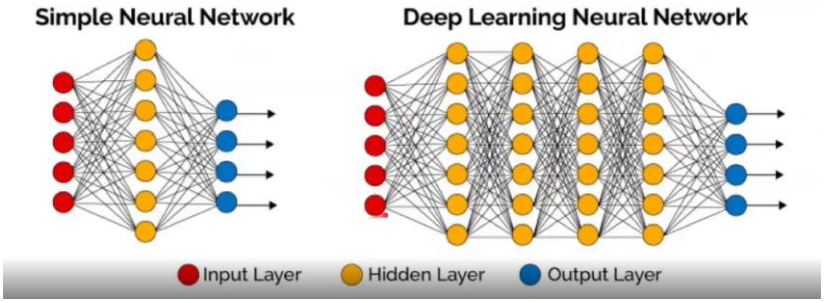

Fig. 3. Workflow of the proposed neural network concrete strength prediction framework.

3.2 Benchmark Machine Learning Models

To gauge the predictive power of the artificial neural network (ANN) we have put forward, it was pitted against a selection of AI paradigms that are well established in the field. Five machine

learning algorithms were trained to this end with an 80/20 train-test split [12–15]. The models are: CatBoost (Categorical Boosting), a gradient boosting framework which relies on symmetric and oblivious decision trees to stave off prediction shift [12]; XGBoost, or Extreme Gradient Boosting, for its scalability as a tree booster and by virtue of its regularized loss objectives and second-order Taylor expansion [13]; and Random Forest (RF), an ensemble bagging technique that randomizes feature subspace sampling to assemble de-correlated decision trees [14]. For non-linear applications, we made use of Support Vector Regression (SVR), a kernel method of structural risk minimization apt for the mapping of features to high-dimensional hyperspaces [4, 5]. As a parametric baseline to judge first-order linear relationships, Multiple Linear Regression (MLR) was also applied.

4 Evaluation Metrics

Model predictive accuracy was evaluated using four standard statistical metrics: Coefficient of Determination (R^2), Mean Absolute Error (MAE), Mean Squared Error (MSE), and Root Mean Squared Error (RMSE).

$$R^2 = 1 - \frac{\sum_{i=1}^{n} \left(y_i - \hat{y}_i\right)^2}{\sum_{i=1}^{n} (y_i - \bar{y})^2} \tag{1}$$

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^{n} \left| y_i - \hat{y}_i \right| \tag{2}$$

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^{n} \left(y_i - \hat{y}_i\right)^2 \tag{3}$$

$$\text{RMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^{n} \left(y_i - \hat{y}_i\right)^2} \tag{4}$$

The variables are defined as follows: y_i represents the measured experimental compressive strength in MPa, $\hat{y}_i$ denotes the compressive strength predicted by the model (MPa), $\bar{y}$ is the mean of the measured experimental values across the dataset, and n is the total number of test samples in the evaluation.

5 Results and Discussion

5.1 Machine Learning Model Performance Benchmarking

An account of how the various models have performed is given in Table 1, which covers the metrics for the entire dataset (N = 1030) as well as the 28-day subset (N = 425).

Table 1. Machine learning model performance comparison for the full dataset (N = 1030) and 28-day concrete strength forecasting (N = 425).

Model Algorithm	Full Dataset R^2	Full Dataset RMSE (MPa)	28-Day Subset R^2	28-Day Subset RMSE (MPa)
CatBoost (Best ML)	**0.9367**	**4.3018**	**0.8303**	**4.8351**
XGBoost Ensemble	0.9245	4.6820	0.8120	5.0210
Random Forest (RF)	0.9110	5.1200	0.7980	5.2400
Proposed Feedforward ANN	0.9280	4.4500	0.8250	4.9100
Support Vector Reg. (SVR)	0.8420	6.8900	0.7150	6.4500
Multiple Linear Reg. (MLR)	0.6120	10.4200	0.5410	8.1200

One need only refer to Table 1 to see the linear baseline significantly outperformed by the non-linear ensemble boosting and neural network algorithms. In a way CatBoost is the machine learning standard here: for the full dataset it has an R^2 of 0.9367 and an RMSE of 4.3018 MPa, while on the 28-day subset the corresponding values are 0.8303 and 4.8351 MPa. Then there is the feedforward ANN we have put forward, its predictive precision is no less impressive. Over all the data it yields a coefficient of determination of 0.9280 with an RMSE of 4.4500 MPa; for the 28-day portion one finds an R^2 of 0.8250 and an RMSE of 4.9100 MPa. They are numbers that speak to the model's capacity to make sense of what multi-component hydration kinetics can throw at it.

5.2 Neural Network Model Validation and Predictive Capability

The data are presented in Figs. 1 to 6 in the form of exploratory correlation heatmaps and some scatter plots that set the predicted compressive strengths up against what was measured, as well as for a comparative benchmarking of the models' metrics. There is no question from the R^2 figures that the non-linear dynamics at play among the cementitious binders, water and chemical

admixtures have been readily handled by the multi-layer neural network. As for the mechanics, large aggregate volumes do not unduly sway the weight updates thanks to feature normalization. The model also holds its own with test data it has never seen before; overfitting is precluded by the use of dropout regularization.

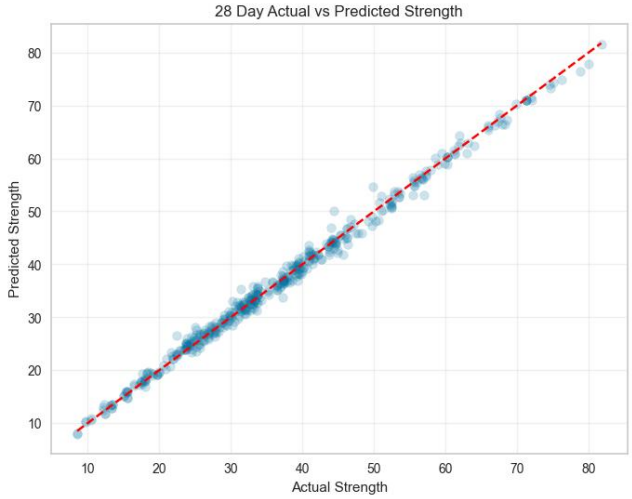

Fig. 6. Actual versus predicted compressive strength values (MPa) using the proposed neural network model.

6 Practical Engineering Applications

The computational framework of this work is of no small practical value in the design of structural engineering and for operating ready-mix concrete batch plants [16]. There are three principal uses to which it can be put.

To begin with, it puts an expedited method of mix formulation at the disposal of the design engineer; in seconds, dozens of binder combinations can be evaluated so that recourse to physical trial batches when a project is first being designed is largely unnecessary [16].

Then there is the matter of sustainable material optimization. The framework lends itself to a proper appraisal of high replacement levels in the form of industrial by-products such as slag or fly ash, thereby reducing the amount of Portland cement called for and bringing down embodied carbon emissions in some cases by 30% [6, 16–18].

As for quality assurance at the plant, ready-mix suppliers may make use of the predictive algorithms in their control software. A case in point is the projection of 28-day strength prior to shipping, which not only precludes the possibility of non-compliance but also ensures that waste is kept to an absolute minimum.

7 Conclusions

To forecast the compressive strength of concrete we put together a neural network framework; after its methodical construction it was validated on experimental data of various ages. The results are:

• A CatBoost ensemble proved to be very accurate on the whole of the data, with an R^2 of 0.9367 and RMSE of 4.3018 MPa. Our feedforward ANN was not far behind, producing R^2 values of 0.9280 (full set) and 0.8250 (28-day subset), the latter entailing an RMSE of 4.9100 MPa against 4.4500 for the former. Such performance is well beyond the capabilities of classical linear models.

• Compressive strength is positively driven above all by the age of curing and the amount of cement; water content is the principal limiting factor.

• There is a need to exercise close control of the water-to-binder ratio, as 28-day curing renders the compressive strength more susceptible to variations in binder proportions.

• We have employed dropout regularization (0.15) and feature normalization to guard against overfitting and see that the model generalizes to test mixtures it has not been exposed to.

• In the end, the proposed architecture is an effective means of non-destructive computation. It offers a way to streamline the proportioning of concrete mixes and do away with some of the laboratory trial batching, which is conducive to sustainable construction practices.

Abstract. The construction sector is one of the largest producers of solid waste globally, and the sustainable management of construction and demolition waste (CDW) has become a critical environmental and engineering challenge. This study investigated the mechanical and physical properties of cements produced by adding recycled concrete fines (RCF) to ordinary Portland cement at replacement ratios of 20% and 30%, by mass, in compliance with the TS EN 197-6 standard for low-clinker cements. The primary objective was to evaluate whether Konya-based RCF could meet the mechanical performance limits defined by TS EN 197-6, thereby offering a viable pathway to reduce clinker consumption and associated CO_2 emissions. The experimental work included compressive and flexural strength testing at standard curing ages under both air-curing and water-curing conditions, together with chemical, physical and durability characterization of the RCF-incorporated cement blends. It was found that curing regime strongly governed whether Konya-sourced concrete fines could be used to produce a Portland-recycled-fines cement satisfying the TS EN 197-6 strength requirements: under water curing, 20% replacement meets the 32.5 strength class threshold at 28 days, whereas under air curing neither replacement ratio met these limits.

Keywords: Construction and demolition waste, recycled concrete fines, TS EN 197-6, supplementary cementitious materials, compressive strength.

1 Introduction

In the 21st century, the construction industry faces two simultaneous global challenges: cement production, one of the principal drivers of the climate crisis owing to its highly energy- and raw-material-intensive manufacturing process [1], and the inevitable increase in construction and demolition waste (CDW) [2]. The clinkerization process in Portland cement production, based on the high-temperature calcination of calcium carbonate, releases substantial amounts of carbon dioxide; cement production is responsible for approximately 7–8% of global CO_2 emissions [1, 3]. It is reported that global annual cement production exceeds 4 billion tons, making the reduction of the environmental impact associated with clinker production critically important for global sustainability targets [1]. In order to reduce the clinker amount, one of the most common approaches is to substitute cement with reliable mineral admixtures. While fly ash, ground granulated blast furnace slag and natural pozzolans have been used for decades, recycled concrete fines (RCF), which can be obtained from the concrete fraction of construction and demolition waste (CDW), have recently emerged as a potential mineral component for low-clinker cement production. The TS EN 197-6 standard,

which entered into force in 2023, has introduced new low-clinker cement classes (CEM II/A-M, CEM II/B-M and CEM II/C-M) that allow the use of RCF which can be obtained from CDWs, in combination with other mineral components [4].

The CDW constitutes approximately 30–37% of total waste generation in European Union countries, making it one of the largest waste streams [2], of which concrete-based waste accounts for approximately 70–80% [5]. In Türkiye, approximately 20 million tons of CDW are generated annually as a result of the destruction of old buildings within the scope of urban renewal projects [6]. The increasing generation of CDW, and hence as a huge part of this, RCF highlight the need for effective recycling and recovery strategies, particularly for concrete-derived fractions that may be suitable for use in cement-based materials.

Although it is reported that in most cases, concrete-based CDW utilized as an ingredient of concrete acts as an inert material, fine grinding and appropriate activation can enable it to exhibit pozzolanic reactivity owing to its SiO_2, CaO and Al_2O_3 phases [7]. However, the performance of concrete waste as a mineral admixture is dependent on numerous variables including the type and quantity of cement in the parent structure, aggregate mineralogy, water/binder ratio, curing regime and the environmental exposure history of the parent structure prior to demolition (e.g., carbonation, weathering) [8, 9]. Curing condition in particular is known to strongly influence the degree of hydration in blended cement systems, since supplementary cementitious materials with limited early reactivity depend on sustained moisture availability to develop later-age strength [10, 11].

Most studies in the literature examine concrete waste utilization on the basis of a single, controlled waste source and a single curing regime; a systematic treatment addressing both source diversity and curing sensitivity remains a clear gap. This paper presents the mechanical performance of the mortar having TS EN 197-6-compliant cements produced by incorporating recycled concrete fines (RCF) obtained from construction and demolition waste collected in Konya, Türkiye at 20% and 30% replacement ratios by mass, under both water-curing and air-curing conditions after conformity tests. The primary objective is to characterize the chemical, physical and mineralogical properties of Konya-based RCF and to evaluate whether the resulting cement blends meet the mechanical performance limits defined by TS EN 197-6 under each curing regime, thereby assessing the utilization of this specific waste source as a pathway to reduce clinker consumption and associated CO_2 emissions.

2 Materials and Methodology

2.1 Materials

The recycled concrete fines (RCF) were obtained from the construction and demolition waste (CDW) of the Eski Sanayi industrial zone of Konya, Türkiye. About 100 kg waste material was obtained from the site with appropriate sampling methods. The waste brought to the laboratory was first crushed using a jaw crusher to reduce oversized fragments, and oven-dried at 105 °C for 24 hours to remove residual moisture. Following drying, the material was ground in a laboratory-type ball mill (internal drum dimensions 30.5 × 30.5 cm with approximately 22 L of volume) operated at a constant speed of 70 rpm; the ball charge was determined on the basis of the standard Bond mill configuration [12]. The grinding duration for the Konya sample was set at 30 minutes to achieve a similar fineness to that of the reference cement. The resulting fine powder was mechanically homogenized and stored in airtight containers to prevent moisture uptake prior to any testing.

The CEM I 42.5 R Portland cement supplied by Baştaş Çimento Sanayi A.Ş., was used as the reference binder. CEN standard reference sand, compliant with TS EN 196-1 and produced by Limak Trakya Cement factory, was used as fine aggregate in the mortar mixtures.

2.2 Mix Design

Table 1 presents the mortar mix proportions used in the study. The replacement ratios of 20% and 30% were selected within the compositional limits defined by TS EN 197-6 for recycled concrete fines (RCF) as a main constituent. Under this standard, RCF (designated as "F") can be incorporated as the sole non-clinker main constituent in Portland-recycled-fines cements, with the CEM II/A-F class allowing 6–20% RCF and the CEM II/B-F class allowing 21–35% RCF by mass. Accordingly, the 20% replacement level corresponds to the upper compositional limit of the CEM II/A-F class, while the 30% replacement level falls within the compositional range of the CEM II/B-F class. Since both replacement levels were obtained using RCF alone, without a second non-clinker constituent, the experimental matrix was designed to evaluate the mechanical and durability performance of RCF-containing Portland cements at replacement levels representing both CEM II/A-F (20%) and CEM II/B-F (30%) compositions. For each mixture, two specimen series were cast from the same batch and subjected to two different curing regimes until the relevant test age: (i) water curing, in which specimens were immersed in a water tank at 20 ± 1 °C in accordance with TS EN 196-1, representing an idealized, continuously moist condition; and (ii) air curing, in which specimens were demolded after 24 hours and thereafter stored in laboratory ambient air at 20 ± 2 °C without further water contact, representing a field-representative condition in which continued hydration relies solely on moisture retained within the specimen. In addition, cement paste specimens were prepared in accordance with TS EN 196-3 for setting time and soundness tests.

Table 1. Mortar mix proportions.

Mixture	Cement (g)	RCF (g)	Sand (g)	Water (g)
Control	450	0	1350	225
Konya 20%	360	90	1350	225
Konya 30%	315	135	1350	225

2.3 Methodology

Mixing of the mortar specimens was carried out in accordance with TS EN 196-1 using a standard mortar mixer. All mixtures were prepared with the same total water/binder ratio for comparing the workability and performance of mixtures containing different proportions of RCF. The specimens were cast into 40 × 40 × 160 mm prismatic steel molds, compacted with a vibrating table, covered with stretch film and stored at 20 ± 2 °C in curing room to minimize moisture loss for 24 hours before demolding. Then each specimen series was assigned to either the water-curing or the air-curing regime described above until the relevant test age. In addition, the durability specimens (28-day water-cured) were also prepared with the same procedure. The following experimental program was applied to the Konya RCF and the resulting cement systems:

Chemical and mineralogical characterization: The oxide composition was determined with X-ray fluorescence (XRF). The methylene blue (MB) value in accordance with TS EN 933-9 and total organic carbon (TOC) content in accordance with TS EN 13639 were found, also.

Physical characterization: The RCF developed was investigated via density (according to ASTM C 188) as well as laser diffraction particle size analysis.

Fresh-state properties: Consistency (flow) in accordance with ASTM C 1437 was determined for each mixture. Standard consistency, setting time (Vicat apparatus) and soundness (Le Chatelier method) tests were conducted in accordance with TS EN 196-3.

Mechanical properties: The flexural and compressive 2nd, 7th and 28th day-strengths of the mortars were determined in accordance with TS EN 196-1. The pozzolanic activity index (PAI) determined on a separate, water-cured mixture series prepared at 25% replacement, calculated as the ratio of the compressive strength of the RCF-substituted mortar to that of the control mortar at the same curing age, expressed as a percentage.

Durability properties (evaluated on water-cured specimens): Combined sulfate/acid resistance was evaluated by immersing 28-day water-cured specimens in a 1% H2SO4 solution and in water (reference) and determining flexural and compressive strength at 28, 56 and 90 days. To determine water permeability of the mortars, rapid chloride ion permeability test, was performed in accordance with ASTM C1202 on 50 × 100 mm cylindrical specimens water cured for 28 days, by applying 60 V DC for 6 hours and measuring the total charge passed (Coulombs). Freeze-thaw resistance was evaluated in accordance with TS EN 12390-9 by applying one freeze-thaw cycle per day and measuring mass loss and remaining flexural/compressive strength at 30, 56 and 76 cycles. The accelerated carbonation resistance was determined in a carbonation chamber, the interior CO2 concentration of which was adjusted at 1% with 80% relative humidity and 20 °C. The carbonation depth was detected using a 1% phenolphthalein indicator solution and remaining flexural/compressive strength determined after exposure.

3 Results and Discussion

3.1.Chemical Characterization

Table 2 presents the oxide composition of Konya-sourced RCF, as determined by XRF analysis, in comparison with the reference cement.

Table 2. Oxide composition of Konya RCF and reference cement (XRF).

Oxide	Konya RCF (%)	Cement (%)
SiO_2	8.0	15.2
Al_2O_3	1.1	4.2
Fe_2O_3	2.4	4.0
CaO	51.9	61.6
MgO	0.3	1.2
SO_3	0.7	3.8
K_2O	0.6	0.96
CO_2	35.0	8.0

The Konya RCF exhibits a markedly low SiO_2 content (8.0%) relative to the reference cement (15.2%), while its CaO content (51.9%) is comparatively close to that of the reference cement (61.6%). This combination indicates that carbonate-based (limestone-derived) components are likely dominant in the aggregate/paste fraction of the parent concrete, rather than a silica-rich composition typically associated with pronounced pozzolanic reactivity [13, 14]. This interpretation is further supported by the material's high CO_2 content, recorded at approximately 35.0%. On the basis of the low SiO2 and high CaO and CO_2 contents, the Konya RCF is expected to behave predominantly as a filler-type addition rather than as a strongly reactive pozzolanic material.

Table 3 summarizes the compliance of Konya RCF with relevant chemical limits defined in TS EN 197-6. The chloride content of the Konya RCF was 0.0715% and the Cl^- limit is stated to be 0.1%; The sulfate content (SO_3) of the Konya RCF was 0.27%, which is substantially below the 2.0% limit specified for recycled concrete fines in TS EN 197-6, confirming compliance with the sulfate requirement. The methylene blue value was 0.50 g/kg (equivalent

to 0.05 g/100 g), which is well below the 1.20 g/100 g limit specified in TS EN 197-6, indicating a low content of clay and clay-like harmful fines. The total organic carbon content (TOC) was 0.76%, which complies with the 0.80% upper limit specified in TS EN 197-6.

Table 3. Chemical compliance of Konya RCF.

Parameter	Konya RCF	Limit	Compliance
Cl^- content	0.0715%	≤ 0.10% (TS EN 197-6)	Compliant
SO_3 content	0.27%	≤ 2.00% (TS EN 197-6)	Compliant
Methylene blue (MB)	0.05 g/100 g	≤ 1.20 g/100 g (TS EN 197-6)	Compliant
TOC	0.76%	≤ 0.80% (TS EN 197-6)	Compliant

3.2.Physical Characterization

Fig.1 presents the particle size distribution curve obtained by laser diffraction (Mastersizer 2000) for the Konya RCF in comparison with the reference cement. The Konya RCF displays a substantially coarser particle size distribution than the reference cement when assessed by laser diffraction. The distribution span (4.041 vs. 2.571) and uniformity coefficient (1.31 vs. 0.801) of the Konya RCF further confirm a wider and more heterogeneous particle size distribution than that of the reference cement.

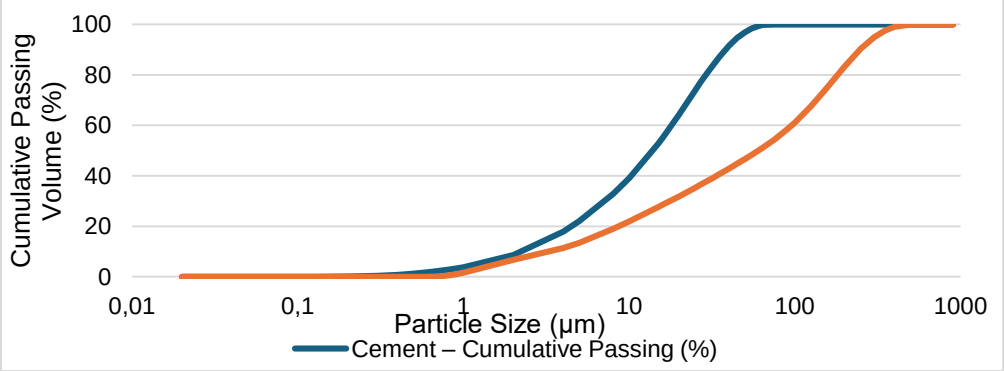

Fig. 1. Particle size distribution.

3.3.Fresh-State Properties

Table 4 presents the flow (consistency) results obtained on the paste mixtures. The control mixture exhibited a flow value of 17.5 cm. The Konya 20% mixture showed a slightly reduced flow (16.25 cm) relative to the control, consistent with the increased water demand typically associated with the finer fraction and angular morphology of the ground recycled aggregate, whereas the Konya 30% mixture exceeded the control (17.75 cm). This recovery — and, at the 30% replacement level, exceedance — of flow relative to the control may be attributed to a "ball-bearing" effect of the coarser, more rounded RCF particles present at the higher replacement level, which can locally improve particle mobility within the fresh mixture, together with a proportional reduction in the fine paste fraction as the replacement level increases.

Table 4. Flow (consistency) results.

Mixture	Control	Konya 20%	Konya %30
Flow (cm)	17.5	16.25	17.75

Table 5. Setting time and soundness results.

Mixture	w/c	Initial set (min)	Final set (min)	Soundness (mm)
Control	0.33	165	225	1
Konya 20%	0.32	165	270	1
Konya 30%	0.31	180	285	1

The water/cement (w/c) ratios reported in Table 5 correspond to the water demand required to achieve standard consistency for each paste mixture, determined in accordance with TS EN 196-3, and are therefore independent of the fixed water/binder ratio used in the mortar mix design (Table 1). The initial and final setting times of the RCF-substituted paste mixtures were both extended relative to the control (165 min / 225 min): the Konya 20% mixture recorded 165 min / 270 min, and the Konya 30% mixture recorded 180 min / 285 min. This extension is consistent with the dilution of clinker content, which slows the early-age hydration reactions responsible for paste stiffening [10]. The Le Chatelier expansion (soundness) values for both the Konya 20% and Konya 30% mixtures remained at 1 mm, well below the 10 mm limit set in TS EN 197-1 and retained in TS EN 197-6, confirming that Konya RCF incorporation does not compromise the volumetric stability of the cement paste at either replacement level.

3.4.Mechanical Properties

Tables 6 and 7 present the flexural and compressive strength results, respectively, obtained for the control and Konya-RCF mortar mixtures under both the air-curing series (tested at 2, 7 and 28 days) and the water-curing series (tested at 2, 7 and 28 days for flexural strength and at 2, 7 and 28 days for compressive strength).

As expected, strength increased with curing age within each series, and water-cured specimens consistently outperformed their air-cured counterparts for every mixture and every property. The effect of curing regime is most evident in 28-day compressive strength: for the control mixture, air curing yielded 43.3 MPa versus 50.9 MPa under water curing — a reduction of approximately 15% attributable to curing regime alone — confirming that, even for an unblended reference cement, the absence of continuous moist curing measurably limits attainable strength [15]. Notably, the air-cured control mixture continued to gain compressive strength between 7 days (35.8 MPa) and 28 days (43.3 MPa), whereas the air-cured Konya 20% series showed the same strength over the same interval (27.4 MPa at both 7 and 28 days), which is consistent with limited continued hydration once moisture within the RCF-substituted specimen is depleted, combined with possible drying-shrinkage-related microcracking under uncontrolled ambient conditions, rather than with genuine further strength development [16, 17]. For the Konya-RCF mixtures, the curing-regime effect compounds the dilution effect already observed under water curing. At 28 days, air-cured compressive strength decreased from 43.3 MPa (control) to 27.4 MPa (Konya 20%, −37%) and to 22.4 MPa (Konya 30%, −48%), exceeding the reductions observed under water curing (−32% and −40%, respectively, relative to the water-cured control) and indicating that the adverse effect of RCF replacement on strength is amplified under air-curing conditions. Flexural strength followed a similar pattern, with the air-cured Konya 30% mixture showing a particularly low 2-day value (1.7 MPa) relative to the control (4.4 MPa), suggesting that early-age flexural capacity is especially sensitive to the combination of high replacement ratio and unfavorable (air) curing.

Table 6. Flexural strength under air curing and water curing (MPa).

Mixture	Air 2 d	Air 7 d	Air 28 d	Water 2 d	Water 7 d	Water 28 d
Control	4.4	5.0	6.0	4.9	6.7	8.1
Konya 20%	3.4	4.1	4.1	3.8	6.3	7.3
Konya 30%	1.7	4.3	4.3	3.0	6.4	6.5

Table 7. Compressive strength under air curing and water curing (MPa).

Mixture	Air 2 d	Air 7 d	Air 28 d	Water 2 d	Water 7 d	Water 28 d
Control	24.8	35.8	43.3	22.1	41.8	50.9
Konya 20%	18.3	27.4	27.4	14.8	29.7	34.4
Konya 30%	13.7	21.2	22.4	11.1	25.9	30.6

TS EN 197-6 classifies RCF-containing cements according to the strength classes defined in EN 197-1, of which the lowest, 32.5, requires a minimum 28-day compressive strength of 32.5 MPa. Under water curing, the Konya 20% mixture (34.4 MPa) satisfies this minimum requirement, whereas the Konya 30% mixture (30.6 MPa) falls just below it. Under air curing, however, neither Konya mixture reaches the 32.5 MPa threshold: the Konya 20% mixture attains only 27.4 MPa and the Konya 30% mixture only 22.4 MPa at 28 days, whereas the air-cured control mixture (43.3 MPa) comfortably exceeds this threshold — confirming that the failure to meet the strength class under air curing is attributable specifically to RCF incorporation rather than to the curing regime itself. This finding substantially refines the answer to the central question posed in the abstract of this study — whether RCF-based supplementary cementitious materials can meet the mechanical performance thresholds defined by TS EN 197-6. For the Konya-sourced material, meeting this threshold is achievable, but only at the lower (20%) replacement ratio and only under adequately moist (water) curing; under field-representative air curing, the tested Konya-RCF blends do not reach the minimum strength class at either replacement ratio within the 28-day period examined. This underlines that, in practical applications, curing management is at least as decisive as replacement ratio in determining whether an RCF-based cement meets TS EN 197-6 requirements.

Pozzolanic activity index (PAI) results obtained for the (water-cured) Konya RCF at a 25% replacement ratio were determined to be 66%, 73% and 66% at 2, 7 and 28 days, respectively — all remaining below the 75% threshold generally accepted as indicative of adequate pozzolanic activity. This can show that the effect of RCF as a pozzolanic material was very limited. This is consistent with its lower SiO_2 content and its coarser particle size. This supports the characterization of Konya RCF as behaving predominantly as a filler-type, rather than strongly pozzolanic, addition — a behavior that is particularly disadvantaged when continuous moisture for late-age pozzolanic reaction is not guaranteed, as under air curing.

3.5.Durability Properties

Table 8 summarizes the durability performance of the (water-cured) Konya-RCF mortar mixtures under sulfate/acid exposure (1% H_2SO_4 solution, 90 days), rapid chloride permeability testing, freeze-thaw cycling (F-T) (76 cycles) and accelerated carbonation exposure.

Table 8. Summary of durability performance water-cured series.

Mixture	Sulfate strength loss, 90 d (%)	RCPT (C) / Class	Freeze-thaw mass loss, 76 cyc. (%)	Residual compressive strength, 76 cyc. (F-T) (MPa)	Carbonation compressive strength (MPa)
Control	12.91	3466 / Medium	0.43	45.7	43.6
Konya 20%	14.90	4601 / High	0.57	32.6	31.0
Konya 30%	23.49	5582 / High	0.51	27.2	29.1

Under sulfuric acid exposure, the compressive strength loss of the control mixture reached 12.91% after 90 days. The Konya 20% mixture exhibited a comparable strength loss of 14.90% at 90 days, indicating a favorable sulfate/acid resistance at this replacement level, potentially attributable to a buffering effect of the calcite-rich RCF, which may act partly as an inert filler that densifies the pore structure while limiting the proportion of reactive aluminate phases susceptible to expansive sulfate-related reaction products [18]. In contrast, the Konya 30% mixture exhibited a substantially higher strength loss, reaching 23.49% at 90 days, indicating that the buffering capacity observed at 20% replacement is insufficient to offset the effects of increased porosity and binder dilution at the higher replacement ratio.

The rapid chloride permeability test (RCPT) results, expressed as total charge passed (Coulombs) in accordance with ASTM C1202, classified the control mixture as exhibiting "Medium" permeability (3466 C). Both Konya-RCF mixtures were classified as exhibiting "High" permeability, with values of 4601 C (20% replacement) and 5582 C (30% replacement) — the latter representing a further increase relative to the 20% mixture. This result indicates that the coarse particle structure and limited pozzolanic reactivity of Konya RCF result increased pore connectivity and permeability [19], an effect that intensifies with increasing replacement ratio.

Under freeze-thaw cycling, mass loss after 76 cycles remained of a broadly similar order across all mixtures (control: 0.43%; Konya 20%: 0.57%; Konya 30%: 0.51%), with residual compressive strength (Table 9) decreasing from 45.7 MPa (control) to 32.6 MPa (Konya 20%) and 27.2 MPa (Konya 30%) at 76 cycles — values broadly proportional to the corresponding unexposed 28-day water-cured strengths.

Following accelerated carbonation exposure, the residual compressive strength of the Konya 20% and Konya 30% mixtures (31.0 MPa and 29.1 MPa, respectively) remained broadly consistent with their corresponding unexposed 28-day water-cured compressive strength values (34.4 MPa and 30.6 MPa), indicating that carbonation exposure under the tested conditions did not cause strength decrements further.

4 Conclusions

Based on the experimental characterization and testing of construction and demolition waste-derived recycled concrete fines (RCF) sourced from Konya, Türkiye, under both water-curing and air-curing regimes, the following conclusions can be drawn:

1. The chemical composition of Konya RCF is characterized by a low SiO_2 content and a high CaO/CO_2 content, indicating a carbonate (limestone)-dominated composition rather than a silica-rich composition typically associated with strong pozzolanic reactivity. Chloride, sulfate, methylene blue and total organic carbon values all remain within the limits defined by TS EN 197-6, confirming the chemical suitability of the material for use as a mineral admixture.

2. Incorporation of Konya RCF extends setting time and slightly alters flow behavior relative to the control mixture, but soundness remains well within the limits defined by TS EN 197-1/197-6 at both 20% and 30% replacement ratios.

3. Curing regime has a decisive effect on mechanical performance. Under water curing, the 28-day compressive strength of the Konya 20% mixture (34.4 MPa) satisfies the minimum requirement of the 32.5 strength class defined in TS EN 197-6, whereas the Konya 30% mixture (30.6 MPa) does not. Under air curing, any mixture reaches this threshold, even though the air-cured control mixture (43.3 MPa) comfortably exceeds it — indicating that the failure to meet TS EN 197-6 mechanical requirements under air curing is driven specifically by RCF incorporation, and that adequate moist curing remains essential for Konya-sourced RCF cement to meet these requirements.

4. The pozzolanic activity index of Konya RCF (66-73% across 2-28 days at 25% replacement, water-cured) remains below the 75% threshold generally accepted for adequately pozzolanic materials, consistent with a predominantly filler-type behavior that is particularly disadvantaged under curing regimes offering limited sustained moisture.

5. Durability results (water-cured specimens) indicate acceptable sulfate/acid resistance at 20% replacement, comparable to the control mixture, but substantially reduced resistance at 30% replacement. Freeze-thaw mass loss after 76 cycles remained low and broadly similar across all mixtures (0.43–0.57%), without a clear trend with replacement ratio. Chloride permeability is classified as “High” at both replacement levels, with permeability increasing with replacement ratio.

6. Taken together, these findings indicate that it is possible to utilize Konya-sourced concrete fines for the production of a TS EN 197-6-compliant Portland-recycled-fines cement from a strength perspective, provided that (i) the replacement ratio is limited to approximately 20% and (ii) adequate moist curing is ensured; a 30% replacement ratio, and air-curing conditions at either replacement ratio, are not recommended for this specific waste source without additional activation (e.g. mechanical, chemical, or nano-suspension activation) or curing control measures.

7. These results, obtained for a single waste source, underline the importance of source-specific characterization of construction and demolition waste and of realistic curing assessment prior to its use as a mineral admixture, and support the broader conclusion that the safe replacement ratio for recycled concrete fines in TS EN 197-6-compliant cements is materially dependent on both the mineralogical and physical properties of the parent waste source and the curing conditions expected in service.

Abstract. The fresh-state behavior of cementitious mixtures is a critical factor in 3D concrete printing, as printable materials must provide adequate workability, continuous extrusion, and buildability after deposition. The use of brick powder as a fine aggregate component provides a sustainability-oriented approach by valorizing ceramic-based construction waste and reducing the demand for conventional fine aggregates. Nevertheless, the fresh-state performance of brick powder-based printable mixtures requires further evaluation, as fine aggregate characteristics directly affect flow behavior, extrusion continuity, and buildability. Therefore, this study investigates the effects of ground granulated blast furnace slag (GGBFS) and fly ash (FA), used as supplementary cementitious materials (SCMs), on the fresh-state performance and printability of 3D printable concrete produced with brick powder fine aggregate. The mixtures were composed of CEM I 42.5 R cement, sand, brick powder fractions, calcined kaolin, polypropylene fibers, viscosity-modifying admixture, superplasticizer, and water. Four mixtures were prepared: a reference mixture and three modified mixtures incorporating GGBFS, FA, or their combined use at a total replacement level of 30% by mass of binder, corresponding to 30% GGBFS, 30% FA, and 15% GGBFS + 15% FA, respectively. The mixtures were evaluated by unit weight, flow table, extrudability, and buildability tests. The results showed that all mixtures exhibited acceptable fresh-state behavior for 3D concrete printing under the adopted laboratory-scale conditions. The combined GGBFS-FA mixture showed the lowest spread diameter of 11.5 cm, indicating a more stable consistency and lower tendency to flow. In terms of working time, the mixture containing 30% GGBFS provided the longest workable period (126 min), while the 30% FA mixture exhibited the shortest period (86 min); however, this duration still indicates an adequate processing window. The buildability results also indicated that the tested mixtures maintained their layer stability, with measured settlement values remaining in a narrow range. These findings suggest that GGBFS and FA can be used to modify the fresh-state behavior of 3D printable concrete with brick powder fine aggregate. Further optimization of SCM replacement ratios and admixture dosage may contribute to developing mixtures with a better balance between workability, extrudability, and buildability.

Keywords: 3D Printable Concrete; Brick Powder Fine Aggregate; Fresh-State Properties; Printability

1 Introduction

Three-dimensional concrete printing (3DCP) offers an alternative to conventional concrete construction by enabling automated, digitally controlled, and largely formwork-free production. In conventional concrete construction, formwork may account for approximately 50-75% of the total execution time and 35-54% of the cost of concrete structures [1]. By reducing the dependence on formwork and automating material placement, 3DCP can provide shorter construction times, lower labor requirements, reduced material waste, and greater geometric freedom. Reported estimates indicate potential reductions of approximately 30-60% in construction waste, 50-80% in labor costs, and 50-70% in production time compared with conventional construction methods [2]. However, improving the sustainability of 3DCP requires not only advances in the production process but also careful consideration of the materials used in printable mixtures. The cement industry is responsible for approximately 7-8% of global greenhouse-gas emissions [3], while construction and demolition waste constitutes a substantial share of the global solid-waste stream [4]. Therefore, reducing Portland cement consumption and incorporating industrial and construction-derived materials into printable mixtures are important strategies for improving the environmental performance of 3DCP.

Achieving these potential benefits strongly depends on the fresh-state performance of the cementitious material. Unlike conventional concrete, a 3D-printable mixture must satisfy several successive and sometimes competing requirements during pumping, extrusion, deposition, and layer-by-layer construction [5,6]. The material must remain sufficiently workable for transport, be extruded continuously without segregation or blockage, retain its geometry after leaving the nozzle, and develop sufficient early structural stability to support subsequent layers. Extrudability and buildability are therefore closely related to workability and open time [7]. From a rheological perspective, adequate flow during pumping and extrusion must be balanced with sufficient yield stress and rapid structural build-up after deposition to maintain layer geometry and prevent collapse [8,9]. Experimental studies have likewise shown that unit weight, flow behavior, extrudability, buildability, open time, and rheological parameters should be considered together when evaluating a printable cementitious mixture [10]. A recent review further emphasizes that flowability, buildability, extrudability, pumpability, and open time are fundamental fresh-state criteria and that all mixture constituents can influence the rheological response of 3D-printable cementitious composites [11].

The aggregate phase can significantly influence this fresh-state balance. Brick-derived fine particles generally differ from natural sand in porosity, water absorption, angularity, and surface roughness. These characteristics can modify the amount of free water available in the mixture, interparticle friction, flowability, and consistency retention; the magnitude of the effect depends on particle size, replacement level, moisture condition, and additional-water management [12]. In 3D-printable concrete, recycled brick aggregate has been shown to require additional water because of its relatively high porosity and absorption, demonstrating the importance of accounting for aggregate characteristics when designing printable mixtures [13]. More recent work has also shown that fine recycled aggregates derived from brick and concrete can be incorporated into cement-based mixtures intended for extrusion, although workability, shape retention, and stability still require careful optimization [14]. Thus, the use of brick powder as fine aggregate provides a promising route for valorizing construction waste and reducing the consumption of conventional natural fine aggregates, while making fresh-state control particularly important.

Binder composition is equally important in controlling fresh-state behavior. Ground granulated blast furnace slag (GGBFS) and fly ash (FA) are widely used supplementary cementitious materials (SCMs), but their influence on 3DCP is not limited to hardened properties. Binder type, particle characteristics, fineness, and interactions with water and

chemical admixtures can alter yield stress, viscosity, structural build-up, consistency retention, and overall printability [15]. Experimental investigations specifically examining FA and GGBFS in cement-based 3D-printing materials have reported measurable changes in fluidity, rheological properties, setting behavior, extrudability, and buildability as their contents are varied [16]. Similarly, 3D-printable concrete mixtures containing different FA and GGBFS replacement levels have been successfully extruded and evaluated through buildability testing, confirming that both the type and dosage of the SCM influence printing performance [17]. Printable cementitious systems containing GGBS have also been assessed through actual printing trials together with density, static yield stress, and time-dependent structural build-up measurements, illustrating the value of evaluating fresh-state behavior under the specific material and process conditions used for printing [18].

Although brick-derived fine aggregates, GGBFS, and FA have each been investigated in 3DCP, comparatively limited information is available on their combined use in the same Portland-cement-based printable system. In particular, the individual and combined effects of GGBFS and FA on the fresh-state behavior of 3D-printable concrete incorporating brick powder as fine aggregate require further evaluation. Therefore, this study comparatively investigates a reference mixture and mixtures containing GGBFS, FA, and their combined use. Unit weight, flow-table spread, workable time, extrudability, and buildability were evaluated to determine how these supplementary cementitious materials influence the balance between flowability, extrusion stability, and shape retention in 3D-printable concrete incorporating brick powder as fine aggregate.

2. Materials and Method

2.1 Materials

Portland cement (CEM I 42.5 R), supplied by the ADOÇİM Tokat plant, was used as the primary binder. Ground granulated blast furnace slag (GGBFS), obtained from the OYAK Cement Bolu plant, and Class C fly ash (FA), supplied by the İSKEN Energy Thermal Power Plant in Hatay, were used as supplementary cementitious materials for partial cement replacement. The aggregate phase consisted of 0.5–1.5 mm quartz sand supplied by Aydınlar Madencilik (İzmir) and recycled brick particles with size fractions of 1–2 mm and 0–1 mm. To improve the printability of the mixtures, BMT-brand calcium sulfate hemihydrate ($CaSO_4 \cdot 0.5H_2O$) was used as a viscosity-modifying component and was included in the total binder content. Calcined kaolin clay, 6 mm polypropylene fibers, and a polycarboxylate-based superplasticizer (Sika ViscoCrete ACE 450 TR) were also incorporated into the mixtures. Potable tap water supplied by Tokat Gaziosmanpaşa University was used as the mixing water.

2.2 Mix designs

Four different mixtures were prepared while keeping the total binder content and water-to-binder ratio constant. The reference mixture contained Portland cement and calcium sulfate hemihydrate, whereas in the other three mixtures Portland cement was partially replaced by 30% GGBFS, 30% FA, and a combination of 15% GGBFS + 15% FA, respectively. The total binder content was fixed at 500 g, including calcium sulfate hemihydrate at 20% of the total binder mass, while the water-to-binder ratio was maintained at 0.66. Superplasticizer and calcined kaolin were added at 1.3% and 5% of the total binder mass, respectively. The polypropylene fiber content was kept constant at 0.2% by volume of the total mixture for all mixtures. The mixture proportions are presented in Table 1.

Table 1. Proportions of 3D Printable Concrete Mixtures (Unit: g)

Mixture	Cement	Wt.	VMA	Clay	FA	GGBFS	Fiber	SP	Sand %20	BP 1-2mm %20	BP 0-1mm %60
Control	400	330	100	25	-	-	1.82	6.5	250	250	750
G30	250	330	100	25	-	150	1.82	6.5	250	250	750
F30	250	330	100	25	150	-	1.82	6.5	250	250	750
G15-F15	250	330	100	25	75	75	1.82	6.5	250	250	750

2.3 Specimen preparation procedure

The mixtures were prepared according to a fixed mixing sequence. First, the dry constituents, including cement, GGBFS, FA, aggregates, polypropylene fibers, calcined kaolin, and calcium sulfate hemihydrate, were mixed at low speed (62.5 rpm) for 2 min. Then, 200 g of water was added, and mixing was continued at the same speed for another 2 min. Subsequently, the remaining 130 g of water and 6.5 g of superplasticizer were added, followed by 1 min of low-speed mixing. Finally, the mixture was mixed at a higher speed of 125 rpm for 2 min to obtain a homogeneous mixture.

The prepared mixtures were subjected to fresh density, extrudability, buildability, flow-table spread, and workable-time tests.

3. Results and Discussion

To evaluate the fresh-state properties and printability of the mixtures, fresh density was determined in accordance with TS EN 12350-6, and the results are presented in Table 2.

Table 2. Density of the Concrete Mixtures

Mixture	Mass (g)	Volume (cm^3)	Density (g/cm^3)
Control	383.35	174	2.20
G30	369.25	174	2.12
F30	387.10	174	2.23
G15F15	390.39	174	2.24

The fresh densities of the mixtures were relatively close to one another, ranging from approximately 2.12 to 2.24 g/cm^3, as presented in Table 2. G15F15 exhibited the highest fresh density, whereas G30 showed the lowest value. The relatively small differences among the mixtures may be associated with variations in the density and fineness of the constituent materials.

Since a full-scale 3D concrete printer was not available during the experimental program, extrudability was evaluated using a mortar injection pump equipped with a nozzle. The mixtures were assessed in terms of their ability to be extruded continuously and homogeneously, while the width and thickness of the extruded filaments were measured to evaluate dimensional stability and shape retention. Buildability was evaluated by depositing successive layers and monitoring their ability to retain their geometry under the load of the overlying layer. The consistency and spread diameter of the mixtures were determined using the flow-table method in accordance with EN 1015-3, which specifies the determination of fresh-mortar consistency by flow value. Workable time was determined in accordance with EN 1015-9, which covers the determination of the workable life of fresh mortar, by monitoring the time required for the flow value to decrease by 30 mm from its initial value.

During the extrudability tests performed using the mortar injection pump, all mixtures were discharged continuously and homogeneously through the nozzle. The measured filament widths and thicknesses showed only small deviations, indicating satisfactory extrusion stability and shape retention under the adopted test conditions. The extrudability results are presented in Table 3 and Fig. 1.

Table 3. Extrudability Test Results

Samples	Extrudability Measurements		
	Thickness	**Width**	**Observation**
REF	1.6 cm	5.75 cm	Printable
G30	1.6 cm	5.70 cm	Printable
F30	1.7 cm	5.70 cm	Printable
G15F15	1.7 cm	5.8 cm	Printable

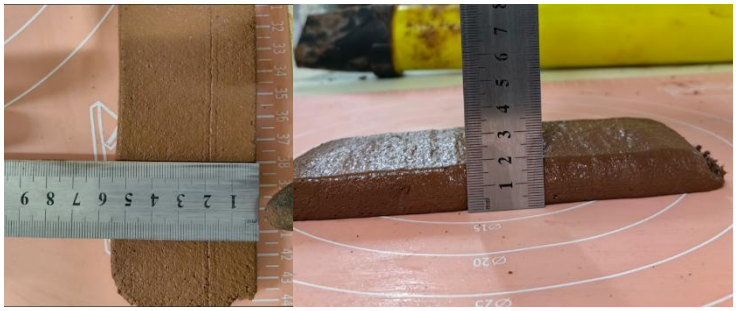

Fig. 1. Extrudability Test

Table 4. Buildability Test Results (ThicknessValues)

Samples	Thickness1 (cm)	Thickness2 (cm)	Thickness3 (cm)	Avg. Thickness(cm)
REF	1.6	1.6	1.6	1.60
G30	1.6	1.6	1.6	1.60
F30	1.7	1.7	1.7	1.70
G15F15	1.6	1.6	1.6	1.60

Buildability was evaluated by examining the ability of successive layers to be deposited while maintaining their geometry. As shown in Table 4, the layer thicknesses of all mixtures remained stable under the self-weight of the deposited layers, with thickness values ranging from 1.6 to

1.7 cm. These results indicate that the mixtures containing recycled brick aggregate exhibited adequate load-bearing capacity and shape retention for the adopted layer-by-layer deposition conditions.

Fig. 2. Buildability Test

In the flow-table test, the G15F15 mixture exhibited the lowest average spread diameter, at 11.5 cm, indicating lower flow tendency and greater fresh-state shape stability. This behavior may be advantageous for maintaining layer geometry during 3D printing. The spread diameters of all mixtures were within the range considered suitable for printable cementitious mixtures, and the results are presented in Table 5.

Table 5. Flow Table Spread Diameters of the Mixtures (cm)

Sample	Average Spread Diameter (cm)
REF	13.25
G30	12.9
F30	12.85
G15F15	11.5

Fig. 3. Flow Table Test

To determine the workable time (open time), the flow-table test was repeated at 15 min intervals, and the elapsed time until the spread diameter decreased by 3 cm from its initial value was recorded as the workable time. G30 exhibited the longest workable time, reaching 126 min, whereas F30 showed the shortest value at 86 min. The G15F15 mixture provided a workable time of 102 min, relatively close to that of the reference mixture, indicating that the combined use of GGBFS and FA maintained an adequate processing window. Overall, GGBFS tended to

extend the workable time, while FA shortened it under the investigated conditions. The results are presented in Table 6.

Table 6. Workable Time of the Mixtures (Time Corresponding to a 3 cm Reduction in Spread Diameter, min)

Reduction in Spread Diameter	REF (min)	G30 (min)	F30 (min)	G15F15 (min)
1 cm	39	42	29	34
2 cm	78	84	58	68
3 cm	117	126	86	102

3. Conclusion

This study investigated the effects of ground granulated blast furnace slag (GGBFS) and fly ash (FA) on the fresh-state properties and printability of 3D-printable concrete incorporating brick powder as fine aggregate. All mixtures exhibited continuous extrusion and adequate layer stability under the adopted laboratory-scale printing conditions, indicating that the incorporation of these supplementary cementitious materials did not prevent satisfactory printability.

Among the mixtures, G15F15 exhibited the lowest flow-table spread of 11.5 cm, indicating greater resistance to flow and improved shape retention after deposition. In terms of workable time, G30 provided the longest processing window at 126 min, whereas F30 showed the shortest workable time at 86 min. The G15F15 mixture maintained an intermediate workable time of 102 min, providing a favorable balance between consistency retention and processing duration. These results demonstrate that GGBFS and FA influence fresh-state behavior differently and that their combined use can provide a suitable balance between flowability, extrusion stability, shape retention, and workable time.

The results also indicate that brick powder can be incorporated as a fine aggregate component together with GGBFS and FA without compromising the fresh-state requirements evaluated in this study. Thus, the combined use of brick-derived construction waste and supplementary cementitious materials offers a promising approach for reducing the consumption of Portland cement and natural fine aggregate in 3D-printable cementitious mixtures.

The present investigation was limited to laboratory-scale extrusion and two-layer deposition because of equipment and operational constraints. Future studies should therefore evaluate the mixtures using a larger number of printed layers and automated printing systems to verify their buildability under more demanding conditions. Further investigations should also quantify the effects of GGBFS and FA through rheological measurements, including yield stress, viscosity, and structural build-up, and examine the influence of viscosity-modifying admixture and superplasticizer dosage on the printing window. In addition, interlayer bond strength, long-term mechanical performance, durability, and resistance to thermal and chemical exposure should be investigated to support the development of optimized mixtures for larger-scale 3D concrete printing applications.

Abstract. Structural lightweight aggregate concrete (LWAC) offers advantages to reduce structural dead loads; however, like conventional concrete, its inherently brittle behavior requires reinforcement to enhance flexural performance. The use of natural fibers as a renewable resource may improve the mechanical response of LWAC. This potential benefit, however, should be evaluated by taking their durability in the alkaline cementitious environment into consideration. This study investigates the mechanical performance of hemp fiber reinforced structural lightweight concrete (HSLWC) incorporating volcanic pumice aggregate (VPA, 2-10 mm) and supplementary cementitious materials (SCMs). Metakaolin (MK), Class F fly ash (FA), and their combination constituted 20% of the total binder content. Binder content was 350 kg/m³ for the reference (C) and MK mixtures, and 400 kg/m³ for the FA and MK+FA mixtures, with a constant water-to-binder ratio (*w/b*) of 0.40. The 100% cement reference was fiber-free, all SCM-containing mixtures contained 1% hemp fiber. Compressive strength was determined at 7 and 28 days, water absorption was measured, and flexural strengths were assessed through three-point bending tests. In addition, 28-day prism specimens were immersed in water at 50 ± 2 °C for seven days to evaluate the effect of accelerated aging. The MK mixture achieved the highest compressive strength and binder efficiency with a total binder content of 350 kg/m³. At a binder content of 400 kg/m³, MK+FA produced higher performance than FA. Water absorption remained within a narrow range of 3.1–4.1% despite the use of 50% VPA by volume. Maximum flexural load increased after accelerated aging, and MK+FA series maintained the highest load before and after aging. Overall, the combined MK+FA system yielded the best balance among compressive strength, flexural performance, water absorption, and sorptivity.

Keywords: Structural lightweight concrete; Hemp fiber; Pumice aggregate; Metakaolin; Class F fly ash; Accelerated water aging.

1 Introduction

Structural lightweight aggregate concrete (LWAC) has a lower unit weight than normal-weight concrete to reduce structural dead loads. This reduction can lead to smaller demands on structural members and foundations and, owing to the mass-dependent nature of earthquake-induced forces, lower seismic actions. Among the lightweight aggregates used in structural LWAC, pumice is a volcanic based natural aggregate that enables the production of concrete with reduced density.

Like conventional concrete, LWAC is inherently brittle; steel or polypropylene fibers were reported to improve its flexural and post-cracking performance, including toughness and energy absorption ([1] [2]). Currently, natural fibers are increasingly investigated as renewable reinforcement materials for cementitious composites. Hemp fibers were previously reported to improve the flexural behavior and energy absorption capacity of concrete [3]. In pumice based

lightweight concrete, hemp fibers have been recently reported to enhance deformation capacity depending on the composition of the cementitious matrix [4]. However, the long-term performance of cellulosic fibers in cementitious matrices remains a critical durability consideration. The alkaline environment of hydrated cement can induce the degradation of lignin and hemicellulose through the penetration of hydration products into the fiber structure, thus leading to fiber mineralization. These mechanisms increase fiber brittleness and consequently impair the long-term reinforcing performance of cellulosic fibers [5].

Supplementary cementitious materials (SCMs) can mitigate the degradation of cellulosic fibers when used as partial replacements for Portland cement. Reductions in $Ca(OH)_2$ content and stabilization of the matrix alkalinity have been identified as mechanisms to enhance durability [6]. Metakaolin can also reduce fiber degradation under accelerated aging conditions [5]. In cellulosic fiber reinforced mortars, its use yielded a marked reduction in capillary absorption [7]. In addition to metakaolin, Class F fly ash was investigated both individually and in combination with other SCMs to mitigate the degradation of cellulosic fiber–cement composites [6].

Accelerated aging procedures provide a means to observe variations in the mechanical performance of fiber reinforced cementitious composites over relatively short experimental periods. Hot-water immersion, a well-established accelerated-aging technique for glass-fiber-reinforced cement composites [8], allows changes under short-term exposure to be related to long-term mechanical behavior.

To the authors' knowledge, only one previous study has combined VPA with hemp fibers to mitigate fiber degradation through SCMs [4]. Against this limited background, the present study focuses on HSLWC incorporating VPA and modified with metakaolin (MK), Class F fly ash (FA), or their combination as partial cement replacements. Compressive strength, water absorption, and sorptivity were determined, while flexural load capacity was assessed before and after accelerated water aging.

2 Materials and Methods

2.1 Materials and Mix Proportions

CEM II/A-S 42.5 R cement was used in all mixtures. Metakaolin (MK) and Class F fly ash (FA) were incorporated as SCMs at a total SCM-to-binder ratio of 20%, comprising 20% MK, 20% FA, or a combination of 10% MK and 10% FA. A fiber-free 100% cement mixture was also designed as the reference mixture (C). The total binder content was 350 kg/m³ for the C and MK mixtures and 400 kg/m³ for the FA and MK+FA mixtures. A constant water-to-binder ratio (*w/b*) of 0.40 was used for all the mixtures. The slump was measured as 16 cm for the reference mixture and ranged from 7 to 10 cm for the fiber reinforced mixtures. The photographs of hemp fiber and VPA as well as production stage are presented in Fig.1. The detailed mix proportions were given in *Table 1.*

Fig.1 Hemp fibers, pumice aggregates, slump test during mixture stage

Volcanic pumice (Nevsehir, 2-10 mm) was used as lightweight aggregate (LWA), constituting 50% of the total aggregate volume. Its bulk density in oven-dry condition is 690 kg/m^3, and the 24-hour water absorption value is 18%. The pumice aggregate was pre-saturated with water prior to mixing. Natural sand and limestone powder were used as normal-weight aggregates.

Hemp fibers with 30 mm length (V_f=1%) were added to MK, FA, and MK+FA mixtures. The fibers were also pre-saturated with water, and excess surface water was removed with a towel before they were added to the mixture.

Table 1. Mix proportions of concrete mixtures

Constituent (kg/m³)	**C**	**MK**	**FA**	**MK+FA**
Cement (C)	350	280	320	320
Metakaolin (MK)	-	70	-	40
Fly ash (FA)	-	-	80	40
Total binder (b)	350	350	400	400
Water (w)	140	126	160	160
Natural sand	558	586	525	527
Limestone powder	375	394	353	354
Pumice LWA	450	474	424	425
Hemp fiber	-	15	15	15
Superplasticizer	1.75	3.15	6.0	6.0
Fresh density	1848	1866	1880	1875

2.2 Preparation of Specimens and Test Setup

After mixing, the fresh concrete was cast into 100 × 100 × 100 mm cube specimens for compressive strength tests at 7 and 28 days and 40 × 40 × 160 mm prism specimens for three-point bending tests at 28 days. The specimens were maintained under ambient laboratory conditions until the specified test ages, without external water curing. The water-storage and gradual-release capacity of the pre-saturated pumice aggregates provided internal curing, thereby eliminating the need for water curing.

Three-point bending tests were performed using a span length of 120 mm. The specimens were loaded at a displacement rate of 0.3 mm/min, and the maximum load was recorded during each test to evaluate their flexural response.

A separate set of prism specimens was subjected to accelerated water aging after 28 days of curing. The specimens were fully immersed in water maintained at 50 ± 2 °C for seven days. Then the maximum loads of the aged specimens were compared with those of the 28-day specimens to evaluate the effect of accelerated water aging on flexural load capacity.

3 Results and Discussion

3.1 Compressive Strength Tests

Compressive strength increased from 7 days to 28 days for all specimens (*Table 2* and Fig.2), with relative increases of 9.5% for C, 22.9% for MK, 53.4% for FA, and 34.5% for MK+FA. The C mixture (V_f=0%) produced the highest compressive strength at both ages, reaching 35.5 MPa at 28 days, followed by MK and MK+FA with 33.3 and 31.2 MPa, respectively. FA had the lowest strength at 7 and 28 days but the greatest relative gain (53.4%) with curing time.

Since the *w/b* ratio was kept constant at 0.40 for all mixtures, the strength differences are primarily attributed to binder composition, total binder content, and fiber incorporation.

Table 2. Compressive strength results

Mixtures	7 Days (MPa)	28 Days (MPa)	Increase (%)
C (0%)	32.4	35.5	9.5
MK (1%)	27.1	33.3	22.9
FA (1%)	16.3	25.0	53.4
MK + FA (1%)	23.2	31.2	34.5

In the first comparison group, C and MK mixtures had the same total binder content of 350 kg/m³, while only MK contained 1% hemp fiber. 28-day strength of MK specimens was only 6.2% lower than that of fiber-free C mixture. A more direct assessment of binder composition is possible for FA and MK+FA mixtures, which had the same binder content of 400 kg/m³ and hemp-fiber volume (1%). The partial replacement of the 20% FA content with MK increased the compressive strength from 16.3 to 23.2 MPa at 7 days and from 25.0 to 31.2 MPa at 28 days. Overall, under the same *w/b* ratio, binder content, and hemp-fiber volume, partial replacement of FA with MK substantially improved compressive strength.

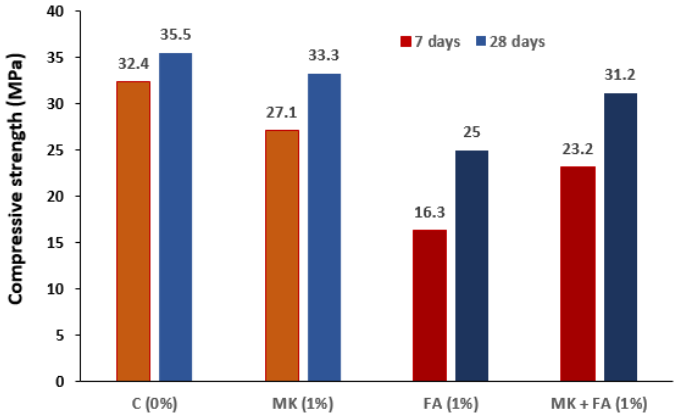

Fig. 2. Compressive strength development of the mixtures at 7 and 28 days.

The variations among the mixtures cannot be attributed solely to the type of supplementary cementitious material. Metakaolin has relatively high pozzolanic activity, particularly at early ages, whereas the effect of Class F fly ash may become more pronounced at later ages. In order to consider the different binder contents of the mixtures, compressive strength was evaluated per unit binder content, namely binder efficiency, as presented in Fig. 3. The C series attained the highest binder efficiency, closely followed by MK. Among 1% hemp fiber-reinforced mixtures, MK ranked first in efficiency despite its lower total binder content. At 28 days, the binder efficiency of MK reached 0.095 MPa.m^3/kg compared with 0.078 MPa.m^3/kg for MK+FA and 0.063 MPa.m^3/kg for FA, further highlighting the beneficial role of MK in the cementitious matrix.

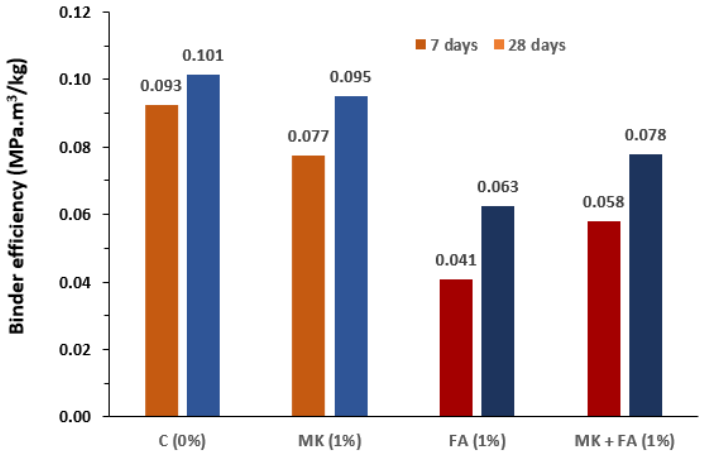

Fig. 3. 7- and 28-day binder efficiency of four mixtures

3.2 Flexural Behaviour and Accelerated Aging

The 28-day flexural behavior of the mixtures was evaluated based on the maximum load recorded during the three-point bending tests. The effect of accelerated water aging was addressed by comparing the results before and after aging, as summarized in *Table 3*. Before aging, MK+FA produced the highest load (2244 N), followed by MK (2040 N) and FA (1795 N). After aging, the values increased to 2428, 2342, and 2153 N, respectively, corresponding to increments of 8.2%, 14.8%, 19.9%. Although FA produced the largest relative increase, MK+FA maintained the highest load both before and after aging.

Table 3. Maximum flexural loads before and after accelerated water aging

Mixtures	28-day (N)	After aging (N)	Change (%)
MK	2040	2342	+14.8
FA	1795	2153	+19.9
MK + FA	2244	2428	+8.2

Examination of the fracture surfaces after aging revealed clear differences in fiber–matrix interaction. In the MK mixture (Fig. 4a), fewer pulled-out fibers were visible, consistent with a denser and more rigid ITZ. This may be attributed to the pozzolanic reaction of MK, which consumes CH and promotes the formation of additional C-S-H/C-A-S-H, thereby strengthening the fiber–matrix interface while reducing the alkaline environment around the fibers. Previous studies have reported that MK reduces pore-solution alkalinity and CH content, limiting fiber mineralization and improving the integrity of the fiber–matrix interface under accelerated exposure conditions [5]. In contrast, numerous exposed fibers were observed in the FA specimen (Fig. 4b), reflecting greater fiber pull-out, although its flexural load was lower than those of MK and MK+FA. More pulled-out fibers were observed in MK+FA than in MK (Fig. 4c), while this mixture also attained the highest flexural load after aging, pointing to a favorable balance between fiber–matrix adherence and pull-out resistance. Moreover, the increase in flexural load after aging may also reflect further strengthening of the cementitious matrix during hot-water exposure rather than changes in fiber behavior alone.

(a) (b) (c)

Fig. 4 View from aged specimens

3.3 Water Absorption and Sorptivity

Since all mixtures were produced at the same *w/b* ratio of 0.40, the observed differences can be considered mainly in relation to binder composition, total binder content, and the presence of hemp fibers (*Table 3*). The C, MK, and MK+FA mixtures had nearly identical water absorption values of 3.1–3.2%, while FA showed a slightly higher value of 4.1%. In the preliminary experiments, by using normal-weight aggregates and 350 kg/m^3 cement, water absorption was determined as 1.5%. Although the porous pumice aggregate constituted 50% of the total aggregate volume and had higher water uptake, water absorption remained within a narrow range of 3.1-4.1%. This is particularly noteworthy considering the differences in total binder content (350 and 400 kg/m^3), binder composition, and the incorporation of 1% hemp fiber.

Capillary water absorption (ASTM 1585-20), commonly used as an indirect indicator of pore connectivity and durability-related transport performance, was evaluated at 4 h in the linear region and at 72 hour in the later nonlinear region (*Table 4* and Fig. 5). Although the C mixture was fiber-free and the MK mixture contained 1% hemp fiber, MK specimens had substantially lower capillary water absorption. This suggests that the pore-refining effect of MK compensated for the water affinity of the hemp fibers and restricted the connectivity of capillary pores. The combined MK+FA mixture yielded the greatest resistance to capillary water transport, with values of 0.00 and 0.30 kg/m^2 at 4 and 72 h, respectively. FA showed the highest total water absorption (4.1%) but considerably lower capillary uptake than C. Moreover, despite the approximately 18% 24-h water absorption of the pumice aggregate, the relatively low water and capillary absorption values may also be associated with its internal-curing effect. The gradual release of stored water from the pumice can promote further hydration in the surrounding cementitious matrix and a denser aggregate–matrix ITZ. This common effect may partly explain why even the C mixture, without pozzolanic replacement, exhibited relatively low water and capillary absorption.

Table 4. Water absorption results of the mixtures

Mixtures	Total binder (kg/m^3)	Water absorption (%)	Capillary water absorption (kg/m^2)	
			4 hours	72 hours
C (0%)	350	3.1	0.6	1.57
MK (1%)	350	3.2	0.23	0.69
FA (1%)	400	4.1	0.20	0.90
MK + FA (1%)	400	3.2	0.00	0.30

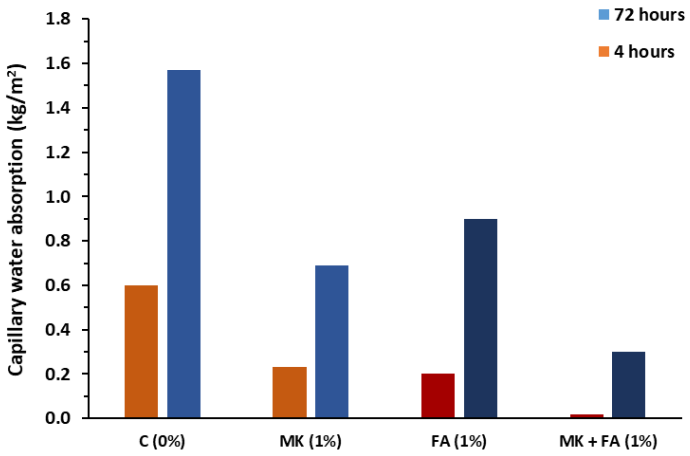

Fig. 5. Cumulative capillary water absorption values of four mixtures

4 Conclusions

The mechanical performance of hemp fiber reinforced structural lightweight concrete containing pumice aggregate was investigated using binder systems modified with metakaolin (MK), Class F fly ash (FA), and their combination. Based on the experimental results, the following conclusions were drawn:

- Among the hemp fiber reinforced mixtures, MK achieved the highest compressive strength and binder efficiency, despite its lower total binder content. Its 28-day compressive strength was only 6.2% below that of the fiber-free C mixture.
- At the same binder content, *w/b* ratio, and fiber content, partial replacement of FA with MK markedly improved performance. MK+FA increased the 28-day compressive strength from 25.0 to 31.2 MPa and provided the highest flexural load among the fiber-reinforced mixtures.
- Water absorption remained within 3.1–4.1%, although pumice constituted 50% of the total aggregate volume and had a 24-h water absorption of 18%. The low absorption of the C mixture and the further reductions in capillary uptake with MK and MK+FA indicate contributions from both pumice internal curing and SCM-induced pore refinement.
- Accelerated hot-water exposure did not reduce the maximum flexural load of any fiber reinforced mixture; instead, increases of 8.2–19.9% were observed. MK+FA maintained the highest load before and after aging, while its fracture surface indicated a favorable balance between fiber–matrix adherence and pull-out resistance.

Acknowledgments

The experiments in this study were carried out in R&D Dept. of NUH Beton Inc. Material, employer and equipment support of the firm to this experimental research are greatly appreciated. The authors would like to thank to Soylu Group providing pumice aggregate and Kaolin EAD providing metakaolin as well. The first author was supported by TÜBİTAK, Directorate of Science Fellowships and Grant Programmes (BİDEB), under the 2211-National Graduate Scholarship Programme.

Abstract. The design of cementitious mixtures for 3D concrete printing (3DCP) requires a careful balance between printability, mechanical performance, and sustainability. The use of brick powder as an alternative fine aggregate introduces a sustainable aggregate phase into printable mixtures; however, the hardened-state response of such systems depends strongly on binder composition and still requires further evaluation. In this context, the incorporation of ground granulated blast furnace slag (GGBFS) and fly ash (FA) as supplementary cementitious materials (SCMs) offers a potential route for tailoring the strength development of 3D printable concrete while improving the sustainability profile of cement-based composites. This study investigates the effects of GGBFS and FA on the mechanical performance of 3D printable concrete in which brick powder was used as a fine aggregate component. The experimental program included a reference mixture and three modified mixtures incorporating GGBFS, FA, or their combined use at a total replacement level of 30% by mass of binder, corresponding to 30% GGBFS, 30% FA, and 15% GGBFS + 15% FA, respectively. Compressive and flexural strength tests were conducted on standard specimens at 7, 14, and 28 days of curing. The results showed that the incorporation of GGBFS and FA generally reduced early-age strength compared with the reference mixture, mainly due to their slower hydration and pozzolanic reaction mechanisms. However, this trend changed at 28 days, when all SCM-incorporated mixtures reached higher strength values than the reference mixture. Among them, the combined GGBFS-FA mixture, incorporating 15% GGBFS and 15% FA by mass of binder, showed the best mechanical performance, reaching a 28-day compressive strength of 41.48 MPa and a flexural strength of 8.91 MPa. These results indicate that using GGBFS and FA together can enhance the hardened-state performance of 3D printable concrete with brick powder fine aggregate and suggest that further optimization of replacement ratios may lead to more effective and sustainable mixture designs.

1 Introduction

Extrusion-based three-dimensional concrete printing (3DCP) is a formwork-free manufacturing method in which a cement-based mixture is deposited layer by layer along toolpaths derived from a digital model. Although pumpability, extrudability, and buildability are essential prerequisites for successful printing, the post-hardening mechanical performance of the printed element is also a key factor determining its suitability for engineering applications [1,2]. The layer-by-layer production process, curing conditions, and mixture composition can influence compressive and flexural strengths as well as orientation-dependent mechanical behavior. Tarhan and Şahin [3] showed that air-entraining admixture dosage, curing method, and specimen orientation significantly affect the physicomechanical properties and microstructure of 3D-printed concrete. Similarly, Tarhan et al. [4] investigated the compressive, flexural, and splitting tensile behavior of sustainable 3D-printed composites and demonstrated that material composition and reinforcement can substantially influence hardened-state performance. Therefore, the design of 3DCP mixtures should consider not only printability but also the systematic evaluation of strength development with curing age.

The use of predominantly fine aggregates together with relatively high binder contents in 3DCP mixtures makes the environmental performance of the technology particularly sensitive to material selection [5]. In this context, recycling fired-clay-based construction and demolition waste through crushing and grinding is valuable both for reintegrating waste into the circular economy and for reducing the consumption of natural raw materials [6]. Waste brick can be used either as a partial cement replacement or as recycled fine aggregate. When used as fine aggregate, its porous and angular particle structure, relatively high water absorption, and differences in the aggregate–paste interface may influence the strength of the hardened composite differently from natural sand. The magnitude of these effects depends on particle size, replacement level, moisture condition, and water management within the mixture [6,7].

In addition to the characteristics of brick-derived fine aggregate, binder composition plays an important role in strength development. Ground granulated blast-furnace slag (GGBFS) is a latent hydraulic material, whereas fly ash (FA) primarily exhibits pozzolanic behavior. Partial replacement of Portland cement with these supplementary cementitious materials can alter hydration kinetics, hydration products, and pore structure, thereby affecting both early- and later-age strength development [8,9]. The relatively slow reactions of these mineral additions may limit early-age strength, whereas secondary reactions at later ages can contribute to matrix densification and improved mechanical performance. In the context of 3DCP, Tarhan and Tarhan [10] experimentally determined the compressive and flexural strengths of a printable cementitious mixture containing GGBFS and directly incorporated these properties into the nonlinear structural assessment of 3D-printed walls. This approach highlights that hardened-state testing provides essential data not only for material characterization but also for evaluating structural performance. Studies on the use of GGBFS and FA as partial cement replacements in 3DCP mixtures have likewise reported that both the type and replacement level of these materials can significantly influence mechanical strength development [11].

Previous studies have investigated brick-derived materials in 3DCP for different purposes. Recycled brick aggregate has been used as a replacement for natural aggregate [12]; replacement levels of up to 100% have been examined using fine recycled aggregates derived from brick and concrete [13]; brick powder has been incorporated together with GGBFS as part of the binder/powder fraction [14]; and it has also been used to replace conventional fine aggregate in fiber-reinforced 3DCP mixtures [15]. In the present study, the individual and combined effects of GGBFS and FA on 3D-printable concrete incorporating brick powder as fine aggregate were comparatively investigated through compressive and flexural strength tests conducted at 7, 14, and 28 days.

2 Material and Method

2.1 Material

Portland cement (CEM I 42.5 R) was used as the primary binder in this study. Ground granulated blast furnace slag (GGBFS), exhibiting latent hydraulic properties, and Class C fly ash (FA), exhibiting pozzolanic properties, were used as supplementary cementitious materials to partially replace cement. The aggregate phase consisted of 0.5–1.5 mm natural sand and brick powder (BP) with particle size ranges of 1–2 mm and 0–1 mm. A viscosity-modifying admixture (VMA), calcined kaolin, polypropylene fibers, and a superplasticizer (SP) were used to improve the printability performance of the mixtures. Potable tap water was used as the mixing water.

2.2 Mixture designs

Four different mixtures were prepared while keeping the total binder content and water-to-binder ratio constant. The binder phase of the reference mixture consisted solely of Portland cement. To investigate the effects of the mineral additions, three modified mixtures were designed: G30, in which 30% of the binder was replaced with GGBFS; F30, in which 30% was replaced with FA; and G15–F15, in which 15% GGBFS and 15% FA were used, corresponding to a total replacement level of 30%. Thus, the individual and combined effects of GGBFS and FA on the mechanical properties of 3D-printable concrete incorporating brick powder (BP) were comparatively evaluated. The mixture proportions are presented in Table 1.

Table 1. Proportions of 3D Printable Concrete Mixtures (Unit: g)

Mixture	Cement	Wt.	VMA	Clay	FA	GGBFS	Fiber	SP	Sand %20	BP 1-2mm %20	BP 0-1mm %60
Control	400	330	100	25	-	-	1.82	6.5	250	250	750
G30	250	330	100	25	-	150	1.82	6.5	250	250	750
F30	250	330	100	25	150	-	1.82	6.5	250	250	750
G15-F15	250	330	100	25	75	75	1.82	6.5	250	250	750

For each mixture and curing age (7, 14, and 28 days), three replicate specimens produced and were stored under controlled laboratory conditions at 20 ± 2 °C and 95 ± 5% relative humidity until testing.

Flexural and compressive strength tests were conducted at the end of each curing period. Flexural strength was determined on 40 × 40 × 160 mm prismatic specimens in accordance with TS EN 1015-11, using a loading rate of 0.05 kN/s. Following the flexural test, the fractured prisms were divided into two halves and were used for compressive strength testing. The compressive tests were then performed at a loading rate of 0.5 kN/s in accordance with TS EN 1015-11. This procedure enabled both flexural and compressive strengths to be determined sequentially from the same original specimens. The results for each mixture and curing age were evaluated based on the corresponding mean values.

3 Results and Discussion

3.1 Flexural Strength

The flexural strength results showed a clear age-dependent effect of GGBFS and FA incorporation (Table 2 and Fig.1). At 7 days, the reference mixture exhibited the highest flexural strength of 4.15 MPa, while G30, F30, and G15F15 reached 3.52, 3.43, and 3.39 MPa, respectively. Thus, all SCM-containing mixtures showed lower early-age flexural strength than the reference, with reductions of approximately 15–18%. This behavior is consistent with the relatively slower early-age contribution of GGBFS and FA compared with Portland cement.

Table 2. Flexural strength results of concrete mixtures (MPa)

Mixtures	7 Days	14 Days	28 Days
Control	4.15	5.80	6.59
G30	3.52	5.77	7.24
F30	3.43	6.14	7.12
G15-F15	3.39	5.89	8.91

By 14 days, the differences between the mixtures had substantially decreased. F30 reached the highest flexural strength of 6.14 MPa, approximately 6% higher than the reference value of 5.80 MPa, while G30 and G15F15 exhibited comparable strengths of 5.77 and 5.89 MPa, respectively. This convergence indicates that the contribution of the supplementary cementitious materials became more pronounced as curing progressed.

A more distinct improvement was observed at 28 days, when all SCM-containing mixtures exceeded the reference mixture. The flexural strengths of G30 and F30 increased to 7.24 and 7.12 MPa, corresponding to improvements of approximately 10% and 8%, respectively, over the reference value of 6.59 MPa. The highest strength was obtained for G15F15, reaching 8.91 MPa, approximately 35% higher than the reference mixture. Moreover, the flexural strength of G15F15 increased from 3.39 MPa at 7 days to 8.91 MPa at 28 days, representing a substantially greater strength development than that observed for the reference mixture. These results suggest that the combined use of GGBFS and FA provides a particularly beneficial effect on later-age flexural performance in 3D-printable concrete incorporating brick powder as fine aggregate.

The representative failures in Figs. 2 also show a consistent flexural failure pattern. In both the reference and G15F15 specimens, a dominant crack developed within the central bending region of the prism, without an apparent premature failure near the supports. The G15F15 specimen exhibited a clearly developed central crack at failure while sustaining the highest measured flexural strength. Overall, the experimental results indicate that although partial cement replacement with GGBFS and FA may reduce early-age flexural performance, their contribution becomes increasingly significant with curing time, with the combined GGBFS-FA mixture providing the most pronounced improvement at 28 days.

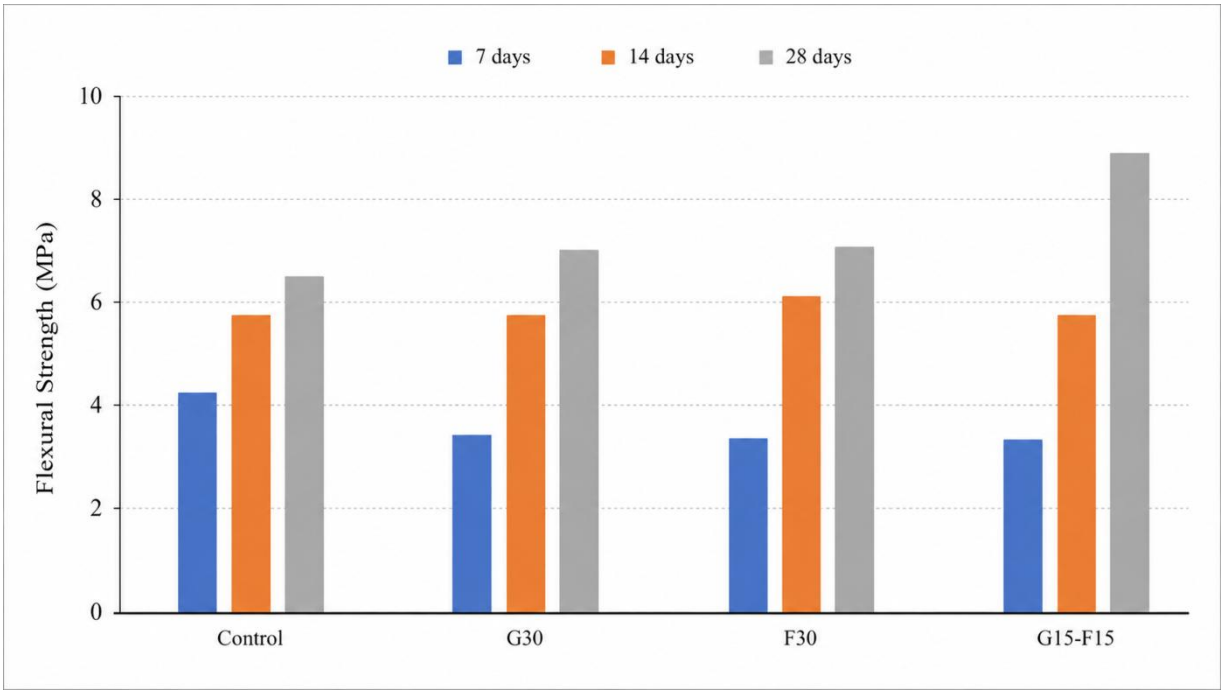

Fig. 1. Flexural strength development of the mixtures at 7, 14, and 28 days

Fig. 2. Typical Flexural Failure Patterns of the Reference and G15F15 Specimens

3.2. Compressive Strength

The compressive strength results are summarized in Table 3 and illustrated in Fig. 3. At 7 days, the reference mixture exhibited the highest strength of 17.33 MPa, while G30, F30, and G15F15 reached 11.51, 12.57, and 12.73 MPa, respectively. These values correspond to early-age reductions of approximately 34%, 27%, and 27% relative to the reference mixture, indicating that partial replacement of Portland cement with GGBFS and FA delayed early strength development.

By 14 days, the differences among the mixtures had narrowed considerably. F30 reached the highest compressive strength of 24.30 MPa, approximately 12% above the reference value of 21.66 MPa, whereas G30 and G15F15 exhibited strengths of 19.31 and 21.31 MPa, respectively.

A clear change in performance was observed at 28 days, as shown in Fig. 3. All SCM-containing mixtures exceeded the reference strength of 27.10 MPa. G30 and F30 reached 31.32 and 29.41 MPa, corresponding to increases of approximately 16% and 9%, respectively. The

most pronounced improvement was obtained with G15F15, which achieved 41.48 MPa, approximately 53% higher than the reference mixture. Its strength increased from 12.73 MPa at 7 days to 41.48 MPa at 28 days, indicating a markedly greater later-age strength development than that of the reference mixture.

Table 3. Compressive strength results of concrete mixtures (MPa)

Mixture	7 Days	14 Days	28 Days
Control	17.33	21.66	27.10
G30	11.51	19.31	31.32
F30	12.57	24.30	29.41
G15-F15	12.73	21.31	41.48

Overall, the results indicate that GGBFS and FA were less effective at early ages but contributed increasingly to compressive strength as curing progressed. The combined use of 15% GGBFS and 15% FA produced the highest 28-day strength, suggesting a beneficial complementary effect between the latent hydraulic contribution of GGBFS and the pozzolanic contribution of FA.

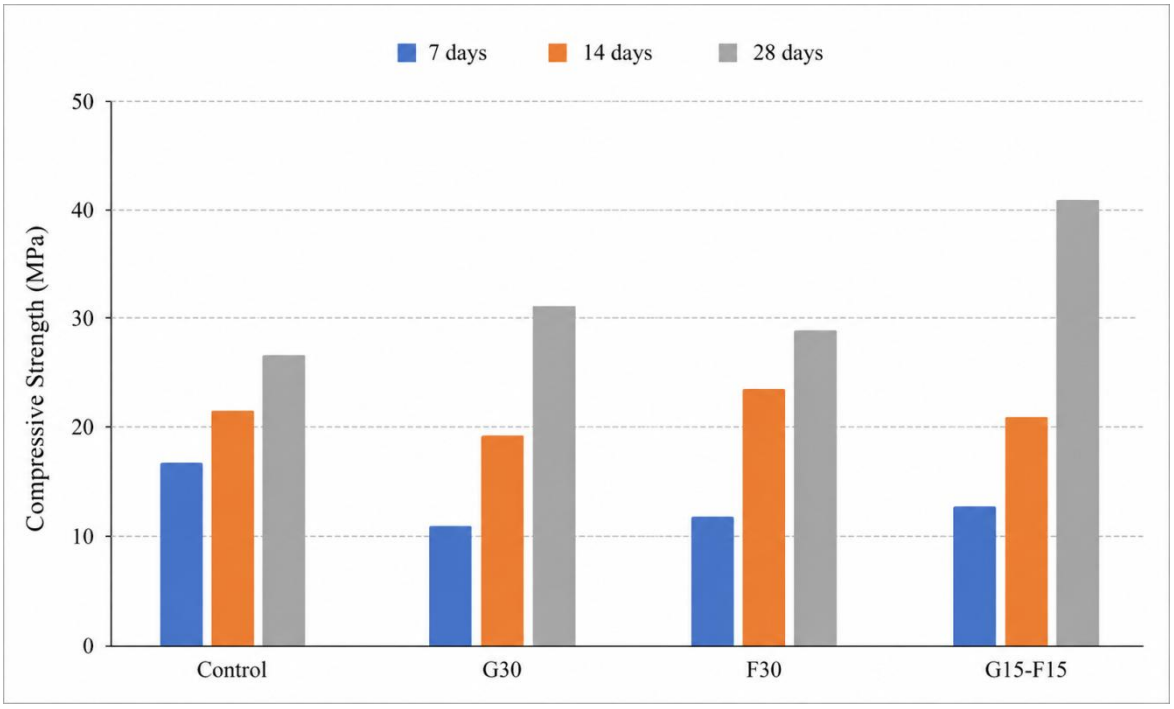

Fig. 3. Compressive Strength Development of the Mixtures at 7, 14, and 28 Days

4 Conclusion

This study experimentally investigated the effects of ground granulated blast furnace slag (GGBFS) and fly ash (FA) on the mechanical performance of 3D-printable concrete incorporating brick powder as fine aggregate. The results showed that the mixtures containing GGBFS and FA exhibited lower early-age compressive and flexural strengths than the reference mixture. This behavior can be attributed to the slower early-age reaction rates of GGBFS and

FA compared with Portland cement, indicating that the typical early-strength reduction associated with these supplementary cementitious materials also occurs in brick-powder-based 3D-printable concrete.

At 28 days, however, the performance of the SCM-containing mixtures improved markedly. In particular, the G15F15 mixture outperformed the reference mixture in both compressive and flexural strength, demonstrating that the combined use of GGBFS and FA can provide a more effective binder system for later-age strength development. These findings show that, despite the reduction in Portland cement content, appropriate combinations of supplementary cementitious materials can maintain and even improve the mechanical performance of 3D-printable concrete incorporating brick powder.

Future studies should investigate the longer-term strength development of the G15F15 mixture and compare a wider range of replacement levels to identify more effective binder compositions. Additional investigations involving microstructural characterization, interlayer bond behavior, and durability performance would also provide a more comprehensive understanding of the behavior of these mixtures under different production scales and service conditions.

Abstract. The production of Portland cement is responsible for the emission of high amounts of carbon dioxide (CO_2) due to the decomposition of limestone and the fuel consumed in the rotary kiln. Low-carbon alternatives to portland cement are actively sought. Magnesium oxalate cement (MgOx) is one such alternative binder proposed in recent years. It is obtained through an acid-base neutralization reaction between a basic powder such as dead burnt MgO (DBM) and oxalic acid ($H_2C_2O_4$) or an oxalic acid salt; its main reaction product is glushinskite ($MgC_2O_4.2H_2O$), a hydrated magnesium oxalate. Even though the use of oxalates made from captured CO_2 can decrease the carbon footprint of MgOx, the chemical and fuel-related carbon emissions of DBM make it difficult for the final product to reach carbon neutrality. Also, despite its high early strength, MgOx sets rapidly and liberates a large amount of heat. The present study investigated the use of olivine, a magnesium-iron silicate mineral, to partially or fully replace DBM, rendering MgOx carbon neutral or negative. Various chemical, mechanical, and mineralogical properties of MgOx made with olivine were examined, using X-ray diffraction, pH, setting time and strength. Replacement of DBM with olivine moderates the exothermic reaction of MgOx systems, leading to slower setting. Olivine is shown to dissolve and contribute magnesium ions to the binder. However, the rate and total amount of dissolution is limited. Compressive strength is retained up to ~60 % replacement, beyond which it sharply decreases.

Keywords: magnesium oxalate, clay, olivine, carbon dioxide.

1 Introduction

Portland cement (PC), the ubiquitous construction binder, is used in very large amounts, annual production surpassing 4×10^9 t [1]. Portland cement production not only requires tremendous amounts of energy and raw materials (clay and limestone), but is also responsible for high carbon emission, related with the burning of fuel in the kiln and the decarbonation of carbonate minerals in limestone. These negative environmental impacts have led to a search for alternatives to PC [2]. Various calcium-based and other alternatives have been proposed, each with its own advantages and disadvantages [3,4,5]. Limestone calcined clay cement, geopolymers, and calcium sulfoaluminate cement are notable examples. Binders based on calcium use limestone as an inexpensive raw material and suffer drawbacks similar to PC. The use of pozzolans or supplementary cementitious materials can only partially curb the associated carbon emissions. Some other binders without calcium suffer from low room-temperature reactivity and slow mechanical property development. Attempts to achieve carbon neutrality have also been made by capturing carbon into minerals such as calcite, by carbonating natural or artificial powders, such as wollastonite, various slags, and even recycled concrete fines,

under controlled temperature and relative humidity conditions [6]. However, this approach is more suitable for precast works as small blocks with predetermined shapes are obtained.

Magnesium oxalate cement (MgOx) is a binder recently proposed as an alternative to PC [7,8,9]. It is made by reacting dead-burned magnesia (DBM) with salts of oxalic acid and water (Eqs. 1-3)

$$MgO + 2H^{+} \rightarrow Mg^{2+} + H_2O \quad (1)$$

$$Mg^{2+} + HC_2O_4^{-} + 2H_2O \rightarrow MgC_2O_4.2H_2O + H^{+} \quad (2)$$

$$Mg^{2+} + C_2O_4^{2-} + 2H_2O \rightarrow MgC_2O_4.2H_2O \quad (3)$$

Oxalic acid ($H_2C_2O_4$) can be made from captured CO_2 via electrochemical reduction or other processes [10,11]. Hence, it can be carbon-negative if renewable energy is used for its production. This can balance the carbon footprint of magnesium oxide, obtained economically by decarbonating magnesium carbonate. Figure 1 shows the production scheme for MgOx.

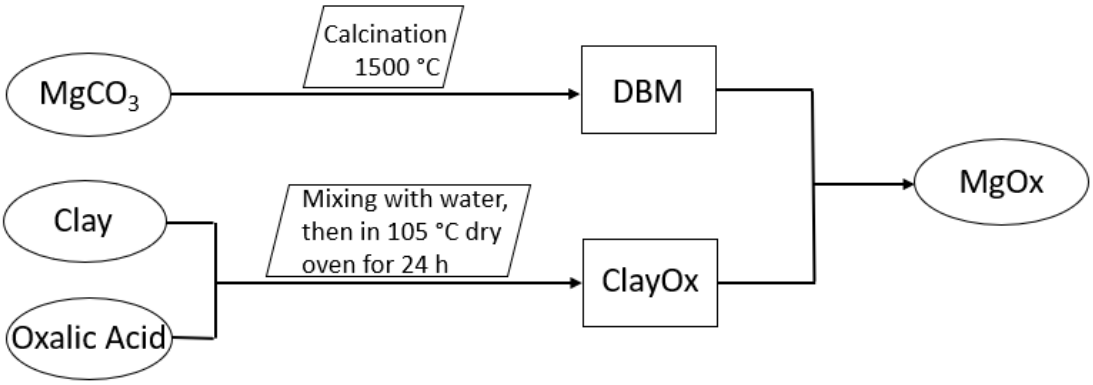

Fig. 1. The production of MgOx (adapted from [12]).

The reaction between light-burned (~600 °C) MgO and oxalic acid is quite exothermic and rapid, leading to a significant rise in the mixture temperature and limiting the size of a feasible mixture. Cracking and the formation of large pores can't be prevented. Hence, two measures are taken. First, oxalic acid is pre-reacted with a suitable base to obtain an acidic oxalate salt. This slightly increases the initial pH of the acidic solution. Next, light-burned MgO replaced with MgO dead-burned at 1400-1500 °C. This reduces the specific surface area and reactivity of MgO. Both of these steps are similar to what is used in magnesium phosphate cement (MPC) production, which uses DBM and an acid salt of phosphoric acid, such as KH_2PO_4.

The reaction in Eqn. 1 is an acid-base reaction which leads to the formation of glushinskite ($MgC_2O_4.2H_2O$), and a near-neutral ultimate paste pH. MgOx differs from other magnesium cements like oxychloride or oxysulfate cements. Owing to the acid-base reaction, MgOx sets rapidly and can gain medium-to-high early strength. Setting time, heat evolution and the development of mechanical properties can be controlled by controlling mixture proportions. Using a high DBM / oxalic acid salt ratio increases the carbon footprint but often benefits property development. A lower ratio decreases the carbon footprint but increases cost. Using an unreactive filler or secondary materials to replace DBM and/or the oxalate salt can decrease both cost and carbon footprint but decrease the total amount of reaction and ultimate strength, beyond a certain replacement ratio. Among those materials used to partially replace DBM and the oxalate salt are ground granulated blast furnace slag and copper slag, which can form new reaction products like calcium or iron oxalates, and silica fume, which does not form any new crystalline reaction products but can alter properties physically [13, 14]. This study investigated

the use of olivine as yet another substitute for DBM. Olivine is a nesosilicate (orthosilicate) mineral represented by the chemical formula $(Mg,Fe)_2SiO_4$. A primary constituent of mafic and ultramafic igneous rocks such as basalt, gabbro, and peridotite, it dominates the composition of Earth's upper mantle, and forms a continuous solid-solution series between the magnesium-rich end-member forsterite (Mg_2SiO_4) and the iron-rich end-member fayalite (Fe_2SiO_4). Given its vast natural abundance, olivine is a potentially viable and sustainable alternative source of magnesium ions without an associated high carbon footprint like DBM [15].

2 Materials and Methods

2.1 Materials

The magnesia (MgO) used was obtained as a light-pink powder. Its rapid neutralization of acetic acid indicated high reactivity in an acid-base system and that it was likely obtained by light burning. This powder was calcined in the laboratory at 1500 °C to obtain dead-burned magnesia (DBM). DBM was ground until 95 % passed a 150 µm sieve. A montmorillonitic clay was obtained from Votorantim Cimentos, Hasanoğlan. The chemical compositions of these materials, determined using x-ray fluorescence spectrometry, and their densities are provided in Table 1.

Table 1. Oxide analysis of the materials used (mass %) [16, 17]

Oxide	MgO	DBM	Clay
SiO_2	10.04	11.02	61.5
Fe_2O3	0.64	0.75	8.6
Al_2O3	0.06	0.08	14.3
MgO	87.3	86.1	2.6
CaO	1.87	1.92	3.7
NiO	0.13	0.14	-
K_2O	-	-	1.6
Na_2O	-	-	0.3
TiO_2	-	-	1.1
SO_3	-	-	0.1
Density	3.10	3.48	2.62

The particular olivine used in this study is magnesium-rich, comprised mostly of forsterite as shown in Fig. 2.

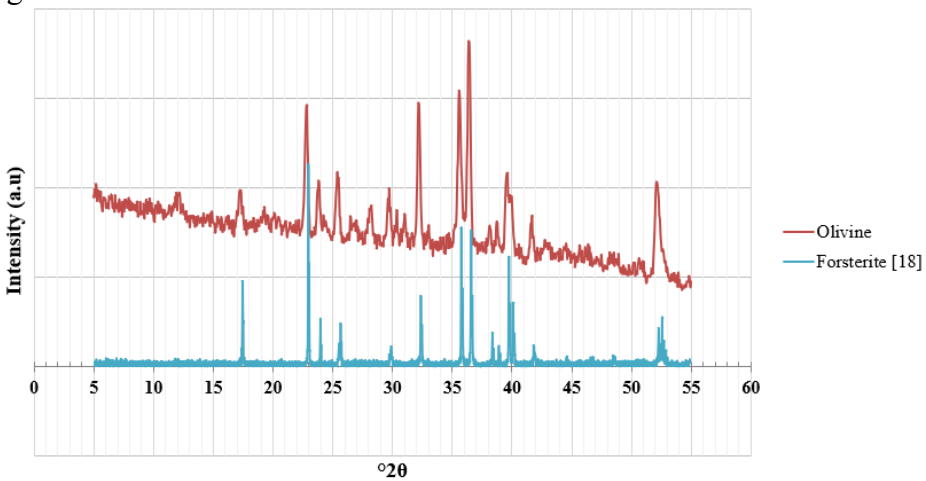

Fig. 2. X-ray diffractograms of the olivine used and forsterite.

2.2 Methods

The clay was ground and mixed with oxalic acid dihydrate and water, at a mass ratio of 1:1:1. The paste obtained was allowed to react in a 105 °C oven for 24 h. The reacted material was further ground in a ball mill to a powder to obtain the component, ClayOx, to react with DBM. ClayOx is the acidic oxalate salt mentioned in Section 1. It contains some free oxalic acid as well as some oxalate salts like iron oxalate, formed between oxalic acid and the clay. Olivine, received as a coarse sand-sized granular material, was ground into a fine powder.

Paste and mortar mixtures were prepared. DBM was gradually replaced with ground olivine as shown in Table 2.

Table 2. Mixture proportions used for sample preparation (by mass)

Mixture	DBM	Olivine	ClayOx	Water	Sand
5D_0O	5	0	5	2.6	22 (mortar samples)
4D_1O	4	1			
3D_2O	3	2			
2D_3O	2	3			
1D_4O	1	4			
0D_5O	0	5			

X-ray diffraction (XRD), pH measurements, and setting time tests were performed on the paste samples. Compressive strength was measured on 10-d-old mortar samples with a sand-to-powder ratio of 2.2. As acid-base cement Silica sand in the 0.2-2 mm size range, conforming to EN 196-1 [19], was used.

3 Results and Discussion

3.1 Chemical and Mineralogical Evolution

Fig. 3 shows the XRD patterns obtained for the paste samples. The main peaks observed correspond to glushinskite (18.4, 28.2 °2θ), periclase (42.9, 36.9 °2θ). Glushinskite is formed by the reaction between Mg^{2+} and $C_2O_4^{2-}$, hence is expected. Periclase is MgO and is therefore associated with unreacted DBM. Naturally, the periclase peak becomes less prominent as the DBM/Olivine ratio decreases and no periclase is observed in 0D_5O.

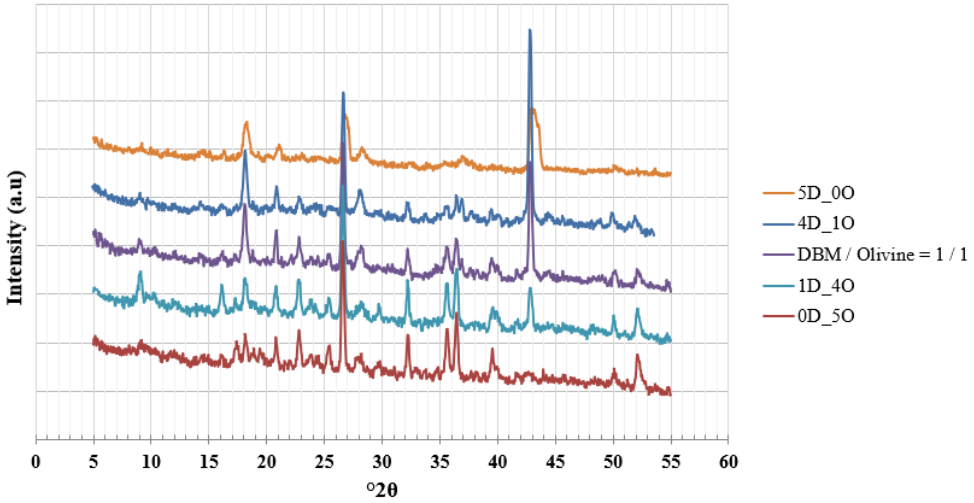

Fig. 3. X-ray diffractograms of the paste samples.

The most intense glushinskite peak is observed for pastes with intermediate DBM/Olivine. The amount of ClayOx is fixed for all pastes. DBM is in excess at very high DBM/ClayOx ratios, hence at high DBM/Olivine ratios. There is not enough dissolved magnesium available for reaction at very low DBM/ClayOx ratios, hence at low DBM/Olivine ratios. The paste containing only ground olivine shows a low-intensity peak for glushinskite, indicating some magnesium has dissolved from olivine and reacted. Fig. 4 shows the pH development of the paste samples.

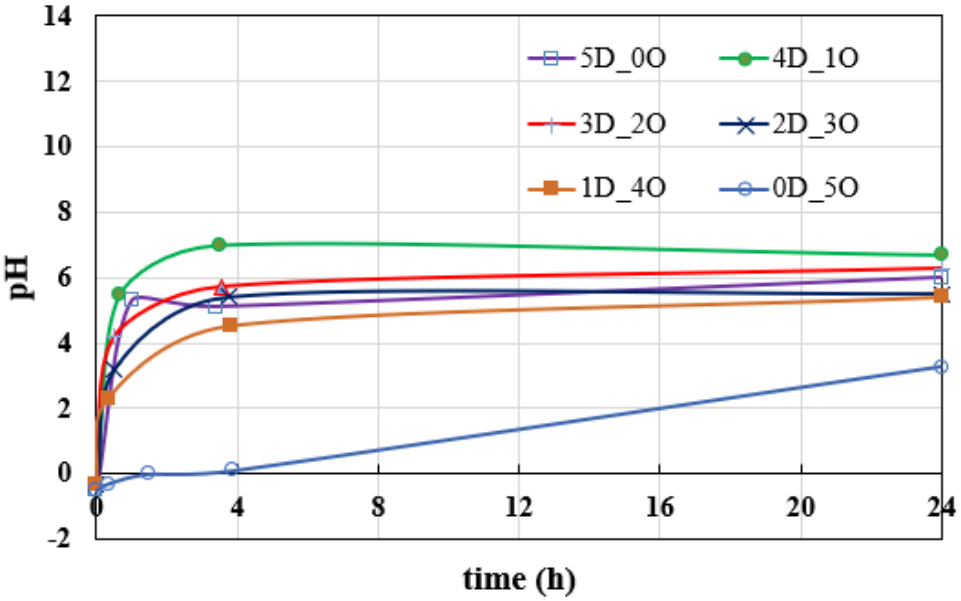

Fig. 4. pH development of the paste samples.

MgOx is an acid-base cement. As such, the initial pH of the paste is dominated by the acidity of ClayOx dissolved in water. This value was measured to be between -0.5 and 0 for all pastes; however, such low pH values measured with glass electrodes carry significant uncertainty. Furthermore, this range falls outside the calibration region of the pH meter. Subsequently, pH rises due to neutralization reactions between oxalate species and magnesium ions. An increase is noticeable for pastes containing DBM, as early as 10-20 min, even before setting. The paste without any DBM, 0D_5O does not show a meaningful rise in pH in the first few hours suggesting that the olivine does not dissolve considerably. After 24 h, all pastes with DBM reach pH values of ~ 5.5-7.0. A neutral or slightly basic pH is expected for a well-performing MgOx, due to the nature of the neutralization reaction and some DBM always remaining unreacted. 0D_5O does reach pH~3.25 indicating some reactions have taken place and partially neutralized the initially acidic solution. Fig. 5 gives the final setting times of the paste samples.

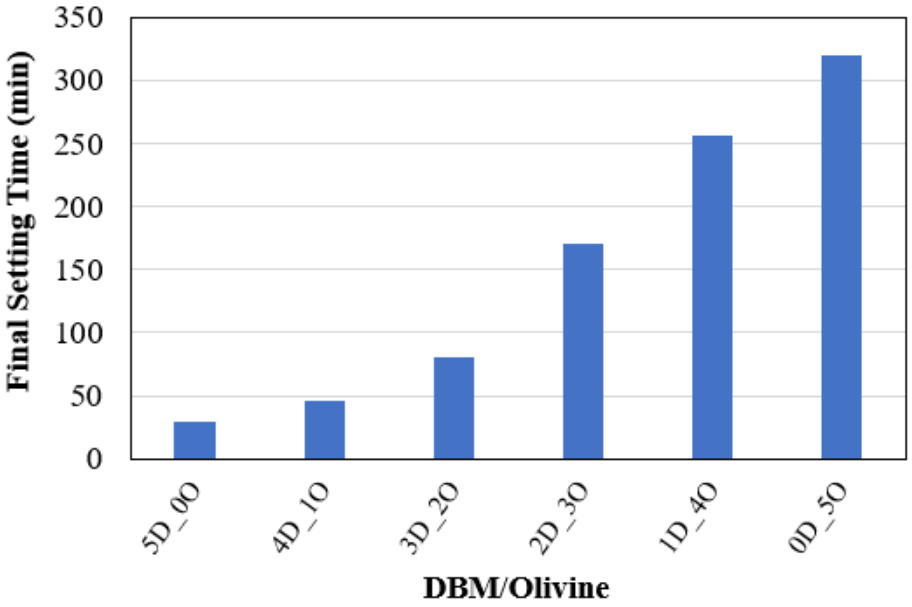

Fig. 5. Final setting times of the pastes.

The mixtures evolve considerable heat and show an initial stiffening upon combining ClayOx with water. However, continued mixing yields a workable paste. Pastes with higher DBM/Olivine ratios set faster, as DBM dissolves much faster than olivine (Fig. 4) and provides magnesium ions for the main glushinskite-forming reaction. The final setting time of 5D_0O is ~0.5 h. In contrast, 0D_5O sets only after several hours.

3.2 Development of Compressive Strength

The compressive strengths of mortar samples are given in Fig. 6.

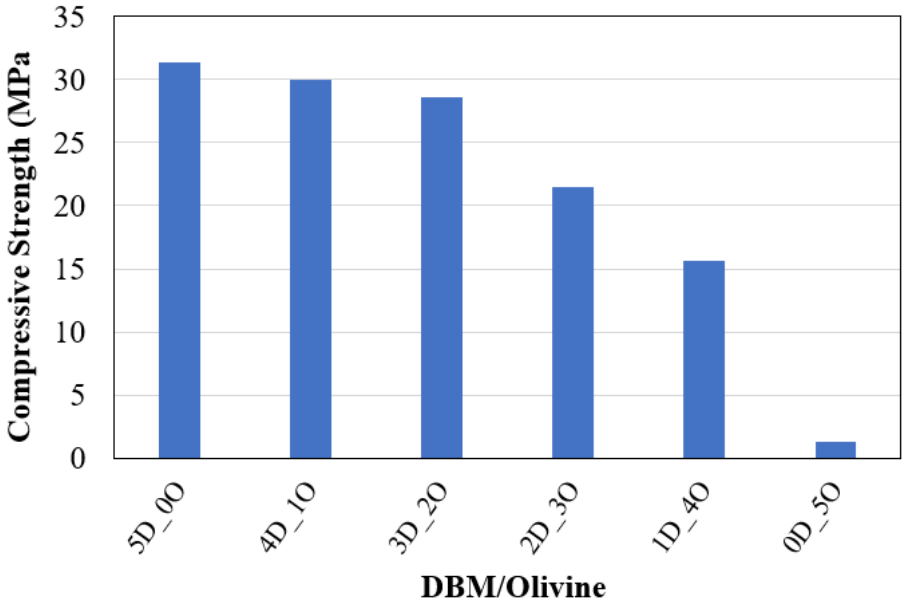

Fig. 6. Compressive strength of mortars.

The replacement of DBM with olivine appears to decrease the strength of mortars, slightly at low ratios but greatly at higher ratios. Mortar samples containing only ground olivine develop minimal strength, indicating that the amount of glushinskite formed (as observed in Fig. 2) is

not sufficient to create a rigid network. A replacement level of 40-60 % is achievable without significantly compromising mechanical properties. This is similar to results reported on the replacement of DBM with silica fume [13], indicating that, despite containing high levels of magnesium and silicon, olivine is not able to dissolve significantly. Thermal or chemical pre-treatment of olivine to reduce its crystallinity and increase its rate of dissolution in the acidic solution of ClayOx and water appears to be necessary to achieve useful mechanical properties at high DBM replacement ratios.

4 Conclusions

The effect of replacing dead-burned magnesia with ground olivine in MgOx mixtures was investigated. The following conclusions were reached:

- Some glushinskite is detected in XRD patterns of pastes without any DBM, suggesting ground olivine partly dissolves in acidic oxalate solutions to provide magnesium ions, despite being a crystalline silicate.
- The amount of dissolved magnesium from olivine is not sufficient to produce significant amounts of glushinskite hence the compressive strength of mixtures with low DBM/Olivine ratios remain low. Nevertheless, mortars with 60 % olivine and 40 % DBM gain > 20 MPa compressive strength.
- The pH of all pastes containing olivine and DBM reach near-neutral values, indicating significant reaction. The pH of the paste containing only olivine remains acidic after 24 h, suggesting the dissolution of olivine is slow and limited.
- Mixtures made with the particular ClayOx used in this study provide long setting times compared with many previous MgOx examples.
- Olivine shows potential as an alternative magnesium source, to obtain MgOx with lower carbon footprints.

Abstract. The rock structures and fairy chimneys in Cappadocia, a UNESCO World Heritage site, consist of low-strength, highly porous volcanic tuffs with high water absorption capacity. These characteristics make the rock structures vulnerable to physical, chemical, and hydro-mechanical deterioration, causing existing microcracks to propagate into macrocracks over time. To evaluate the effectiveness of consolidation treatments applied to these natural stones, this study proposes a fracture mechanics-based approach. In the literature, material performance is typically assessed via uniaxial compressive strengths. However, this approach inadequately represents heterogeneous materials containing discontinuities, which induce crack-tip stress concentrations and cause premature failure. Therefore, performance must incorporate specimen geometry, notch length, and crack propagation behavior. Consequently, this study adopts a fracture mechanics evaluation, linking loading stresses to fracture toughness rather than yield strength. To assess the fracture toughness of volcanic tuff, three-point bend testing (3PB) was executed. Prismatic specimens measuring 30 × 60 × 280 mm were prepared with notch depths ranging from 3 to 30 mm at 3 mm intervals. Throughout the experimental process, applied forces and crack mouth opening displacement (CMOD) values were acquired concurrently. The load–CMOD data were modeled using polynomial regression, and the derivatives of the regression functions were used to calculate the fracture energy of the specimens. This testing methodology provides a practical means to assess how notch depth impacts the fracture behavior of volcanic tuff, while simultaneously serving as a mechanics-based framework to measure consolidation efficiency. The obtained results demonstrated satisfactory performance of the proposed approach for fracture evaluation.

Keywords: Volcanic Tuff, Fracture Energy, CMOD, Three-Point Bending Test

1 Introduction

Volcanic tuffs are rocks formed as a product of the compaction and cementation of pyroclastic materials to varying degrees; they have high porosity and mechanical properties that can vary widely. Prominent throughout Cappadocia, ignimbritic tuffs have traditionally supported architectural masonry, rock-cut complexes, underground cities, and cultural artifacts. However, prolonged exposure to mechanical, chemical, hydro-mechanical, and environmental effects leads to material deterioration, crack initiation, and a reduction in mechanical strength. Previous studies [1,2] have characterized Cappadocian tuffs as rocks with low unit weight, high porosity, and relatively low mechanical strength. These characteristics highlight the need to investigate and evaluate the propagation behavior of pre-existing cracks and natural discontinuities within the tuff.

Fracture toughness is an important mechanical parameter in evaluating the engineering behavior of rocks. It is defined as the resistance exhibited against the propagation of an existing

crack within the material. Incorporating this property allows for a more realistic representation of rock performance across various engineering domains, such as tunneling, slope stability analysis, natural stone extraction, underground infrastructure design, and dimension stone processing. In brittle geological formations such as volcanic tuffs, the Linear Elastic Fracture Mechanics (LEFM) approach is commonly used to analyze crack formation and propagation; this approach provides a quantitative basis for evaluating fracture toughness and crack propagation under external loads [3,4].

Evaluating Mode I fracture toughness (K_{IC}) in rocks relies on LEFM theory. To this end, researchers widely utilize techniques such as single edge notched bend (SENB) testing, semi-circular bending (SCB), along with disk- and rod-based geometries such as cracked chevron notched Brazilian disc (CCNBD), chevron bend (CB), and short rod (SR). Earlier studies have demonstrated that measured fracture toughness depends significantly on specimen geometry, notch length, and loading configuration [5,6].

Several studies have investigated the physical, mechanical, and durability aspects of the Cappadocia Region tuffs [1,2,9]. Examples of fracture mechanics studies on volcanic tuffs include investigations conducted on the Ogino tuffs in Japan [7] and Mode I fracture toughness studies on Nevada tuff [10]. It has been established through these works that recorded fracture toughness values for tuffs exhibit substantial variation based on porosity, specimen dimensions, and crack configuration. Nevertheless, based on the available literature, the K_{IC} of Cappadocia Region tuffs has not yet been evaluated using standardized fracture mechanics testing methods.

In the present study, the K_{IC} value of volcanic tuff specimens collected from the Cappadocia Region was experimentally evaluated following the ASTM E399 (American Society for Testing and Materials) procedure. The findings are expected to contribute to addressing the existing gap in the literature regarding the fracture behavior of Cappadocia Region tuffs.

2 Materials and Methods

2.1 Materials

Volcanic tuff specimens evaluated in this work were collected from the Cappadocia region as part of a TÜBİTAK-funded project [9]. The natural stone, locally referred to as “Dağ Taşı” and classified as Weak Rock (R2) by the International Society for Rock Mechanics (ISRM), is characterized by the physical and mechanical properties listed in Tables 1 and 2 [9].

Table 1. Mechanical properties of the volcanic tuff [9].

Specimen Name / Classification	Uniaxial Compressive Strength (MPa)	Poisson's Ratio	Elastic Modulus (MPa)
Dağ Taşı/ R2	6,5	0.25	700

Table 2. Physical properties of the local stone [9].

Specimen Name / Classification	Specific Gravity (g/cm³)	Porosity (%)	Water Absorption by Volume (%)	Water Absorption by Mass (%)	Bulk Density (g/cm³)	Compacity (%)
Dağ Taşı/ R2	2.4	41.6	40.8	40.8	1.4	58.4

2.2 Methods

Specimen Preparation. Test samples were fabricated from original volcanic tuff obtained from the Cappadocia Region in accordance with the ASTM E399 standard. A total of ten prismatic SENB specimens with dimensions of 30 × 60 × 280 mm were fabricated. The notch lengths varied from 3 mm to 30 mm in 3 mm increments (3, 6, 9, …, 30 mm), with each specimen corresponding to a distinct notch length. An overview of the prepared test specimens is presented in Figure 1.

Fig. 1. SENB specimens with notch lengths ranging from 3 mm to 30 mm in 3 mm increments.

Verification of Specimen Geometry. Prior to testing, the geometry of all SENB specimens was checked against the criteria specified in ASTM E399. The notation adopted in this study defines "B" as the specimen width, "W" as the specimen height, "a" as the notch length, and "S" as the support span. The dimensional requirements recommended by ASTM E399 for SENB specimens are given in Equations (1) – (3). The specimen dimensions were evaluated based on these criteria, and all prepared specimens were confirmed to satisfy the geometric requirements specified in the standard.

$$B = 0.5W \tag{1}$$

$$0.45 \leq \frac{\mathrm{a}}{\mathrm{W}} \leq 0.55 \tag{2}$$

$$\mathrm{S} = 4\mathrm{W} \tag{3}$$

Experimental Procedure. Ten notched SENB specimens were tested on a three-point bending (3PB) test machine. Once the specimens were symmetrically positioned on the supports, loading was initiated at the span center, and the load was monotonically increased until specimen failure. The SENB configuration and the actual experimental apparatus used in this research are depicted in Figure 2.

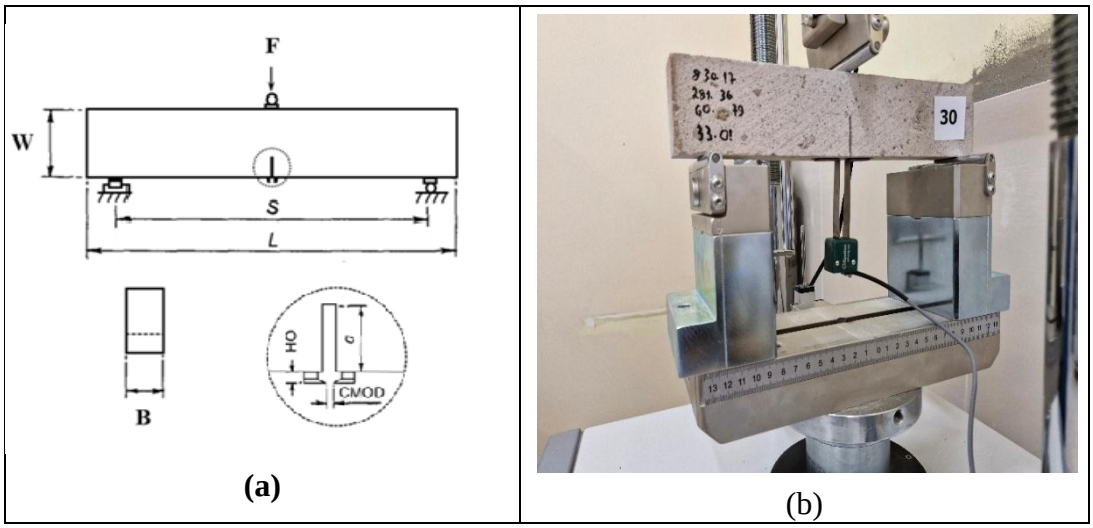

Fig. 2. SENB Setup: **(a)** Schematic model **(b)** physical configuration for CMOD measurement.

To determine the Crack Mouth Opening Displacement (CMOD) during testing, metallic knife edges were fixed onto either side of the crack mouth, serving as mounting points for the clip gauge. Throughout the experiments, a data acquisition system continuously logged both the CMOD data and the corresponding applied force. Figure 3 illustrates the experimental setup, including the specimen-mounted knife edges and the CMOD measuring unit.

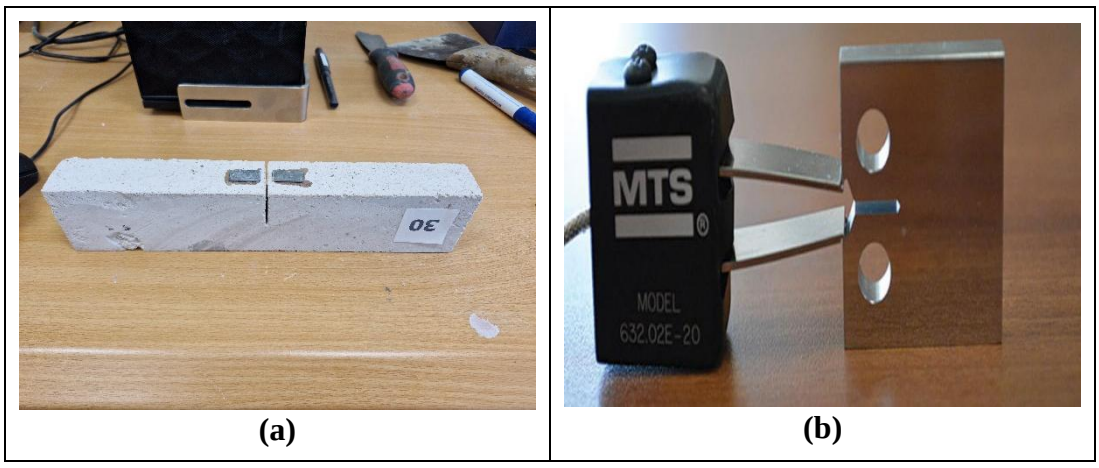

Fig. 3. (a) Knife edges mounted on the specimen **(b)** CMOD measurement system.

Fracture Toughness Calculation. Fourth-order polynomial curves were fitted to the load–CMOD data obtained from each SENB specimen. The compliance values for each specimen were calculated from the linear elastic portion of the fitted curves corresponding to **20%–70%** of the maximum load. Subsequently, the relationship between compliance and notch length was modeled using a fourth-order polynomial based on the compliance values obtained from specimens with different notch lengths. Consequently, the rate of change in compliance with respect to notch length, (dC/da), was determined from the compliance–notch length relationship.

As a core parameter in fracture mechanics, the critical energy release rate (G_{IC}) quantifies the energy dissipated per unit area of newly created crack surface during crack propagation. In this study, $G_{IC}$was calculated using the compliance method according to Equation (4). Finally, K_{IC} was determined from the relationship between the critical energy release rate and the plane strain condition for linear elastic materials using Equation (5). Here, "**F**" denotes the applied

load, "**C**" the compliance, "**a**" the notch length, "**E**" the elastic modulus, and "$\boldsymbol{\nu}$" Poisson's ratio.

$$G_{IC} = \frac{F^2}{2B}\frac{dC}{da} \tag{4}$$

$$K_{IC} = \sqrt{\frac{EG_{IC}}{1-\vartheta^2}} \tag{5}$$

3 Results and Discussion

As a result of the 3PB tests, Load–CMOD curves were obtained for ten SENB specimens with notch depths from 3 mm to 30 mm. Given the consistent mechanical response across all samples, representative curves for 15 mm and 30 mm notch lengths appear in Figs. 4 and 5. An analysis of the curves revealed that linear elastic behavior predominated during the initial loading phase, and deviations from this behavior occurred as the load approached the maximum. After the maximum load was reached, a decrease in the specimens' load-bearing capacity was observed due to crack propagation.

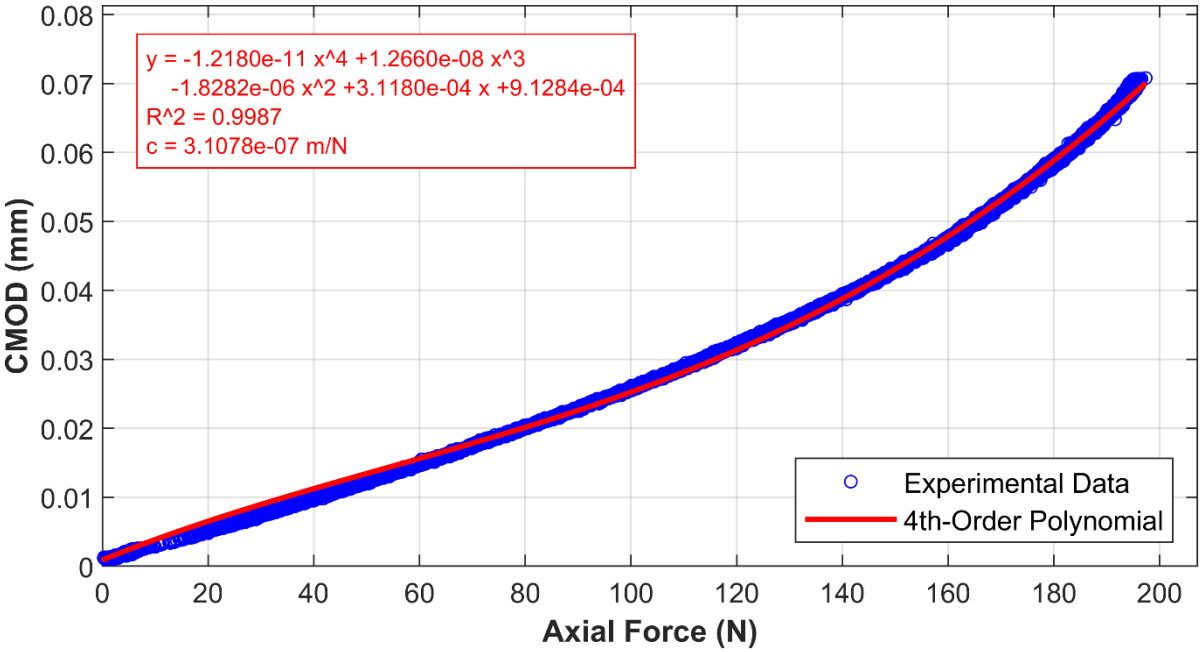

Fig. 4. 4th-Order Polynomial CMOD-Load Curve for 15 mm Notched Specimen

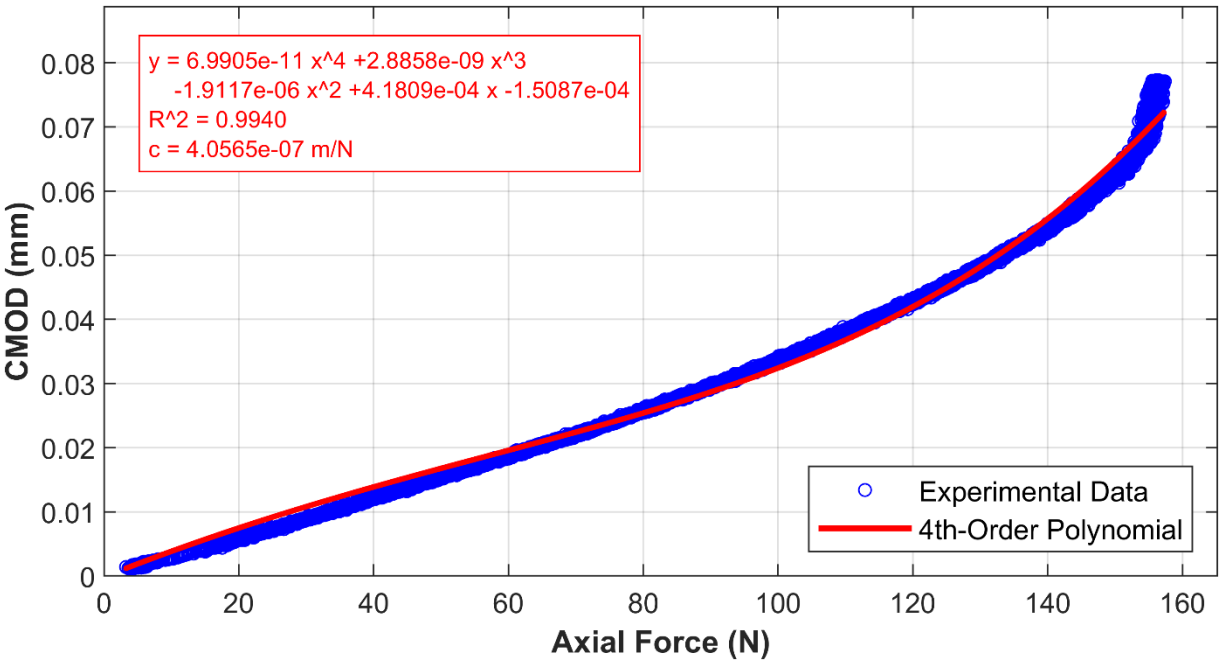

Fig. 5. 4th-Order Polynomial CMOD-Load Curve for 30 mm Notched Specimen

The relationship between compliance and notch length for specimens with different notch lengths is presented in Figure 6. A fourth-order polynomial regression was fitted to the experimental data, yielding a coefficient of determination of $R^2 = 0.81$. This result indicates that the fourth-order polynomial provides an adequate representation of the compliance–notch length relationship.

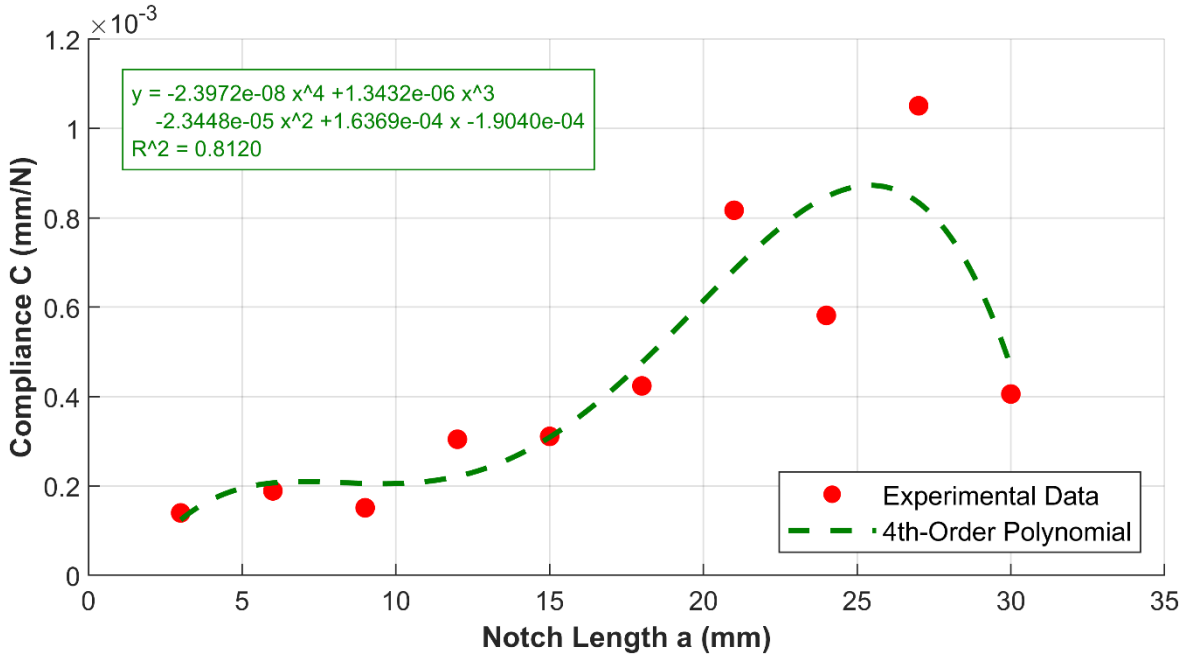

Fig. 6. Relationship between notch length and compliance with the fitted fourth-order polynomial.

Based on the computational approach detailed in the Methodology section, a peak load of 157.38 N recorded for the 30 mm notched sample yielded $K_{IC} = 0.2517$ MPa$\sqrt{\text{m}}$ for Cappadocia tuff.

For the Cappadocia tuff samples, K_{IC} was measured via the ASTM E399 compliance calibration approach. This parameter represents the material's resistance against crack extension within LEFM theory. These findings provide foundational reference values for future research on the failure response of Cappadocia tuffs, with the complete experimental dataset summarized in Table 3.

Table 3. Experimental data and derived fracture parameters

Parameter	**Value**
Rock type	Cappadocia volcanic tuff
Test standard	ASTM E399
Specimen type	SENB (Single Edge Notched Bend)
Number of specimens	10
Specimen dimensions (B × W × L)	30 × 60 × 280 mm
Support span (S)	240 mm
Initial notch length range	3 – 30 mm
Notch length increment	3 mm
(a/W) ratio	0.50
(S/W) ratio	4.00
Loading configuration	Three-point bending
Linear elastic region	20–70% of the maximum load
Maximum load (30 mm notch length)	157.38N
Compliance–notch length equation	$\boldsymbol{C(a) = -2.3972 \times 10^{-8}a^4 + 1.3432 \times 10^{-6}a^3 - 2.3448 \times 10^{-5}a^2 + 1.6369 \times 10^{-4}a - 1.9040 \times 10^{-4}}$
Polynomial order	4
Coefficient of determination, R^2	**0.81**
Calculated G_{IC}	**84.8397 N/m**
Calculated K_{IC}	**0.252 MPa√m**

4 Conclusions

In this study, K_{IC} and G_{IC} of volcanic tuff obtained from the Cappadocia Region were experimentally determined based on the ASTM E399 standard, yielding the following key insights:

The 3PB tests executed on ASTM E399-compliant SENB specimens enabled a reliable characterization of the fracture behavior of the volcanic tuff.

The load–CMOD curves obtained from the SENB tests exhibited predominantly linear elastic behavior during the initial loading stage, followed by a reduction in load-carrying capacity due to crack propagation after the maximum load was reached. This response is characteristic of the brittle fracture behavior of volcanic tuff.

The relationship between compliance and notch length was successfully modeled using a fourth-order polynomial. The resulting model yielded a coefficient of determination of $R^2 = 0.81$, demonstrating that the proposed method can be applied with satisfactory accuracy.

Based on ASTM E399 compliance calibration, K_{IC} for Cappadocia tuff was determined as 0.2517 MPa$\sqrt{\text{m}}$.This result reflects a low capacity to resist crack growth, implying that substantial void spaces and internal structural flaws heavily govern the material's cracking response.

The obtained fracture toughness value provides a fundamental material parameter for engineering analyses supporting the restoration, conservation of rock-carved structures, and consolidation of Cappadocia tuff.

The experimental approach and compliance-based calculation method proposed in this study offer a practical methodology for determining the fracture parameters of other low-strength, porous natural stones with similar characteristics.

The data obtained in this study are expected to serve as reference data for evaluating the fracture behavior of specimens consolidated with grout materials within the scope of the TÜBİTAK 1001 research project.

It is recommended that future studies investigate the fracture behavior more comprehensively by considering the effects of different loading rates, moisture contents, material anisotropy, specimen geometries, and specimens consolidated using grout materials.

Abstract. Plastic materials have been widely used in many sectors for over a century due to their advantages such as low density, ease of production, and design flexibility. However, the negative environmental impacts of plastic waste generated at the end of their lifespan have become an increasingly significant problem. In this scope, the utilization of plastic waste as aggregate in concrete production stands out as a sustainable alternative in terms of both waste reuse and the reduction of natural resource consumption. However, plastic aggregates can cause negative effects on some performance characteristics in concrete, and the use of additional supplementary materials may be necessary to mitigate these effects. In this study, the combined effect of plastic waste (PA) and silica fume (SF) on the fresh-state (workability and density) performance of concrete was experimentally evaluated. %20 and %40 plastic aggregate ratios have been determined to be critical threshold values in terms of workability. As the PA content increased, the unit weight of the mixtures tended to decrease. Similarly, an increase in the SF replacement ratio generally resulted in a decrease in unit weight. The effect of PA on reducing unit weight was considerably more pronounced than that of SF.

Keywords: Plastic aggregate; silica fume; concrete; performance; combined effect

1 Introduction

Plastics are widely used in many different sectors due to their numerous advantageous properties such as low density, low cost, abrasion resistance, insulating properties, and ease of production and design [1-2]. These types of plastics include polyester, polyethylene, polycarbonate, high-density polyethylene, polyvinyl chloride (PVC), low-density/linear low-density polyethylene, polylactic acid, polypropylene, and polystyrene, and these materials are widely used in many different fields. According to OECD data, global plastic consumption was 460 Mt in 2019 and is expected to reach 1.23 Mt in 2060. This high volume of plastic use, coupled with misuse and inadequate waste management practices, is currently causing significant pollution and various environmental problems [3-4]. To reduce environmental

problems and contribute to sustainability in the construction sector, various studies are being conducted on the use of plastic waste in the construction industry. In this scope, numerous studies have investigated the use of plastic materials in mortars and concrete. In concrete production, plastic materials are generally used to replace fine or coarse aggregates in certain proportions, or different types of plastic aggregates are used in combination [5-7].

The use of plastic materials in mortar and concrete can improve some properties while negatively impacting others. Therefore, to mitigate the disadvantages of using PA, it may be necessary to use supplementary cementitious materials (SCMs) with plastic aggregates. Various SCMs such as silica fume, nano-silica, fly ash, slag, etc., are used to improve the strength and durability of concrete. It is stated that mechanical properties are improved to a certain extent depending on factors such as the type and dosage of the cement used, but more comprehensive research is still needed [8].

A study on the effects of electronic waste plastic and silica fume on the mechanical properties and thermal performance of concrete indicates that plastic fine aggregate degrades the mechanical properties of concrete but improves its thermal properties, while silica fume mitigates the negative effects caused by plastic fine aggregate [9]. In another study, the combined use of SCMs and waste plastic fibers was proposed as a sustainable approach. It was stated that the combined use of SCMs and RPFs improved both fresh and hardened concrete properties. Furthermore, it was indicated that the addition of SCMs increased the tensile and adhesion strength in mixtures containing RPFs, and that the combined use of SCMs and RPFs provided additional gains in overall performance [10].

In this study, the combined effects of plastic waste (PA) and silica fume (SF) on the fresh properties of concrete were experimentally investigated. Workability and unit weight were evaluated using data obtained from 45 concrete mixtures. For comparison purposes, mixtures without SF and PA were also produced as reference mixtures.

2 Materials and Methods

2.1 Materials

In the experimental study, three types of aggregates were used: coarse aggregate (4-16 mm), fine aggregate (0-5 mm), and sand (0-2 mm). The aggregate mixing ratios were determined as 55%, 33%, and 12% respectively to meet the conditions specified in the TS 802 [4]. standard (a total of 55% coarse and 45% fine aggregates). Silica fume was obtained from a private company. The water/cement ratio in the mixtures was selected as 0.55. SF and superplasticizer, acquired from private company and cement (CEM II/A-L 42.5R) obtained from the Aşkale Plant (Trabzon, Türkiye). In this study, a total of 45 different concrete mixtures were designed and produced by substituting fine aggregate with PVC at volumetric percentages of 0%, 5%, 10%, 15%, 20%, 25%, 30%, 35%, and 40%; and cement with silica fume at weight percentages of 0%, 2.5%, 5%, 7.5%, and 10%. Chemical composition of materials used in experimental study is shown in Table 1.

Table 1. Chemical composition of materials.

Material	SiO_2	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	K_2O	Na_2O	LOI	MnO
Cement	11.9	3.15	3.61	0.33	65.6	1.56	0.93	0.20	0.03	0.05
SF	74.9	0.32	0.74	-	0.05	11.11	2.22	1.42	0.015	0.05

When the PVC substitution rate was increased to 45% and 50%, the desired homogeneity and consistency could not be achieved due to a significant decrease in workability, increased void formation, and problems in the setting process during the production of the mixtures. As these negative effects could not be overcome even with the use of plasticizer admixtures, it was

concluded that mixtures containing 45% and 50% PVC could not be produced with suitable properties, and these percentages were not included in the study. Figure 1 shows concrete samples containing 45% PVC and 2.5% SF. The sample surfaces appear quite rough and heterogeneous. This can be attributed to the weaker adhesion between the cement paste and natural aggregates due to the high PVC aggregate content. Furthermore, it was observed that increasing the PVC content made compaction more difficult and resulted in significant voids in the samples. Therefore, workability and compaction problems are evident at high PVC ratios.

Fig. 1. Concrete samples of 2.5SF-45 PVC mixture.

2.2 Mix Design

The experimental study was designed to produce a total of 55 batches, but some batches could not be produced due to a lack of uniformity. Therefore, it was not possible to produce concrete samples at these ratios and consequently, to conduct the relevant experiments. Excluding non-uniform mixtures, a total of 45 productions were carried out.

2.3. Methods

Unit weight determination was carried out on 7.1 cm cube and 10×20 cm cylindrical samples, based on the method specified in the TS EN 12350-6 [11]. standard. Slump tests were applied to each concrete mixture to determine its workability, and measurements were taken in accordance with the TS EN 12390-2 [12] standard. For compressive strength determination, 10 cm cube samples were used, and the tests were conducted according to the TS EN 12390-3 [13] standard. Compressive strength tests were performed on three samples for each mixture at 7, 14, and 28 days of curing age, and the arithmetic mean of the measured values was accepted as the compressive strength of the respective mixture. The loading rate was kept constant at 0.6 MPa/s in all compressive strength tests.

3 Results and Discussions

Observations of the fresh concrete properties within the experimental study indicated that plastic aggregate replacement ratios of 20% and 40% (as a replacement for fine aggregate) represented two critical threshold levels in terms of workability.

As the plastic aggregate content increased, the slump values of the fresh mixtures tended to decrease. This reduction can be attributed to the irregular shape of the plastic particles and the presence of sharp edges on some particles, which may increase interparticle friction [14]. The

slump values and amounts of chemical admixture used for the concrete mixtures are presented in Table 3.

Table 3. Relationship between slump-quantity of chemical admixture

5SF-20 PVC	7.5	80	*First and second codes indicate SF and PA.		

Since the target consistency class was S2, chemical admixture was used in some mixtures to achieve the desired consistency, whereas no admixture was required for several mixtures. Overall, the slump values of all mixtures ranged between 5 and 10 cm. The reference mixtures represent those containing neither silica fume nor plastic aggregate. As the SF replacement ratio increased, the consistency values tended to decrease, which can be attributed to the considerably higher fineness of SF compared with cement. The reference mixtures without SF and those containing 2.5% SF, both without PVC aggregate, satisfied the target S2 consistency; therefore, no chemical admixture was required. For the other reference mixtures containing SF, only a limited amount of chemical admixture was required.

Similarly, an increase in the PVC replacement ratio generally resulted in a decrease in slump values. Accordingly, the amount of chemical admixture required tended to increase. However, despite keeping the other mixture parameters constant, the amount of chemical admixture did not increase consistently with increasing PVC replacement ratio in all cases. For example, approximately 121 g of chemical admixture was used in the mixture coded 5SF-35 PVC, whereas this amount decreased to approximately 103.5 g in the 0SF-40 PVC mixture, despite the PVC replacement ratio increasing to 40%. This observation suggests that variations in the required amount of chemical admixture may be associated with differences in the slump values of the mixtures.

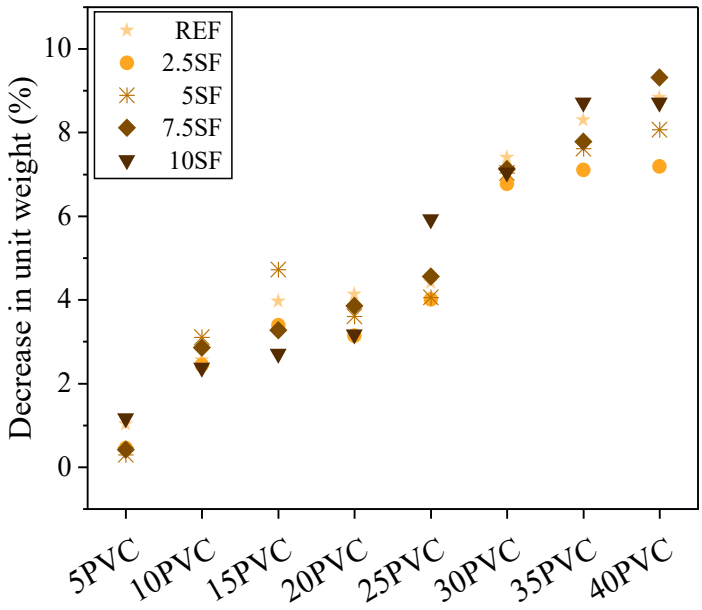

Fig. 2. Percentage reduction in unit weight for mixtures.

Figure 2 shows the percentage decrease in unit weight for the mixtures compared to the reference concrete. As the PA content increased, the unit weight of the mixtures generally tended to decrease. This reduction can be attributed to the lower specific gravity of the plastic aggregate used as a replacement for fine aggregate. Although a decrease in unit weight was expected with increasing PVC content in mixtures with consecutive PVC replacement ratios, slight increases in unit weight were also observed in some mixtures. These variations may be attributed to differences occurring during mixture preparation and placement into the molds. Similarly, an increase in the silica fume replacement ratio generally resulted in a decrease in unit weight, which can be explained by the lower specific gravity of silica fume compared with cement. Overall, increasing PA and SF contents resulted in a decrease in unit weight compared with the reference mixtures. The effect of PA on reducing unit weight was considerably more pronounced than that of SF.

A previous study investigating the use of waste plastic in concrete reported a significant reduction in unit weight with the incorporation of PA. The density of the plastic aggregate was reported to be approximately 70% lower than that of sand [15]. In this study, the density of the PA was approximately 45% lower than that of sand. In addition, the density of silica fume was approximately 25% lower than that of cement.

4 Conclusions

The main findings obtained within the scope of the experimental study are summarized below.

- %20 and %40 plastic aggregate ratios have been determined to be critical threshold values in terms of workability.
- Increasing the PVC replacement ratio generally reduced slump values and increased the required amount of chemical admixture. However, in some cases, the decrease in chemical admixture requirement with increasing PVC content was attributed to variations in slump values.

- As the PA content increased, the unit weight of the mixtures tended to decrease. Similarly, an increase in the silica fume replacement ratio generally resulted in a decrease in unit weight.
- The effect of PA on reducing unit weight was considerably more pronounced than that of SF.

Abstract. Textile reinforcements offer new possibilities to realize novel thin-section concrete structures due to their structural slenderness, mechanical performance, and durability benefits. When applied in construction, however, a significant challenge emerges due to the limited roll dimensions of commercial textiles. This dictates that the structure needs to be reinforced using multiple textile mesh segments, making the overlapping of these segments essential for adequate stress transfer and structural integrity. In this study, this critical aspect of textile-reinforced cementitious composites was investigated. Textile-reinforced mortars with varying overlap configurations were tested under three-point bending to determine their flexural strength and pseudo-ductility characteristics. Three overlap connection approaches were evaluated, and their effects on structural performance in relation to two different overlap lengths were revealed. The results show that when sufficient overlap length and anchorage are present, clamping the textile reinforcements detrimentally affects both flexural strength and overall toughness in the pseudo-ductility regime. Conversely, for configurations with limited overlap length and insufficient anchorage, the clamps were able to connect the textile segments, providing significant pseudo-ductility for the cementitious composites. However, due to the disruption of matrix continuity, a notable loss in flexural strength was detected for all clamped configurations. Overall, this study enhances the understanding of this critical design consideration, potentially leading to efficient practices that reduce material use while avoiding detrimental connection approaches.

Keywords: Textile-reinforced cementitious composites; reinforcement overlapping; flexural behavior; pseudo-ductility.

1 Introduction

Textile reinforcements have emerged as a promising solution for thin-section concrete shell structures. They are innovative reinforcement alternatives composed of high-strength fibers such as carbon, glass, or basalt fibers arranged in a mesh grid structure. As they are non-metallic, textile-reinforced concrete (TRC) does not need thick concrete cover, which significantly reduces the required structural thickness. They also exhibit high mechanical performance, making them well-suited for the reinforcement of thin sections [1-3]. As they are inherently corrosion-resistant, textile reinforcements provide a longer service life, which is particularly important for structural safety [4]. By enabling thinner and more lightweight

structures, TRC systems can offer significant design freedom, sustainability benefits, and more practical on-site handling compared to traditional materials [5-8].

In practice, the textile reinforcements used in construction are typically provided in roll form with a predetermined roll width by the manufacturers. This essentially means that large structures cannot be reinforced with a single continuous reinforcement layer, and several reinforcement segments must be used for full reinforcement of the structure. For structural integrity, these segments need to be sufficiently overlapped along their intersection to ensure adequate stress transfer between them [8-9]. Proper stress transfer is critical to carry and resist stresses through the reinforcement within the concrete; otherwise, these regions can become vulnerable weak spots for failure, compromising the overall structural integrity of the thin-section cementitious composite. Thus, reinforcement overlapping becomes an important aspect in the design of textile reinforcements, and applying a proper textile connection methodology is critical to attain sufficient structural integrity along these regions.

In this study, we focus on this aspect and investigate the mechanical performance of various textile overlap configurations embedded in textile-reinforced mortars. The primary objective is to evaluate how different overlap connection approaches and overlap lengths influence flexural strength and pseudo-ductility using a three-point bending testing scheme. We demonstrate the effectiveness of these connection approaches in relation to different overlap lengths to provide valuable guidelines for the effective treatment of this critical design aspect.

2 Experimental Methodology

2.1 Materials

In this study, we used textile-reinforced mortars for the overlap configuration investigation. The cementitious matrix was composed of Portland cement, natural sand, tap water, and superplasticizer (SP). The mixture composition is provided in Table 1.

Table 1. Mixture composition.

Material	Mass/Binder
CEM I	1
Natural Sand	1.5
Water	0.45
Superplasticizer	0.0055

For the reinforcements, we used an alkali-resistant (AR) glass fiber textile mesh, which consisted of periodically arranged glass fiber rovings in two orthogonal directions with an epoxy coating. The individual fiber strands had an approximate width of 3 mm and a thickness of 0.3 mm. The textile mesh had square openings of 10 mm in both directions, which allowed the mortar to pass through during casting. This provided sufficient bonding between the textile reinforcements and the cementitious matrix after curing. The reinforcement stiffness and tensile strength are 78 GPa and 1.7 GPa in both weft and warp directions, respectively.

Following standard three-point bending testing procedures for mortar prisms, specimens were cast with a length, width, and thickness of 160 mm, 40 mm, and 40 mm, respectively (see Fig. 1). The textile reinforcements were placed 5 mm above the bottom surface in the tensile region. After casting, specimens were cured in water for 7 days. For each configuration, 3 specimens were prepared and tested. A schematic of the overlap specimens is provided in Fig.

1. In these overlap specimens, two textile segments extend from each side of the specimen along the longitudinal direction such that they overlap at the center of the specimen.

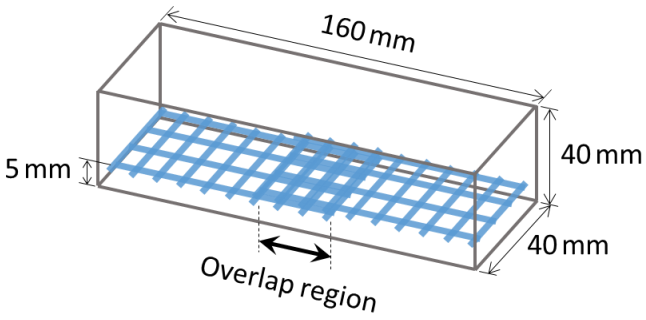

Fig. 1. Specimen dimensions and textile placement.

In this study, 5 different overlap configurations were developed and tested for their flexural behavior. Fig. 2 presents the textile meshes with different overlap approaches, and Table 2 provides the configuration names together with their descriptions. In these configurations, the overlap region was varied based on two parameters: overlap mesh opening number and connection method. For the first parameter, we investigated configurations with overlap lengths corresponding to 1 and 3 mesh openings (equivalent to 1 cm and 3 cm, respectively). For the connection methods, we used 3 different approaches for the overlap regions:

1) Plain overlapping of the two textile segments at the center section. Here, the two textile segments were essentially bonded via the thin cementitious matrix between the layers along the overlap region.
2) We stitched the two textile segments using a thin copper wire with a diameter of approximately 0.25 mm (see Fig. 2a).
3) In addition to plain overlapping, we clamped the two textile segments using plastic clamps along the overlap region as shown in Figs. 2b and 2c.

For the specimens with a 1-mesh opening overlap, we investigated two configurations. Plain overlapping was not tested here as it was not expected to exhibit pseudo-ductility after major crack formation along the center due to the limited anchorage length. We focused on the clamping and wire stitching approaches in configurations 1M-LC and 1M-W, respectively. For the 3-mesh opening overlap, we investigated plain overlapping and clamping approaches in configurations 3M-NC, 3M-LC, and 3M-2CC. Wire stitching was not investigated for the 3-mesh series because it was unable to provide sufficient connection and ductility in the 1M-W specimens, as discussed later in the results section. Instead, we focused on two different clamping configurations: in 3M-LC, 2 clamps were introduced at the center of the specimen (see Fig. 2b); in 3M-2CC, two clamps were introduced along diagonal directions positioned near the ends of the overlap region away from the center (see Fig. 2c).

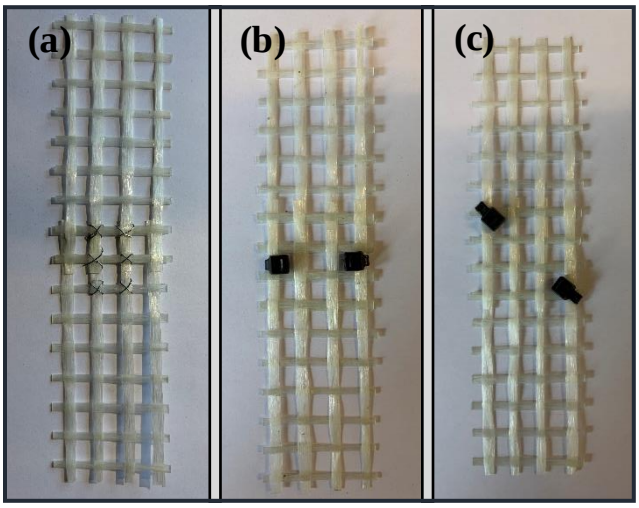

Fig. 2. Illustration of the overlap approaches; **(a)** wire stitching (named W), **(b)** clamping along the longitudinal direction (named LC), **(c)** clamping along the diagonal direction at two locations (named 2CC).

Table 2. Specimen configurations.

Name	Configuration Description
Ref	Reference specimen with a single continuous textile mesh
1M-LC	Overlap region with 1 mesh opening clamped along the longitudinal direction
1M-W	Overlap region with 1 mesh opening stitched using a copper wire along the overlap region
3M-NC	Overlap region with 3 mesh openings without any clamps
3M-LC	Overlap region with 3 mesh openings clamped along the longitudinal direction
3M-2CC	Overlap region with 3 mesh openings clamped at 2 diagonal locations away from the center

2.2 Testing

The specimens with various overlap configurations were tested using a three-point bending scheme to determine their flexural strength and detect if they exhibit pseudo-ductility after matrix rupture. As flexural loading in thin-section panels can be critical, we selected this testing scheme to apply concentrated loading directly along the overlap regions, causing severe flexural deformations. This provided a conservative benchmark for evaluating overlap performance under severe loading conditions.

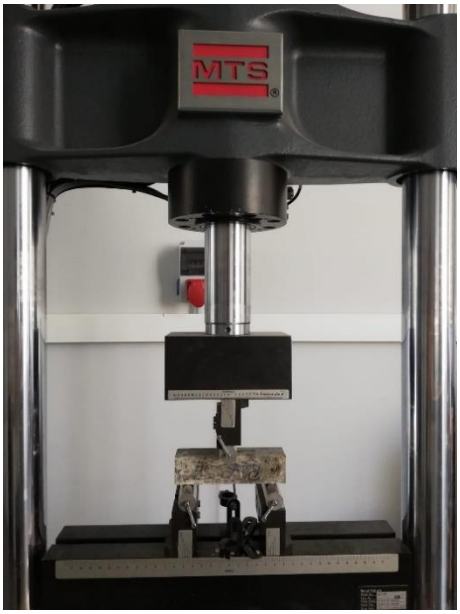

Fig. 3. The 3-point bending test experimental setup.

An MTS closed-loop universal testing machine was used for the flexural tests (see Fig. 3). Testing was conducted in load-controlled mode with a rate of 50 N/s and span length of 100 mm following EN 1015-11. The nominal stress and strain corresponding to the measured force and displacement of the specimens were calculated using the following equations [10]:

$$\sigma = \frac{3FL}{2bd^2}, \tag{1}$$

$$\varepsilon = \frac{6Dd}{L^2}, \text{ and} \tag{2}$$

where L is the span length, b is the width of the beam, d is the thickness of the beam, F is the flexural load, D is the maximum deflection of the center of the beam, σ and ε are the nominal stress and strain at the center of the bottom tensile surface, respectively.

Using these formulations, flexural strengths and nominal strains along the pseudo-ductility regime of the specimens were determined. The flexural strength (modulus of rupture) was determined based on the load corresponding to major matrix crack formation along the center. Matrix rupture was subsequently followed either by a significant drop in stress or by a pseudo-ductility regime depending on the specimen configuration.

3 Results and Discussion

The flexural strength results of the configurations are provided in Fig. 4. The configuration 3M-NC with plain overlapping and no clamps showed the highest flexural strength. The results indicate that using clamps and wires for overlap connection reduces the strength. This can be attributed to the fact that they cause localized stress concentrations leading to early rupture of the cementitious mortar. For the wire stitching approach, this reduction was limited; however, for clamped configurations, strength was significantly reduced. Because the plastic clamps occupied much larger volume than the thin wires, they disrupted matrix continuity significantly, causing higher stress concentrations that led to lower flexural strength. Furthermore, when comparing the clamped configurations, 3M-2CC showed higher flexural strength than 3M-LC.

When the clamps were placed away from the center and the concentrated load, as in 3M-2CC, stress concentrations were less severe, leading to higher flexural strength.

In this study, we also compared the pseudo-ductility behavior of the configurations. Fig. 5 presents the results of the configurations that exhibited pseudo-ductility. The remaining configurations, Ref and 1M-W, did not exhibit ductility after the peak rupture stress. For the reference specimens (Ref) with continuous reinforcement without an overlap, the single layer reinforcement ratio was not sufficient to sustain the cracking load, resulting in immediate tensile rupture of the mesh. For configuration 1M-W, although there was double reinforcement at the center due to the overlap, there was a sudden load drop and premature failure because the anchorage length was insufficient, causing the textile to pull out immediately upon matrix rupture. The wire stitching was not able to provide sufficient connection between the two textile segments to prevent slippage.

The potential of wire stitching needs further study to reach a definitive conclusion on its effectiveness. The stitching methodology can be further investigated in future studies with alternative techniques for more effective connection and enhanced overlap performance.

Among the configurations exhibiting pseudo-ductility, the 3M-NC configuration with plain overlapping and no clamps showed the best overall toughness (see Fig. 5). Due to a casting defect, one specimen was excluded for 3M-NC, and data for the remaining two specimens are presented in Fig. 5. Compared to configuration 1M-W, the embedment length of this configuration with 3 mesh openings was able to provide sufficient anchorage, which introduced post-cracking pseudo-ductility after peak load. The double reinforcement with adequate embedment length at the center ensured sufficient resistance for post-cracking hardening. Because there were no clamps, flexural strength was much higher, which also contributed to higher toughness in the ductility regime.

When we compare configuration 3M-NC with clamped configuration 3M-LC, the results demonstrate the adverse effect of additional clamps due to localized stress concentration. Here, the clamps did not improve the pseudo-ductility regime; in fact, the hardening observed in 3M-NC was replaced by post-cracking softening in 3M-LC at high deformation levels (corresponding to a nominal strain of 0.1), leading to significantly lower overall toughness, as observed in Fig. 5.

On the other hand, the 1M-LC results show that clamping was able to introduce an effective mechanical connection between the textile segments, leading to significant pseudo-ductility with post-cracking softening for the cementitious composite. This was not the case for 1M-W, where the wire stitches failed to hold the textile segments together. This indicates that when the overlap length is below the critical length for sufficient anchorage, clamps can have a positive effect by providing a physical connection and introducing pseudo-ductility to the system. For reduced reinforcement material use, the overall toughness of short-overlap specimens can be significantly increased via this induced pseudo-ductility.

Furthermore, when comparing the clamped configurations with 3 mesh openings, 3M-2CC exhibited higher overall toughness than 3M-LC. With reduced stress concentrations due to positioning the clamps away from the center and the concentrated load, higher overall toughness was attained along the pseudo-ductility regime.

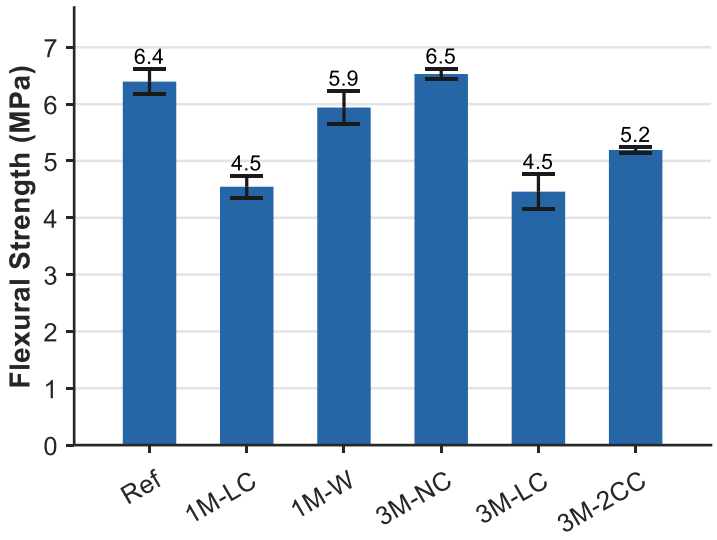

Fig. 4. Flexural strength results for various overlap configurations with standard deviation error bars and mean strengths.

The adverse effect of mechanical clamping on flexural performance warrants careful consideration. While clamping mechanisms are intended to enhance the overlap and maintain continuity, the results indicate that they act as stress concentrators and degrade flexural strength and overall toughness when sufficient bond length already exists. Clamps became beneficial only when the overlap length was insufficient to provide adequate anchorage for pseudo-ductility, as seen in the 1M-LC results. In contrast, configuration 3M-NC, which relied entirely on the cementitious matrix to transfer stresses across the overlap, attained the highest flexural strength and toughness. This indicates that a continuous, undisturbed matrix-to-fiber bond in the overlap region is more effective than mechanically forced connections such as clamping. However, this comes at the cost of using more reinforcement material for the overlap region.

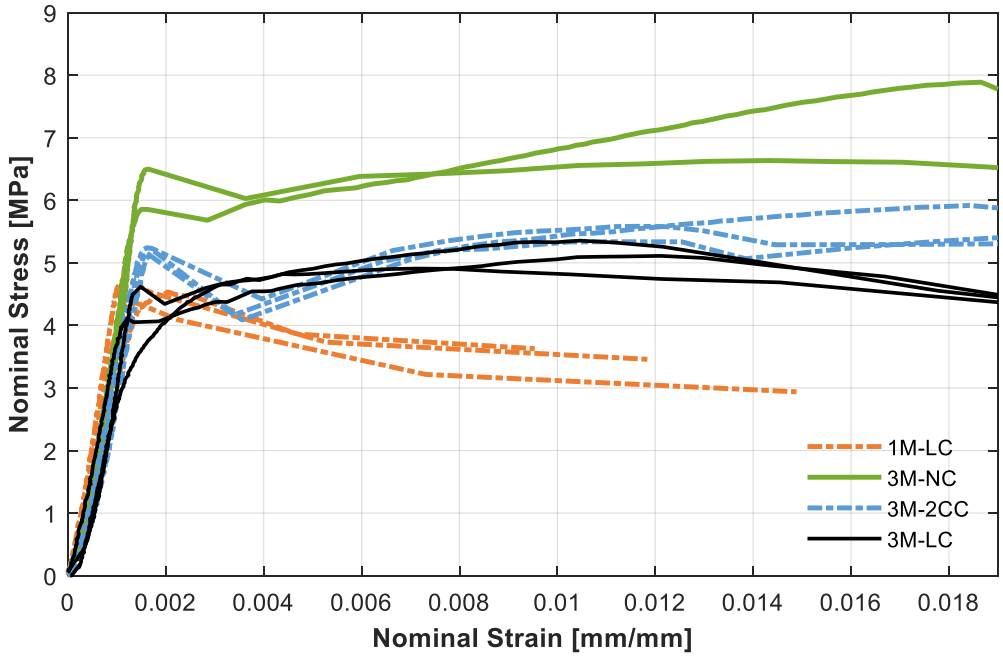

Fig. 5. Nominal stress-strain curves of configurations exhibiting significant ductility due to reinforcement pull-out.

Furthermore, for a comprehensive understanding of these connection approaches and how their influence depends on overlap length, future research can focus on size effects by testing these configurations in larger-scale, thin-section structural elements to determine their global flexural and pseudo-ductile performance.

4 Conclusion

The structural slenderness and high mechanical performance of thin-section textile-reinforced cementitious composites offer new avenues for novel construction applications. However, their effective utilization in real-life structures requires studies on critical design aspects such as reinforcement overlapping. Due to practical reasons such as the limited roll width of reinforcements, different textile segments must be carefully overlapped to ensure structural integrity. To enhance understanding of this critical design aspect, this study investigated textile-reinforced mortars with different overlap configurations and determined their flexural behavior using 3-point bending tests. Based on the findings, the following are concluded:

- The overlap configuration 3M-NC (with no clamps, relying entirely on the cementitious matrix to transfer stresses across the discontinuity with sufficient overlap length) exhibited the best performance, showing the highest flexural strength and overall toughness with pseudo-ductile post-cracking hardening.

- Using plastic clamps along overlap regions significantly reduces flexural strength by creating localized stress concentrations and disrupting matrix continuity; for overlap regions with sufficient bond length, clamping also significantly lowers overall toughness.

- The wire stitching applied in this work did not provide sufficient connection to induce pseudo-ductility in the 1M-W configuration. However, these specimens showed first-crack flexural strength close to the reference case because the thin wire caused minimal matrix disruption compared to plastic clamps. Alternative stitching approaches can be investigated in the future to improve connection efficiency to induce pseudo-ductility.

- When the overlap length is short and anchorage is insufficient, clamping is able to introduce sufficient mechanical connection and pseudo-ductility (exhibiting post-cracking softening), as observed in configuration 1M-LC (compared to abrupt failure in 1M-W). However, when overlap length is already sufficient, clamping has an adverse effect (3M-LC), lowering flexural strength and post-cracking toughness compared to specimens with no clamps (3M-NC).

Optimizing overlap configurations is critical for improving the structural integrity and mechanical performance of thin-section textile-reinforced cementitious composites. This study provides key considerations and guidelines for the effective design of overlap regions, enabling efficient material use and avoiding disadvantageous connection approaches.

Abstract. This study demonstrates that mechanochemical activation (MCA) can be used as an effective methodology to significantly enhances the reactivity of pyrophyllite, enabling its potential use as a supplementary cementitious material (SCM) for partial replacement of CEM II cement and the development of clinker-reduced binders. The R^3 bound water content increased from 1.22% to 10.05% (approximately 724%), after intense milling, corroborating with delamination and amorphilisation observed in the XRD results. These changes also contributed to improved

mechanical performance, increasing compressive strength from 32.92 MPa for untreated pyrophyllite to 48.79 MPa for activated pyrophyllite, exceeding the CEM II-based PCC reference strength of 41.83 MPa by approximately 16.6%. Overall, MCA enhances pyrophyllite reactivity, which is not possible by using traditional methods, and its potential to replace PCC.

Keywords: SCMs; Pyrophyllite; MCA; R^3 test; Natural pozzolans.

1. Introduction

Replacing a portion of Portland cement with supplementary cementitious materials (SCMs) is one of the most effective approaches to reducing the carbon footprint of the cement and concrete industries [1]. The cement industry is globally responsible for approximately 8–9% of anthropogenic CO_2 emissions [2]. The use of supplementary cementitious materials such as fly ash (FA), ground granulated blast-furnace slag (GGBFS), silica fume, and limestone as partial replacements for cement has long been one of the key strategies for reducing the environmental impacts of the cement and concrete industries [1].

However, the current production of FA and GGBFS is insufficient to meet the increasing global demand for cement. At the same time, the availability of these materials is expected to decline further with the phase-out of coal use and the transition of the steel industry toward more sustainable practices [3], [4]. Therefore, it is necessary to expand the boundaries of this field by developing new SCMs from sustainable sources [5]. Due to their potential to significantly reduce energy consumption and CO_2 emissions, natural pozzolans have increasingly been used in recent years as alternative supplementary materials to Portland cement in the production of Portland pozzolanic cement and concrete [6].

However, one of the major challenges limiting the widespread use of these materials is the low pozzolanic reactivity of natural pozzolans. Previous studies clearly demonstrate this limitation. Replacing 20% of cement with untreated natural pozzolan reduces the 28-day compressive strength by approximately 6.9%, from 68.5 MPa to 63.8 MPa [7]. At higher replacement levels, such as 36% and 56%, even greater reductions in 90-day compressive strength of 18.3% and 42.5%, respectively, have been reported [8]. Furthermore, the 28-day Pozzolanic Activity Index (PAI) values of natural pozzolans such as trachyte and rhyolite are only 89% and 87%, respectively. Rhyolite, however, fails to meet the accepted threshold of 80% for the 90-day PAI [9].

The primary reason for this low reactivity is the mineralogical structure of these materials. Although these materials contain high amounts of silicon dioxide (SiO_2) and aluminium oxide (Al_2O_3), these oxides are predominantly present within stable crystalline structures [9], [10]. Consequently, they react slowly with calcium hydroxide and cannot generate sufficient amounts of strength-contributing C-S-H phases. Furthermore, conventional fine grinding is often insufficient to significantly enhance their reactivity [10]. A large proportion of natural pozzolans do not exhibit a dehydroxylation peak because their crystal structures contain neither hydroxyl groups nor chemically bound water. Therefore, conventional thermal activation methods based on dehydroxylation are ineffective in enhancing the reactivity of these materials

[11]. Recent studies have demonstrated that mechanochemical activation (MCA) has significant potential.

In one study, pumice, perlite, and raw meal were subjected to mechanochemical activation. Following activation, the chemically bound water content and strength activity index were found to be 7.5% and 106% for pumice, 7.07% and 98% for perlite, and 3.40% and 71.05% for raw meal, respectively [12]. Furthermore, pyrophyllite has attracted interest because of its high SiO_2 and Al_2O_3 contents and its potential as a supplementary cementitious material. However, the ordered crystal structure of untreated pyrophyllite can limit the dissolution and the pozzolanic contribution of pyrophyllite. Erdemoğlu et al. [13] showed that mechanical activation dramatically alters pyrophyllite structure and enhances its chemical response. Terzić et al. [14] also showed that the mechanochemical activation state of pyrophyllite is strongly determined by the milling conditions, and that selection of the appropriate activation regime is important. These results demonstrate that mechanochemical activation can significantly enhance the pozzolanic reactivity of these materials. These results demonstrate that mechanochemical activation can significantly enhance the pozzolanic reactivity of these materials. In the MCA process, high-energy milling disrupts crystalline structures, induces structural disorder, and increases the dissolution of reactive Si and Al species.

Although MCA has shown promising results for clay minerals, its systematic application to a pyrophyllite remains insufficiently investigated. In addition, Limestone Calcined Clay Cement (LC^3) systems have successfully reduced clinker content through the use of highly reactive calcined clays. Nevertheless, CEM II–SCM (supplementary cementitious material) systems with compositions similar to Limestone Calcined Clay Cement (LC3) binders have been investigated only to a limited extent in Türkiye, despite the increasing adoption of CEM II cements as part of decarbonisation strategies in the cement and concrete sector and the widespread availability of locally sourced supplementary cementitious materials (SCMs).

The use of commercially available CEM II cements in combination with locally sourced SCMs offers the potential to achieve clinker replacement levels comparable to those of LC3 systems while maintaining similar mechanical and durability performance. Accordingly, the primary objective of this study is to investigate the feasibility of developing LC3-like low-clinker binder systems using commercially available CEM II cements and locally sourced SCMs, thereby providing a practical, scalable, and readily implementable solution for the Turkish cement industry.

2. Materials and Methods

This study systematically assessed the effect of mechanochemical activation (MCA) on the pozzolanic reactivity of pyrophyllite and investigated the changes induced in its crystal structure. First, the pozzolanic reactivity of untreated and MCA-treated pyrophyllite was evaluated using the R³ bound-water test to identify the most effective activation condition. The structural and chemical changes induced by MCA were subsequently investigated using X-ray diffraction (XRD), and their relationship with the bound water test results was assessed. Finally, the pyrophyllite exhibiting the highest bound-water content was evaluated at a 20% cement replacement level through compressive strength testing.

2.1 Materials

The pyrophyllite used in this study were collected as a powder shape from Cimsa Cement, in Turkey. CEM II 42.5 R type Portland composite cement (PCC), containing 8 wt.% pumice, 5 wt.% gypsum, 4 wt.% limestone and 4 wt.% fly ash, from Cimsa Cement was used for preparing the blended cement pastes and mortars. The chemical composition of the raw materials was determined via X-ray fluorescence analysis using the fused beads method (Figure 1). The loss on ignition (LOI) was evaluated by heating for 2 h at 1050 °C.

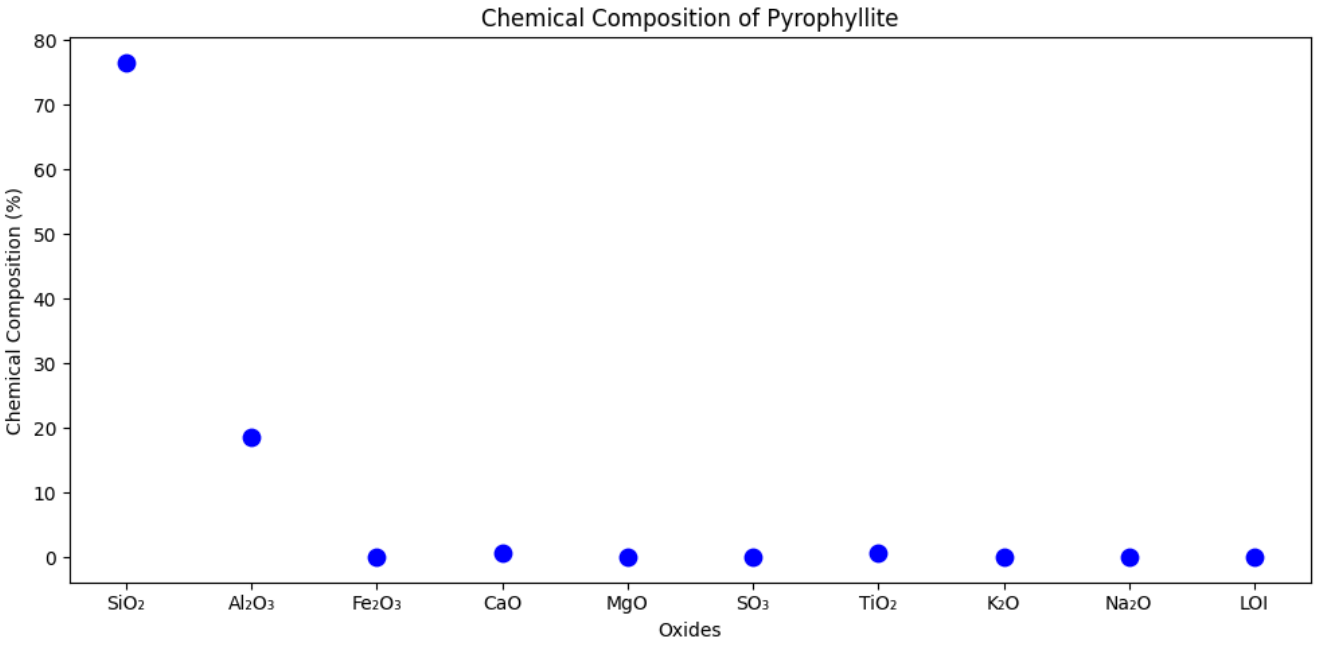

Figure 1. Chemical composition of PCC and natural pyrophyllite determined by XRF (wt.%).

Calcium hydroxide [$Ca(OH)_2$], calcium carbonate ($CaCO_3$), potassium hydroxide (KOH), and potassium sulfate (K_2SO_4) from Sigma Aldrich were used for the R³ reactivity test and standardized sand was used for mortar preparation.

2.2. MCA parameters

The activated samples were produced under different combinations of ball-to-powder ratio (BPR), rotational speed, and milling time in order to evaluate the influence of activation conditions on pyrophyllite reactivity. The activation conditions are expressed as (5–10–20)–(300–400–500)–(20–40–60), where the first number represents the ball-to-powder charge ratio, the second stands for the milling speed (rpm), and the third represents the milling time (min), as shown in Table 1.

Table 1. R³ bound-water content of untreated and mechanochemically activated pyrophyllite samples.

Sample	Activation condition
P1	Untreated
P2	10-300-20
P3	10-400-20
P4	20-500-60
P5	05-500-60
P6	10-500-60
P7	10-500-40
P8	10-500-20

2.3 R³ Bound Water Test

The pozzolanic reactivity of untreated and mechanochemically activated pyrophyllite was evaluated using the Rapid, Relevant and Reliable (R^3) bound-water test. Pyrophyllite was subjected to seven combinations of ball-to-powder ratio (BPR), rotational speed, and milling time. Untreated pyrophyllite (P8/SAF) was used as the reference. For the R^3 mixtures, pyrophyllite was combined with calcium hydroxide [$Ca(OH)_2$] and calcium carbonate ($CaCO_3$) using an SCM:$Ca(OH)_2$ mass ratio of 1:3 and an SCM:$CaCO_3$ ratio of 2:1. The alkaline solution was prepared using 4 g of KOH and 20 g of K_2SO_4 per litre of water. The prepared mixtures were cured at 40 °C, after which chemically bound water was determined. All activation conditions were evaluated to identify the treatment providing the highest pozzolanic reactivity.

2.4 X-ray Diffraction (XRD) Analysis

The crystal structures of the untreated and mechanochemically activated pyrophyllite were determined by the Rigaku-SmartLab X-ray diffractometer using Cu-Kα radiation with a wavelength of 1.5408 Å. The tests were conducted with a step size of 0.02° and a counting time of 3 s/step, from 5° to`` 60° (2θ).

2.5 Mortar Preparation for Compressive Strength Test

Blended cement pastes (20% pyrophyllite + 80%PCC) and mortars were prepared using differently mechanochemically activated and untreated pyrophyllite. Reference samples were prepared with 100 % PCC. The pastes were prepared using a high shear overhead mixer. The paste samples were cured in sealed plastic containers at room temperature (20 ± 2 °C) for 28 days. The mortar samples were produced using BS EN 196-1 standard [15] with a binder to sand ratio of 1:3, and cast using 40 mm × 40 mm × 40 mm moulds.

Figure 2. Mortar specimens prepared for compressive-strength testing.

Following curing, the mortar specimens were subjected to compressive-strength testing to evaluate the mechanical performance of untreated and mechanochemically activated pyrophyllite [12]. The compressive strength of the mortar cubes was evaluated at 28 days of curing.

3. Results and Discussion

3.1 R³ test

R³ bound-water content of MCA pyrophyllite and its untreated counterpart are summarized in Figure 3. Results demonstrate that mechanochemical activation leads to significant increase on the R³ bound-water content of pyrophyllite. The untreated reference sample (P1) showed lowest bound-water content with 1.22%, assigned the lowest pozzolanic reactivity. The bound-water content increased to 3.27% for P2 and 4.85% for P3, and for P8 it reached 3.50% for different milling speed, which can be related with increasing milling speed results in increasing activation efficiency due to further delamination and amorphization. As for charging ratio, highest bound water was observed for P6, which was 10.05%, which also corroborated with amorphization as shown in Figure 3. As for milling time, extended milling leads to improve bound water content, which can be related with further amorphization.

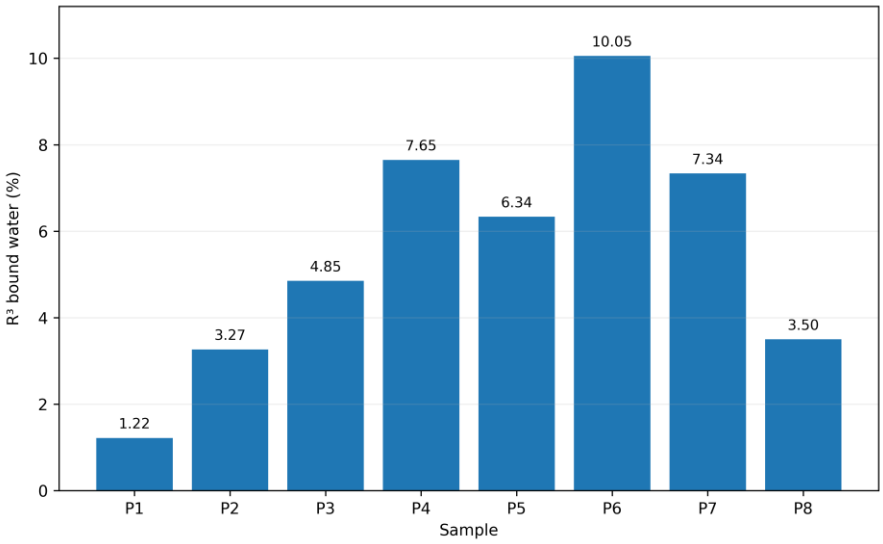

Figure 3. R³ bound-water content of untreated and mechanochemically activated pyrophyllite samples.

These findings is also corroborated with reported literature, where MCA enhances pozzolanic reactivity through particle refinement and progressive disruption of the original mineral structure, increasing structural disorder and availability of reactive sites. Tole et al. [16] also showed that intense mechanochemical activation of natural clay minerals enhances pozzolanic activity through structural disruption and increased amorphization. Another study conducted by Baki et al. [10] showed that high-energy milling can significantly improve the reactivity of aluminosilicate minerals through particle-size reduction and physicochemical modification. Particularly for pyrophyllite, Erdemoğlu et al. [13] reported that mechanical activation changes the mineral structure and increases its chemical responsiveness. The non-monotonic R³ response that we have observed here shows that the effect of activation is more about the milling intensity, structural disorder, and particle agglomeration than about the increase in treatment severity [17].

3.2 XRD

The mineralogy and gel structure of un-treated and mechanochemically activated pyrophyllite minerals were characterized using the XRD, as shown in 3, where XRD pattern of un-treated pyrophyllite indicates the presence of mainly pyrophyllite (Powder diffraction file, PDF# 79-1570) and a small amount of diaspore (PDF# 26-0911) and quartz (PDF# 79-1910 and 79-1911). The results show that the mechanochemical process was able to effectively delaminate and amorphized the crystal structure of the un-treated pyrophyllite after 60 minutes of activation, as indicated by the significant reduction of the pyrophyllite. Similar crystal structure evolution was also observed in literature for pyrophyllite minerals. The trace dickite and Kyanite phases were also completely disappeared after intense milling but the quartz phase still remained after mechanochemical activation, consistent with reported literature.

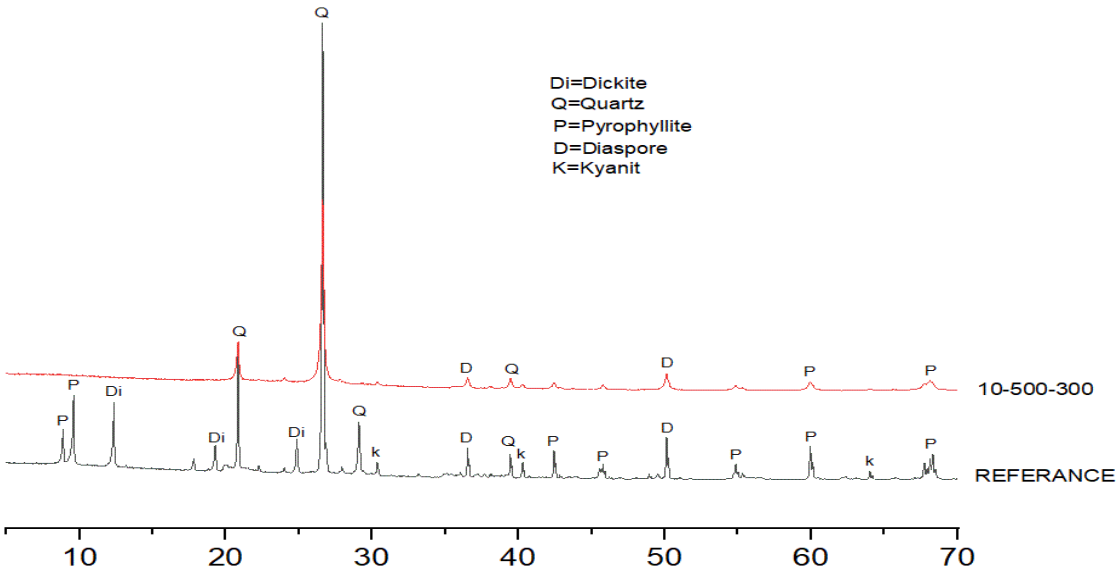

Figure 4. XRD patterns of untreated and mechanochemically activated pyrophyllite samples over the 4-80° 2θ range.

The observed structural modifications are consistent with the increase in R^3 reactivity and with the mechanical response of the selected activated material. Sengul et al. [18] showed that mechanical activation of pyrophyllite produces substantial structural modification and facilitates subsequent chemical attack. Ababneh et al. [19] showed that mechanochemical treatment changes the structural characteristics of pyrophyllite, confirming the sensitivity of this mineral to intensive milling. Tole et al. [20] showed for natural clay minerals that the reduction of crystalline order and the development of structural disorder are associated with enhanced pozzolanic activity. Baki et al. [11] likewise showed that mechanochemical activation can increase the reactivity of aluminosilicate minerals through combined structural and surface modifications. In the present study, the simultaneous XRD modification and increase in R^3 bound water for P6 support the interpretation that milling-induced structural disorder contributed to the enhanced reactivity of activated pyrophyllite [21].

3.3 Compressive strength

To evaluate the effect of mechanochemical activation on pyrophyllite reactivity, compressive strength tests were conducted using the reference Portland cement paste (PCC), untreated pyrophyllite, and mechanochemically activated (MCA) pyrophyllite exhibiting the highest bound water content. The results are summarized in Table 2 and compared graphically in Figure 5.

Table 2. Compressive strength of reference and pyrophyllite-containing mortar mixtures.

Binder system	Strength (MPa)
100% PCC	41,8
20% untreated pyrophyllite	32.92
20% MCA pyrophyllite (selected optimum)	48.79

The mechanochemically activated pyrophyllite system achieved a compressive strength of 48.79 MPa, representing a 48.2% increase compared with untreated pyrophyllite (32.92 MPa). This improvement is attributed to enhanced pozzolanic reactivity following intensive milling. The strength development is consistent with the increased R^3 reactivity and the greater amorphization observed by XRD, suggesting that mechanochemical activation increased the availability of reactive phases and enhanced their contribution to strength development [22].

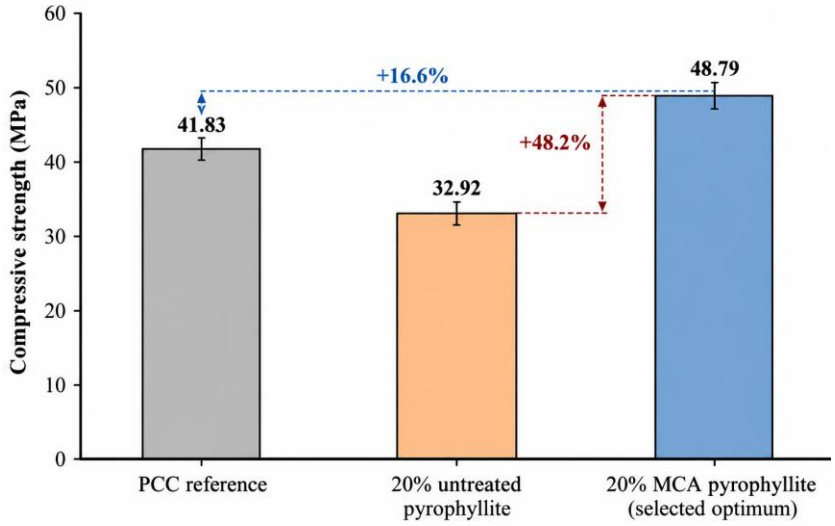

Figure 5. Compressive strength of untreated-pyrophyllite mortar and selected mechanochemically activated pyrophyllite mortar.

Similar finding were also observed in literature, where Terzić et al. [14] showed that the degree of mechanochemical activation of pyrophyllite is closely related to processing conditions and can be used to predict its suitability for cement-binder applications. Amroun et al. [23] showed that mechanochemically activated SCMs can provide improved mechanical performance in cement pastes and mortars when activation sufficiently increases their reactivity. Xu et al. [24] also showed that mechanical activation modifies the pozzolanic response of SCM systems and can enhance their

contribution to strength development. In the present study, the increase in R^3 bound water from 1.22% to 10.05% was accompanied by an increase in compressive strength from 32.92 to 48.79 MPa. The XRD changes observed for P6 provide structural evidence supporting this behavior. These complementary results indicate that the improved strength is associated with milling-induced structural modification, enhanced chemical reactivity and a greater contribution of activated pyrophyllite to hydration and matrix densification [12].

4. Conclusions

This study demonstrates that mechanochemical activation (MCA) can be used as a effective methodology to significantly enhances the reactivity of pyrophyllite, enabling its potential use as a supplementary cementitious material (SCM) for partial replacement of CEM II cement and the development of clinker-reduced binders. The R^3 bound water content increased from 1.22% to 10.05% (approximately 724%), after intense milling, corroborating with delamination and amorphilisation observed in the XRD results. These changes also contributed to improved mechanical performance, increasing compressive strength from 32.92 MPa for untreated pyrophyllite to 48.79 MPa for activated pyrophyllite, exceeding the CEM II-based PCC reference strength of 41.83 MPa by approximately 16.6%. Overall, MCA enhances pyrophyllite reactivity, which is not possible by using traditional methods, and its potential to replace PCC.

Abstract. Due to the worldwide expansion of Waste-to-energy plants, the management of municipal solid waste (MSW) incineration bottom ash (IBA) presents a significant global environmental challenge. IBA, due to its low pozzolanic reactivity, high porosity, the potential leaching of heavy metals, and the presence of metallic aluminum, limits its use as a construction material. Current stabilization methods, including thermal treatment, stabilization/solidification (S/S), chemical treatment, and conventional carbonation, are respectively energy-intensive, volume-increasing, dangerous to handle, time-consuming, and do little to enhance the material's pozzolanic activity. In this study, innovative methods such as Mechanochemical Activation (MCA) and Mechanochemical Carbonation (MCC) were designed to transform IBA into a suitable replacement binder for cement. Initially, MCA was utilized to enhance the pozzolanic reactivity of the IBA structure, increase its specific surface area, and form unique physicochemical properties. Secondly, Mechanochemical Carbonation was also performed to maximize CO_2 sequestration and solidify the structure, encapsulating both heavy metal ions and metallic aluminum. This research thoroughly examines the effects of MCA and MCC on IBA by evaluating chemical and bond structure changes using XRD and TGA analysis. Moreover, the influence of MCC and MCA on pozzolanic

characteristics will be investigated using the R3 bound water test. Based on the R3 bound water test, activated bottom ash with the highest bound water will be used to determine the compressive strength values of mortar by replacing 30% of the cement with treated IBA.

Keywords: MSW incineration bottom ash, Mechanochemical activation, Mechanochemical carbonation, R³ test

1 Introduction

In recent years, Municipal Solid Waste (MSW) has drastically grown due to the worldwide population rise and urbanization. It is now created at a rate of 2 billion tonnes per year, with projections estimating that this value would rise to 3.40 billion tonnes by 2050 (Kaza, Yao, Bhada-Tata, & Van Woerden, 2018; Valavanidis, 2023). It is estimated that 33% of MSW is not being treated in an ecologically acceptable way, frequently ending up in open landfills or being directly burnt, resulting in air, water, and land pollution and considerably contributing to greenhouse gas emissions. (Koliyabandara et al., 2024; Sharma & Jain, 2020). Traditional landfilling is becoming insufficient to handle the growing waste volume, and it also carries significant environmental risks such as methane emissions and leachate formation. (Nanda & Berruti, 2021). From an economic perspective, landfill costs are steadily rising, especially in European countries. In the United Kingdom, the standard landfill tax will increase to £130.75 per ton by April 2026, making alternative waste management methods necessary. (Government, 2025 ; Wang et al., 2023).

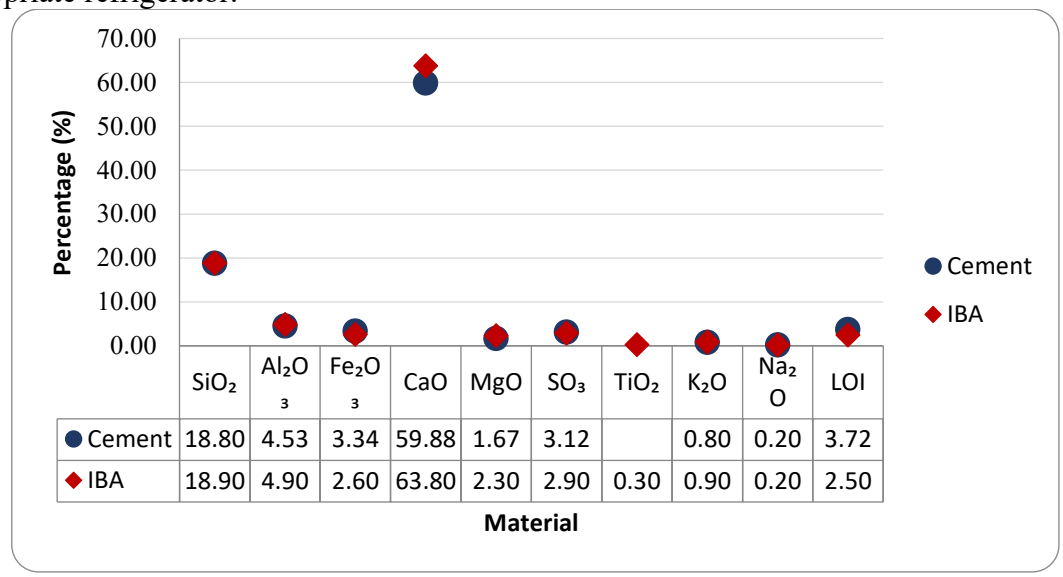
In this regard, waste-to-energy (WtE) incineration facilities play a crucial role in sustainable waste management by burning MSW at temperatures between 700 and 1000°C, reducing waste volume by 80–95% and mass by 70–80 % (Khan et al., 2022; Xuan, Tang, & Poon, 2018). The recovered thermal energy is utilized to generate electricity from renewable resources, lessening reliance on traditional fossil fuels. (Kaur, Bharti, & Sharma, 2023; Lombardi & Castaldi, 2024).

Despite the waste-reducing benefits of WtE incineration plants, the process generates three main types of solid residues: boiler fly ash, air pollution control (APC) residues, and incineration bottom ash (IBA) (He & Kasina, 2023; Nguyen et al., 2023). Among these residues, IBA is the most abundant byproduct, accounting for roughly 80-90 percent of the total residues produced (Govindan & Kumar, 2025; Wehrung et al., 2025). Considering that about 0.2-0.3 tons of IBA is generated per ton of waste incinerated, Istanbul's facility alone produces approximately 525,000 tons of IBA annually. Therefore, the sustainability of WtE technology largely depends on the safe and efficient management of this ash.

IBA is a highly heterogeneous, porous, and granular substance mostly made up of slag, glass, ceramics, ferrous and nonferrous metals, and unburnt organic compounds (Magnuson et al., 2023). The fine IBA fraction, particularly particles below 2 mm, contains more heavy metals and metallic aluminum than the coarser fraction, limiting its direct use as a construction material. Fine IBA particles have naturally high porosity and water absorption capacity (averaging around 9.7%), requiring more water when combined with cement, affecting workability and hydration products, resulting in a slowdown of the hydration process (Lynn, Obe, & Ghataora, 2016; Tang, Xuan, Poon, & Tsang, 2019). A further disadvantage of using bottom ash is the presence of metallic aluminum (Al) in IBA, which combines with water and hydroxyl ions in cement's highly alkaline environment, releasing hydrogen gas. This reaction causes expansion, swelling, and internal cracking in the mortar or concrete during setting,

severely damaging the structural integrity of the material (Chen et al., 2024; Saffarzadeh, Arumugam, & Shimaoka, 2016).

To address these problems, researchers have developed various pre-treatment methods. Previous research has demonstrated that natural weathering over a period of 90 days reduced the leaching of hazardous heavy metals by stabilizing the IBA pH and reducing the solubility of metal hydroxides (Chimenos et al., 2000). On the contrary, washing is effective at removing soluble chlorides and sulfates but is insufficient for heavy metal immobilization and generates wastewater that requires further treatment (Sun & Yi, 2020). Thermal treatment can oxidize metallic Al and remove organic residues, but it is energy-intensive and may cause particle sintering, reducing reactivity (Chai et al., 2025).



One of the most effective ways to improve the properties of IBA is using accelerated dry carbonation. In this process, IBA is exposed to CO_2 gas under controlled conditions to convert calcium oxide and hydroxide into calcium carbonate ($CaCO_3$). The carbonate minerals formed can physically encapsulate heavy metals and consume free lime, reducing expansion potential. CO_2 uptake ranging from 3% to 14% by weight through dry carbonation, with fine-grained IBA showing higher uptake capacity compared to coarse fractions, has also been reported (Sun, Xu, & Yi, 2024). Research indicates that carbonation generally reduces the leaching of Pb, Zn, and Cu, but results for Cr and Cd are contradictory; some studies report decreased leachability, while others report increases (Sun et al., 2024). Importantly, dry carbonation is primarily a stabilization technique; while it reduces environmental risk, it shows limited effects on the pozzolanic reactivity of the IBA or increases its value as a cement additive. Using treated IBA in concrete, even at replacement rates up to 20%, leads to a noticeable decrease in compressive strength, which has also been reported in a study (Low Shi Li, 2025). However, in accelerated carbonation, an increase in 10-20% compressive strength has been observed, with a 15% replacement of cement(Fan, Cai, Wang, & Liu, 2025). While accelerated carbonation has shown improvement in strength at lower replacement levels, more effective treatment methods are necessary to fully unlock the potential of IBA as a high-performance cement replacement.

On the contrary, MCA has been shown to significantly increase the pozzolanic reactivity of bottom ash (BA). It is observed that combining MCA with diethanol isopropanolamine (DEIPA) increased hydration and induced pozzolanic reactions, resulting in a strength gain of over 20% at 25% BA replacement(Kang, Yang, Kim, Lim, & Moon, 2024). The ball milling combined with $Ca(OH)_2$ treatment enhances early hydration and produces a compact matrix, outperforming milling alone, as reported in a study(Zhu et al., 2026). These findings clearly support using MCA to release the latent reactivity of bottom ash as a high-performance SCM.
While existing approaches generally focus on stabilizing the waste, there is a lack of an integrated method that simultaneously activates the material's pozzolanic reactivity to improve its performance, reliably immobilizes a broad spectrum of heavy metals, and maximizes CO_2 uptake. To address these limitations, two separate treatment methods with varying parameters are explored. The first is Mechanochemical Activation (MCA), where, with the help of a high-energy ball mill, the crystalline structure of IBA particles will be amorphized, producing unique physicochemical properties and creating new reactive surfaces. Secondly, mechanochemical carbonation (MCC) will be performed, where the material will be exposed to CO_2 under controlled moisture conditions. Unlike dry carbonation, the wet environment increases the solubility of CO_2, accelerating reaction kinetics and promoting the formation of a denser carbonate network. The calcium carbonate ($CaCO_3$) phases formed will fill the porous structure of IBA, densifying the microstructure and physically and chemically encapsulating heavy metals, ensuring environmental safety. This process also directly contributes to carbon capture and utilization (CCU) technology, transforming waste material into a carbon sink.

2 Materials and Methods

2.1 Materials

In the experimental study, IBA was collected from the Istanbul waste-to-energy facility in both fine and coarse fractions, but only the fine fraction was used for further research. The chemical composition of Fine IBA was determined using XRF and is shown in Table 1. XRF data show a significant amount of silica, calcium, alumina, and iron oxide, which is comparable to cement raw material and shows the basic chemical composition to function as a supplementary cementitious material. A cement of type CEM II/B-M (P-L) 42.5 R was used and obtained from the Çimsa Plant (Mersin, Turkey), and the XRF results are given in Table 1. For Mechanochemical Carbonation, dry ice as a source of CO2 was obtained and stored in an appropriate refrigerator.

	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	TiO_2	K_2O	Na_2O	LOI
Cement	18.80	4.53	3.34	59.88	1.67	3.12		0.80	0.20	3.72
IBA	18.90	4.90	2.60	63.80	2.30	2.90	0.30	0.90	0.20	2.50

Figure 1. Chemical composition of materials

2.2 Mix Design

The experimental investigation was planned to develop a total of seven MCA mixes with varying charge ratios, speeds (rpm), and times. A total of 13 MCC mixes were created with different charge ratios, speeds, times, water/material ratios, and dry ice.

2.3. Methods

The methodology for the study was separated into five major sections. The first stage was the process of treating IBA with MCA and MCC procedures in a Retsch PM 100 planetary ball mill equipped with a 125 mL jar. Also, as a reference treatment procedure, an accelerated carbonation test on untreated IBA was performed in a controlled-environment carbonation chamber. The chamber maintained a constant temperature of 23°C, relative humidity of 65%, and CO_2 concentration of 20% (v/v) throughout the process. In the second stage, an X-ray diffraction (XRD) test was performed to identify crystalline phases and assess the degree of amorphization and carbonation caused by MCA and MCC. Thermogravimetric analysis (TGA) was also performed to evaluate CO_2 uptake by measuring mass loss during carbonate decomposition. Following this, the pozzolanic reactivity of treated IBA samples was evaluated using the R^3 test (rapid, relevant, and reliable) according to ASTM C1897. Finally, utilizing the

R3 test data, the best-performing MCA-treated and MCC-treated IBA samples will be chosen to determine the compressive strength of mortar containing 30% treated IBA.

3 Results and Discussions

3.1 Pozzolanic Reactivity:

Table 1

Mix	Bound Water (%)
Untreated IBA	2.79
MCA-10-500-60	11.56
MCC-18-500-10-D5-W150	9.62

The R3 results in Table 2 indicate that untreated IBA had very low pozzolanic reactivity, with a bound water content of 2.79 percent. However, the MCC-treated IBA showed an increase in water bounding of 11.56%, indicating a significant increase in reactivity due to amorphization of the crystalline structures and physicochemical alterations. The MCC-treated IBA samples had a water content of 9.62%, which showed that the combined action of carbonate formation and particle refinement increased reactivity. The lower reactivity of MCC compared to MCA was due to the formation of a dense carbonate layer, which limits access to some reactive sites.

3.2 Compressive Strength Results:

The compressive strength of the reference mortar sample was 41.83 MPa; however, when 20% of the cement is substituted with untreated IBA, the compressive strength lowers to 23.18 MPa, representing a 44.57% reduction. While the MCC-treated IBA showed a compressive strength of 21.35 MPa, it decreased further and was 7.8% lower than the untreated IBA mix. The decrease in compressive strength values was caused by increasing the reactivity of metallic aluminum by exposing fresh surfaces, resulting in increased formation of hydrogen gas. This produces hydrogen gas, resulting in swelling and microcracking in the mix, as seen in the figure.

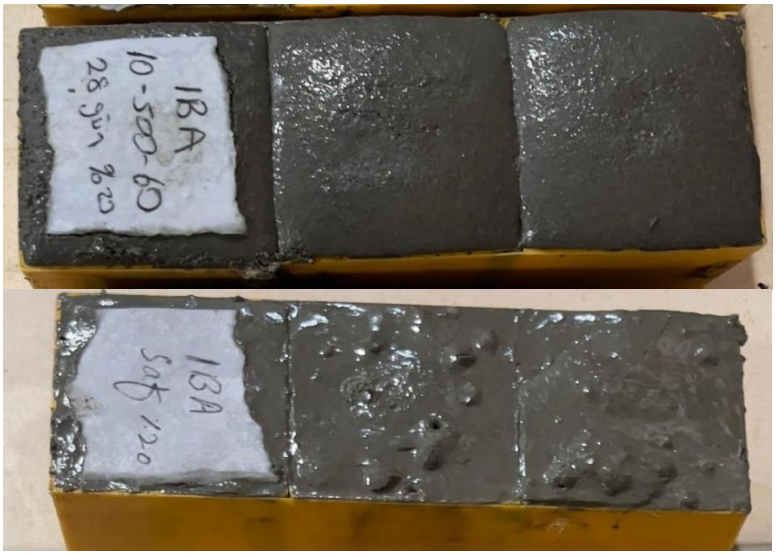


Figure 2. Untreated and MCC-treated IBA mortar Mix.

In contrast, the MCC sample demonstrated an increase in compressive strength values when compared to the mortar mix replaced with 30% IBA in cement. The MCC mix with a charge ratio of 18, milling speed of 500 rpm, dry ice as a CO2 source of 5g, and water content of 150

g for a period of 10 minutes showed a compressive strength of 22.35 MPa, which was higher than both the untreated and MCA-treated mixes. MCC not only densifies the microstructure by creating CaCO3, but it also passivates the metallic aluminum by encapsulating it in carbonate mixes. These dual advantages of the MCC mix decreased the possibility of hydrogen gas formation while also boosting the density and strength of the mix.

Table 2. Mix designs produced in the experimental study.

Mix	Compressive Strength-28 days (MPa)	Relative to Reference
Reference	41.83	-
Untreated IBA (20%)	23.18	-44.57
MCA-10-500-60	21.35	-7.8
Untreated IBA (30%)	21.48	-48.64
MCC-18-500-10-D5-W150*	22.35	+4.05 (w.r.t. untreated)

**18 (Charge ratio), 500 (Rpm), 10 (minutes), D5 (5g dry ice), W150 (150g water)*

3.3 XRD Analysis:

The mineralogical composition of IBA samples was determined using XRD, and the results are displayed in Figure X. The principal crystalline phases discovered are quartz (Q), calcite (C), albite (A), and dolomite. The XRD results of untreated IBA show portlandite (CH) and hydrocaluminate (HC), which are mainly calcium hydroxide and a layered mineral. However, considerable changes were observed in MCC-treated IBA, where the CH and HC peaks totally disappeared while the calcite peaks increased in size, due to carbonation.

$Ca(OH)2 + CO2 \rightarrow CaCO3 + H2O$ ……(1)

The physical influence of the "Mechano" part of the MCC can be seen, particularly between 20 and 35 2 theta, where the curve seems bumpier, indicating amorphous content. This is because high-energy milling broke down the perfect crystalline structures, allowing Co2 to enter and react. For example, the albite crystal peak between 26 and 28 2 theta vanishes completely. This is because albite is a soft mineral, and high-energy milling destroys the crystal structure.

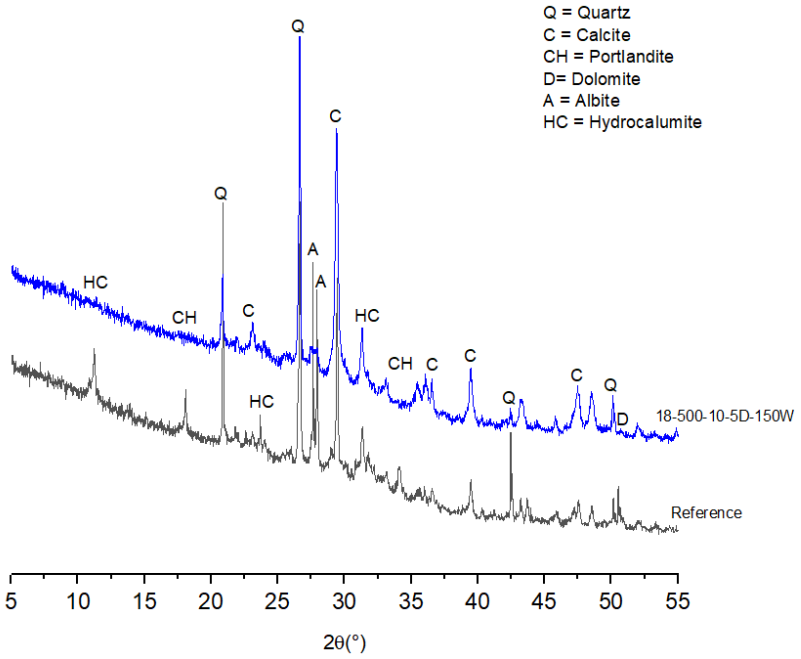

Figure 3. XRD Results of raw and MCC-treated IBA.

Figure 2 shows the XRD patterns for raw IBA and MCA-activated IBA samples of 10-500-60. Clear peaks of Quartz (Q), A (Albite), Calcite (C), and Portlandite (CH) can be observed. Significant shifts can be noticed between 15 and 35 C (°), where the amorphization increased significantly. Furthermore, peaks for portlandite and hydrocalumite completely disappear in MCA-activated samples, implying that the hydrated phases are more susceptible to MCA and are totally transformed into amorphous structures. Following this, the Quartz peak at 26.6 2θ (°) is still evident due to its great hardness and resistance to amorphization. The smaller quartz peaks and albite have either broadened or gone completely into the amorphous background, indicating a loss in crystalline structures and partial structural breakdown**.**

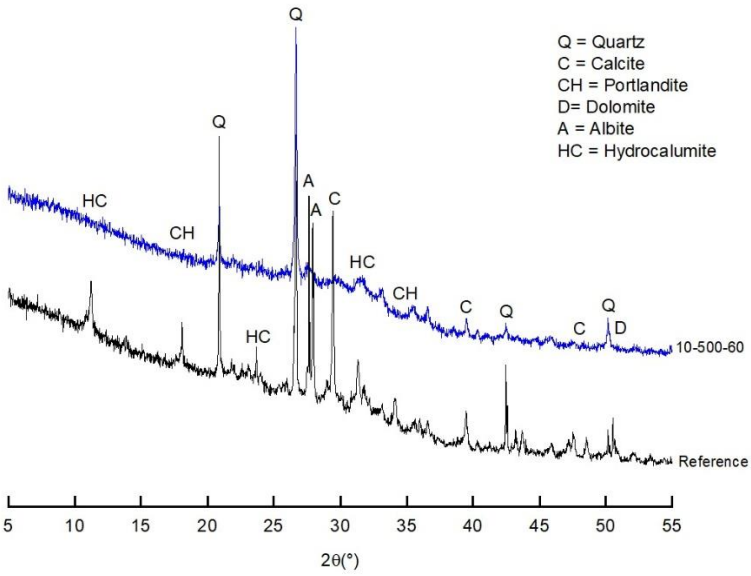

Figure 4. XRD Results of raw and MCA-treated IBA.

3.4 Thermogravimetric Analysis (TGA):

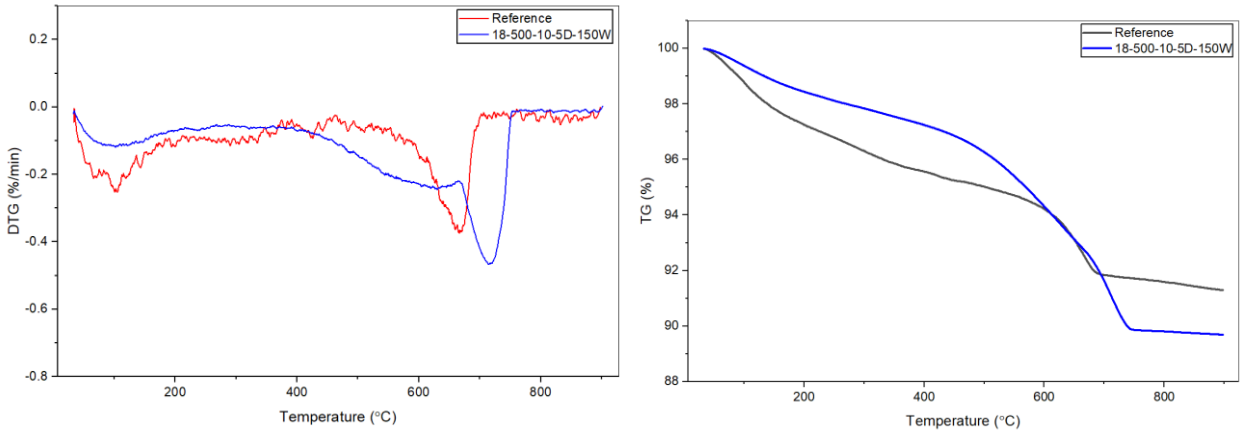

Figure 5. TGA Results of raw and MCC-treated IBA.

Figure 4 shows the thermogravimetric (TG) and derivative thermogravimetric (DTG) profiles of raw IBA and MCC-treated IBA (18-500-10-5D-150W). The DTG curve for raw IBA between 0 and 200 °C reveals a minor peak indicating free moisture evaporation. While the MCC-treated IBA had a much lower peak between 0 and 200 °C, this indicates that the high energy-intensive milling generated sufficient heat to evaporate the water in the IBA. A significant difference between raw and MCC-treated IBA was observed between 600 and 750

°C. First, a peak shifted from approximately 660-680 °C to approximately 700-720 °C from raw to MCC-treated IBA, and second, the MCC-treated IBA's peak became much stronger, showing -0.47%/min while the raw peak shows -0.37%/min. These significant alterations in MCC-treated samples are due to the enhanced reactivity of Ca-bearing phases, which favors the production of $CaCO_3$. As a result, the carbonated IBA exhibits a high DTG peak, which is due to the thermal breakdown of $CaCO_3$ with the emission of CO_2. The TG graphs also show that the carbonated IBA has a sharper TG drop and substantially higher mass loss, particularly at high temperatures, with an 18.5% increase relative to the raw sample. The CO_2 absorption of raw and carbonated IBA was determined from the carbonated-associated mass loss in the TG curve, which was 34.36 and 74.816 g CO_2 per kg IBA, respectively, with a percentage increase of 117.63%.

Table 3. Comparison of CO_2 Uptake (Dry Carbonation vs. MCC treated Samples)

Treatment Method	Processing Time	CO_2 Uptake (g CO_2 / kg IBA)	Relative Efficiency
Dry Carbonation (Reference)	7 days	36	1 x (Baseline)
MCA-10-500-60	10 minutes	74.8	~2× higher

Compared to the dry carbonation results, which exhibit a maximum of 36.0 g/kg after 7 days, the MCC-treated IBA displays a significantly higher carbon capture capacity, showing 74.8 g/kg. This Co2 uptake occurs in under 10 minutes, which is approximately twice the amount of C2 acquired by dry carbonation over a full week.

4 Conclusions

The main findings obtained within the scope of the experimental study are summarized below.

- The R3 water-bound test confirmed an increase in pozzolanic reactivity in both MCC and MCA-treated samples, with MCA exhibiting the highest reactivity due to amorphization and particle refining.
- MCA-treated samples showed a higher water bounding percentage, but lower compressive strength compared to MCC samples due to increased metallic aluminum reactivity. Unlike untreated and MCA-treated mixes, MCC-treated samples perform better overall due to metallic aluminum passivation and microstructural densification.
- MCC treatments caused a dense carbonate network, as proven by XRD and TGA graphs. Additionally, XRD data revealed amorphization of crystalline material due to MCA.

Increasing the Reactivity of Natural Pozzolans in Cementitious Systems

Sevgi Özen
0000-0002-5699-3000, Recep Tayyip Erdoğan University, Geological Engineering Department, Rize, Türkiye, sevgi.ozen@erdogan.edu.tr

Abstract. Clinker production at high temperatures (approximately 1430ºC) for cement manufacturing is associated with substantial CO_2 emissions, which requires the development of alternative binder cement systems. In this context, extensive scientific research has focused on blended cements incorporating natural pozzolans as supplementary cementitious materials, due to their widespread availability in nature. Although natural pozzolans contribute to sufficient long-term mechanical development and durability with pozzolanic reactions, their low early-age strength development often limits their replacement levels for cementitious systems. In order to overcome this limitation many activation techniques have been investigated to enhance the reactivity of pozzolanic materials. Among these, calcination is one of the most effective techniques. Calcination significantly improves the chemical reactivity of pozzolans by increasing their amorphous phase content and modifying their mineralogical structure, thus promoting more efficient pozzolanic reactions. As a result, higher replacement levels can be made without decreasing mechanical performance and durability. In this regard, the use of calcined pozzolans in blended cements is considered a promising strategy for reducing clinker content and associated carbon emissions, while maintaining performance characteristics. Furthermore, this approach supports current sustainability goals in the cement industry by enabling the development of low-carbon cement systems.

Keywords: Pozzolan; Calcination; Blended cement; CO_2 emissions.

1 Introduction

Cement production is associated with substantial carbon emissions. Although blended cements provide an effective approach to reducing these emissions, the limited availability of conventional supplementary cementitious materials, such as fly ash and blast-furnace slag, has increased the need for alternative natural pozzolanic resources. In this context, natural pozzolans, zeolites or clay minerals, which are widely available in Türkiye, represent a promising alternative source of natural raw materials. In recent years, limestone calcined clay cement (LC3) has emerged as a low-carbon cement system capable of reducing the clinker content to approximately 50% while achieving mechanical performance comparable to that of conventional cement. Owing to its high clinker replacement level, LC3 can reduce associated CO_2 emissions by up to approximately 30%. In Türkiye, particularly in western Anatolia, the utilization of widely available clay deposits is therefore of considerable importance, both for reducing carbon emissions and for promoting the value-added use of domestic clay resources.

The literature indicates that LC3 cements can significantly reduce carbon emissions and therefore represent a promising alternative to conventional Portland cement [1]. Nevertheless, several challenges associated with the incorporation of calcined clays into cementitious systems have been reported, including increased water demand, reduced workability, and, under certain conditions, lower early-age strength. For instance, Scrivener et al. (2019) reported that the high

specific surface area of calcined clay minerals adversely affects the workability of LC3 systems, thereby increasing the demand for chemical admixtures to achieve a comparable level of flowability [2]. Furthermore, the mineralogical, chemical, and physical characteristics of natural clay resources can vary considerably depending on their geological origin. Such variations directly influence the optimum calcination temperature and, consequently, the reactivity and mechanical performance of calcined clays obtained from different sources. Previous studies have demonstrated that the performance of LC3 cements is strongly governed by several clay-related parameters, including clay content, mineralogical composition, specific surface area, particle size and morphology, as well as the calcination conditions applied.

Similar considerations also apply to natural zeolites. Although the use of natural zeolites in construction materials dates back many years, they have not yet achieved widespread acceptance as commercially established supplementary cementitious materials. One of the major factors limiting their broader utilization in cementitious systems is their relatively low early-age strength development. As the clinker content of cement is reduced and replaced by a natural pozzolan, such as natural zeolite, the dilution of the highly reactive clinker phases, combined with the relatively slow pozzolanic reaction of natural zeolite at early ages, may result in insufficient early-age strength development. Although numerous studies have attempted to overcome this limitation through different activation and modification approaches, the development of cementitious systems containing high proportions of natural zeolite remains challenging. In particular, cement products incorporating natural zeolite at replacement levels as high as approximately 50% have not yet become widely available on the commercial market. Therefore, enhancing the early-age reactivity and mechanical performance of natural zeolite is essential for enabling its use at substantially higher clinker replacement levels and for developing low-carbon cementitious systems with performance comparable to conventional Portland cement.

To overcome these challenges and improve the performance of cementitious systems containing natural pozzolans, various activation methods have been investigated to enhance their pozzolanic reactivity. These methods mainly include mechanical, chemical, and thermal activation techniques, which aim to modify the physical, chemical, and mineralogical characteristics of natural pozzolans.

2 Activation Methods

2.1 Mechanical Activation

Mechanical activation is one of the commonly applied methods for enhancing the pozzolanic reactivity of natural pozzolans. This technique is generally based on intensive grinding, which reduces particle size and increases the specific surface area of the pozzolanic material, thereby providing a larger reactive surface for interaction with hydration products in cementitious systems [3]. In addition to particle size reduction, prolonged or high-energy grinding may induce structural disorder and physicochemical changes in mineral phases, which can further enhance their reactivity. Consequently, mechanical activation can accelerate pozzolanic reactions and improve the contribution of natural pozzolans to strength development, particularly when their initial reactivity is relatively low [4]. Korkmaz and Kayıran (2022) demonstrated that mechanical activation significantly influenced the performance of high-volume natural pozzolanic cements, with grinding conditions playing an important role in the resulting pozzolanic activity and mechanical properties [5]. Similarly, recent studies on natural volcanic materials have shown that mechanical activation can enhance their pozzolanic activity and improve their suitability as supplementary cementitious materials [6]. However, the effectiveness of mechanical activation depends strongly on the mineralogical and physical characteristics of the pozzolan as well as the grinding conditions. Moreover, excessive grinding

may increase energy consumption without providing a proportional improvement in performance. Therefore, optimization of grinding time, particle size distribution, and specific surface area is essential for achieving an appropriate balance between enhanced pozzolanic reactivity and the energy demand associated with mechanical activation.

2.2 Chemical Activation

Chemical activation is another approach used to enhance the reactivity of natural pozzolans and to overcome their relatively slow reaction kinetics at early ages. In this method, chemical activators are introduced into the cementitious system to accelerate the dissolution of reactive silica and alumina species and promote the formation of hydration products. Various compounds, particularly alkali and salt-based activators, have been investigated for this purpose. Shi and Day (2001), for example, investigated the chemical activation of a natural pozzolan using Na_2SO_4 and $CaCl_2$ and compared its effectiveness with mechanical and thermal activation methods [7]. Their results showed that chemical activation considerably accelerated the pozzolanic reaction and improved early-age strength development, although the effectiveness strongly depended on the type and dosage of the activator. The enhancement in reactivity is generally associated with changes in the chemical environment of the pore solution, which can facilitate the dissolution of reactive Si and Al species from the pozzolan and accelerate their subsequent reactions with available calcium species. Accordingly, chemical activation can provide an effective strategy for improving the performance of cementitious systems containing relatively high amounts of low-reactivity pozzolanic materials. However, the selection and dosage of chemical activators must be carefully optimized, since their effectiveness depends on the chemical and mineralogical characteristics of the pozzolan, while excessive addition may adversely affect hydration, setting behavior, durability, or the overall environmental benefits of clinker replacement. Therefore, chemical activation should be designed specifically according to the characteristics of the natural pozzolan and the targeted performance of the cementitious system.

2.3 Thermal Activation

Among the activation methods used to enhance the pozzolanic reactivity of natural pozzolans, thermal activation has received considerable attention due to its ability to directly modify the mineralogical and structural characteristics of the material. Unlike mechanical activation, which primarily modifies the physical characteristics of pozzolans, or chemical activation, which promotes their reaction through the addition of external activators, thermal activation can induce fundamental changes in the crystalline structure of natural pozzolans. When exposed to an appropriate temperature range, thermally induced structural transformations may decrease crystallinity and increase the availability of reactive silica and alumina species, thereby enhancing their participation in pozzolanic reactions. The effectiveness of this process, however, strongly depends on the mineralogical composition of the raw material and the applied calcination conditions, particularly temperature and duration. Therefore, understanding and controlling the structural transformations occurring during calcination is essential for converting relatively low-reactivity natural pozzolans into more reactive supplementary cementitious materials.

One of the key characteristics that should be modified to improve the suitability of natural pozzolans for cement production is their long-range ordered crystalline structure. Due to this structural arrangement, the silica- and alumina-bearing phases present in natural pozzolans may require a relatively long period to dissolve and subsequently participate in pozzolanic reactions. This relatively slow reaction kinetics can contribute to limited strength development at early ages. Therefore, enhancing the early-age reactivity of natural pozzolans requires modification of their crystalline structure into a more disordered and reactive state. Calcination is one of the

most effective approaches for inducing such structural transformations. Through appropriate calcination, the degree of structural order can be reduced and the availability of reactive aluminosilicate species can be increased, thereby accelerating pozzolanic reactions and potentially mitigating the low early-age strength associated with the use of untreated natural pozzolans.

The use of calcined natural pozzolans is also recognized within the EN 197-1 cement classification framework, in which the designation “Q” refers to natural calcined pozzolans used as cement constituents, including in composite cement systems such as CEM V. Several studies have investigated the thermal activation of natural pozzolans and demonstrated that appropriate calcination can significantly modify their mineralogical characteristics and enhance their pozzolanic performance [8-9]. Accordingly, calcination represents a promising strategy for improving the reactivity of natural pozzolans and facilitating their use at higher replacement levels in low-clinker cementitious systems.

3 Results

The reviewed literature demonstrates that the relatively low early-age reactivity of natural pozzolans can be improved through mechanical, chemical, and thermal activation. Mechanical activation mainly enhances reactivity by reducing particle size and increasing the available surface area, whereas chemical activation accelerates the dissolution of reactive silica and alumina species by modifying the chemical environment of the system. However, the effectiveness of these methods strongly depends on the mineralogical and physical characteristics of the natural pozzolan as well as the applied activation conditions. Therefore, optimization of the activation process is essential for improving pozzolanic reactivity and enabling higher clinker replacement levels without compromising cement performance. Chemical activation, on the other hand, modifies the reaction environment and can accelerate the dissolution of reactive silica and alumina species. The addition of suitable chemical activators can therefore promote pozzolanic reactions and improve early-age performance. However, the effectiveness of chemical activation is highly dependent on the type and dosage of the activator and the mineralogical and chemical composition of the pozzolan. Among these approaches, thermal activation by calcination is particularly promising because it can directly modify the crystalline structure of natural pozzolans. Appropriate calcination can decrease structural order and increase the availability of reactive aluminosilicate species, thereby accelerating pozzolanic reactions and improving their contribution to strength development. Furthermore, an optimum calcination condition should be determined for each natural pozzolan to maximize its reactivity and facilitate its use as a supplementary cementitious material in low-clinker cement systems.

4 Conclutions

- Mechanical, chemical, and thermal activation methods can enhance the pozzolanic reactivity of natural pozzolans and contribute to overcoming their relatively low early-age reactivity.
- The effectiveness of activation strongly depends on the mineralogical, chemical, and physical characteristics of the natural pozzolan. Therefore, activation conditions should be optimized according to the specific raw material.
- Thermal activation through calcination is particularly promising because it can modify the crystalline structure of natural pozzolans and increase the availability of reactive aluminosilicate species. However, an optimum calcination temperature and duration should be determined for each pozzolan.

- The effective activation of locally available natural pozzolans can enable higher clinker replacement levels, thereby reducing clinker consumption and associated CO_2 emissions and contributing to the development of more sustainable low-carbon cement systems.

Abstract. One of the most common problems encountered in retaining structures is excessive deformation or more severe cases, structural failure due to inadequate drainage conditions. Such issues not only cause economic losses but can also lead to injuries and fatal accidents. Therefore, to improve the performance of existing retaining structures and alleviate these problems, engineering solutions must be developed to safely drain water accumulated behind the structure. In this context, drainage holes known as “weep holes” are created in the retaining structure to prevent the buildup of hydrostatic water pressures. However, the backfill material behind these holes and walls often lacks adequate filtering properties in practical applications, leading to the transport of fine particles. Additionally, due to external factors, the drainage holes might become clogged over time and cease to function, preventing the retaining structure from consistently providing the expected drainage performance. In this study, a contemporary weep hole model was created that can demonstrate active performance for a much longer period than the traditional solutions for solving inadequate drainage conditions in retaining structures, and a comparison was made between the two.

Within the scope of this study, wall models were created using the PLAXIS 3D software. In addition to the traditional weep hole model, a contemporary weep hole that increases total surface area for the drainage of water by penetrating the soil inside the wall was used. The drainage performance of truncated square pyramid (contemporary weep hole model) and traditional weep holes with varying diameters of 5, 10, and 15 cm were examined with finite element modelling analysis of the flow conditions. Since the models were intended solely to examine the drainage of the water behind the wall, the stresses caused by water and the soil were ignored, and only the permeability effects were examined by assigning different permeability coefficients to differentiate the soils. Furthermore, the effect of various rainfall intensities on the drainage volume were also investigated within the models. Since drainage in low-permeability soils is controlled by the soil’s permeability, the effect of rainfall intensity was not examined. However, because drainage occurs rapidly in high-permeability soil conditions, the effects of rainfall intensity were also examined.

1 Introduction

The strength and service life of many structures depend on the effective removal of water from above-ground and below-ground structural elements. Exposure of building materials to water causes degradation of their engineering properties and performance loss over time. The failure to provide the material parameters specified or calculated during the design phase is among the most significant consequences of these effects. For this reason, the proper design of drainage systems is of critical importance in all structural designs. Inadequate drainage practices are one of the most common causes of poor performance observed in retaining structures. If this issue is not dealt with using the necessary engineering approach, problems that directly reduce the life of the structure and require costly remediation solutions are inevitable. One of the methods commonly used to improve drainage performance in retaining structures is the application of weep holes (drains) that reduce hydrostatic pressure by providing controlled water discharge along the wall surface. Saturation of the backfill material, however, can cause a significant increase in active lateral earth pressures behind the retaining structure. For these reasons, a new generation weep hole type was modeled that penetrates the backfill behind the retaining wall and has a larger surface area than a conventional one. The performance differences between these two types were compared using numerical analyses.

2 Model Design

The model dimensions consist of a wall 1 meter high and wide, with a depth of 1 meter extending backward. The weep hole was placed 20 cm above the lower elevation of the simulated box shaped wall backfill (**Fig.1.**). The study aimed to examine the effect of varying drainage diameters by testing weep holes with diameters of 5, 10, and 15 cm. The dimensions and schematic of varying weep holes are given **Fig.2.** and **Table 1.** The effect of permeability was examined using different types of soil in the backfill, and the impact of varying rainfall intensities (5 mm/hour, 10 mm/hour, and 20 mm/hour) on drainage performance were analyzed.

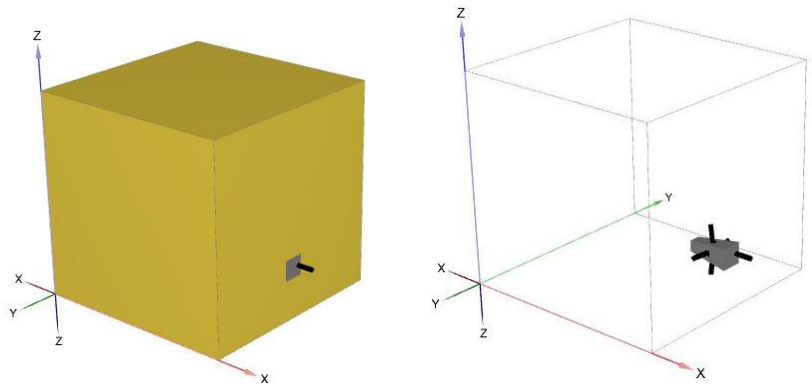

Fig. 1. Model View

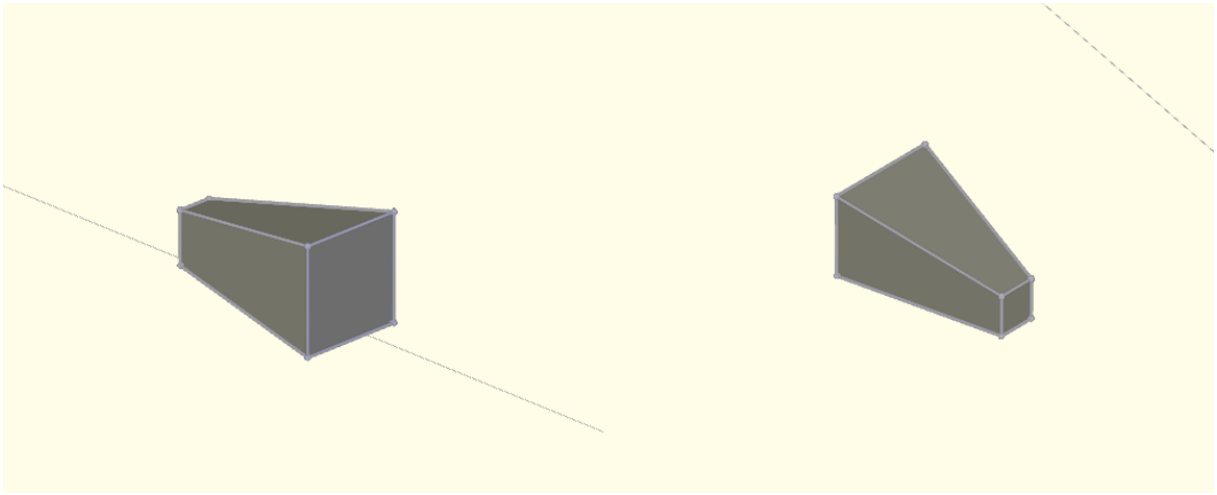

Figure 2. Truncated Square Pyramid Weep Hole View

Table 1. Weep Hole Dimensions

Diameter (cm)	Front Face (cm)	Back Face (cm)	Length (cm)
Q5	5	2.5	8
Q10	10	5	17
Q15	15	7.5	25

Four different soil types were considered in order to evaluate how flow behavior varies depending on the fill material used. The study examined sand–gravel, silty sand, silty clay, and graywack based fill materials, which are widely preferred in the field due to their ease of application. The permeability coefficients for these soils were taken as 1×10^{-2} cm/s, 5×10^{-5} cm/s, 1×10^{-8} cm/s, and 1×10^{-6} cm/s, respectively, in accordance with the literature and engineering standards [3].

The permeability value specified for the gravel material was selected based on the assumption that, following excavation and placement, the material will break down and take on the characteristics of a fine-grained fraction, rather than on its behavior in the natural rock environment. In other words, it was assumed that the hydraulic behavior of the graywack material used as fill is controlled primarily by the properties of the fine-grained matrix rather than by the properties of the intact rock.

In the analyses, a rainfall intensity of 5 mm/hour, representing average conditions, was used as the rainfall input; the relevant reference values are provided in **Table 2**. In the modeling, all boundaries except for the weep holes were assumed to be impermeable, and rainfall effects were defined only from the top surface of the system. The primary objective of this approach is to evaluate the drainage behavior within the system solely based on the performance of the weep holes. In addition, the experimental scenarios developed to examine the effect of rainfall intensity on system behavior were reanalyzed for rainfall conditions of 10 mm/hour and 20 mm/hour, and the results were presented in a comparative manner in the report.

As part of the numerical analysis studies, drainage performance was observed based on hydrostatic pressure data behind a fictitious wall with different soil types, by continuously applying different rainfall intensities to the model over a 30 day period. For highly permeable material (sand-gravel), rainfall was applied directly to the dry soil model. In models with materials of lower permeability, the rainfall could not reach the weep hole level from the top of the model within 30 days; therefore, the material was assumed to be fully saturated to prevent the model solution times from becoming excessively long. The groundwater level was set at the upper part of the soil elevation in the model and left to drain freely without applying rainfall.

Therefore, while the effects of rainfall intensity and weep hole diameter variation were examined in the highly permeable sand-gravel material, the effect of diameter variation was examined in the remaining soil models with relatively lower permeability. In addition, to evaluate the time-dependent effects of the drainage process in low-permeability soil models, models of silty sand, graywack and silty clay were allowed to settle under free drainage conditions for 10, 20, and 30 days, respectively; the hydrostatic pressure distributions and changes behind the wall were examined at the end of each period.

Table 2. Rainfall Intensity Classification [5]

Hourly Rainfall Intensity (mm/hour)	Intensity Class
<4	Light to Moderate Rain
4-10	Heavy Rain
10-50	Heavy Shower
>50	Violent Shower

3 Results and Evaluations

Numerical analyses were performed, and the results presented in **Table 3** and **Figure 3** were obtained. When the graph is evaluated as a whole, it is observed that the truncated square pyramid shaped weep hole type demonstrates more successful drainage performance behind the wall compared to the conventional weep hole across the time range under all experimental conditions. The results indicate that the truncated square pyramid shaped (New Generation) weep hole exhibits more controlled and stable performance under different diameters and rainfall intensities.

Table 3. Properties of Analysis

Analysis No.	Diameter (cm)	Soil Type	Rainfall Intensity (mm/hour)	Duration (Day)
1	5	Sand–Gravel	5	30
2	5	Sand–Gravel	10	30
3	5	Sand–Gravel	20	30
4	10	Sand–Gravel	5	30
5	10	Sand–Gravel	10	30
6	10	Sand–Gravel	20	30
7	15	Sand–Gravel	5	30
8	15	Sand–Gravel	10	30
9	15	Sand–Gravel	20	30
10	5	Silty Sand	-	30
11	10	Silty Sand	-	30
12	15	Silty Sand	-	30
13	5	Silty Clay	-	30
14	10	Silty Clay	-	30
15	15	Silty Clay	-	30
16	5	Graywack	-	30
17	10	Graywack	-	30
18	15	Graywack	-	30

In particular, for sand-gravel material, it is observed that the difference between the new type and the conventional type weep hole increases significantly as rainfall intensity rises. For example, when rainfall intensity for a 5 cm diameter increased from 5 mm/h to 20 mm/h, the hydrostatic pressure ratio behind the wall decreased from 80% to 59%. A similar trend was observed for diameters of 10 cm and 15 cm. This suggests that as rainfall intensity increases, performance loss becomes more pronounced in the conventional type weep holes, whereas the new type weep holes exhibit more stable behavior.

The results for the graywack material reveal a notable effect of diameter increase on system behavior. As the diameter increases, the advantages of the new system become more noticeable. In particular, it was observed that at a diameter of 15 cm, the hydrostatic pressure behind the wall in the new system decreased by 50% compared to the standard system, demonstrating more effective performance.

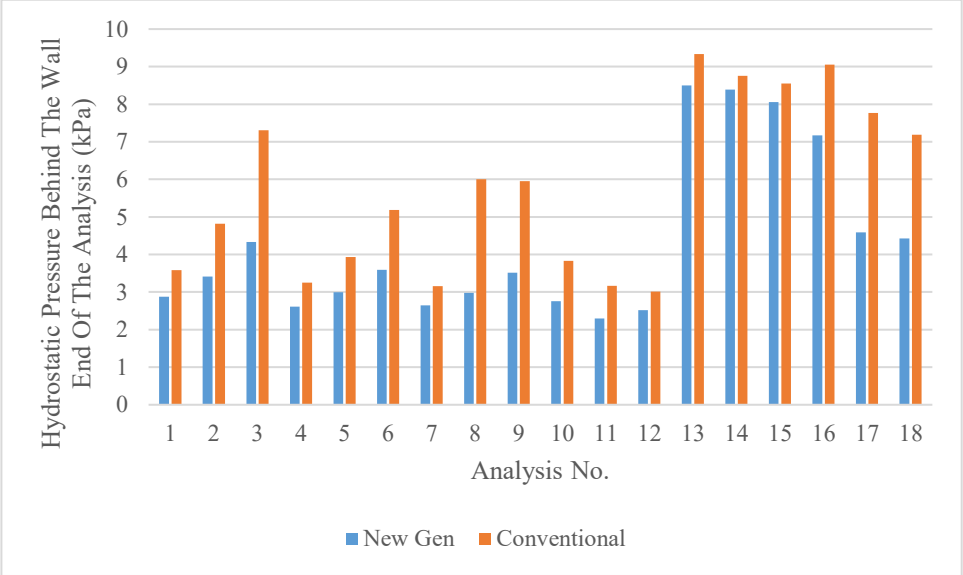

Fig. 3. Comparison of Conventional and New Generation Weep Hole Results

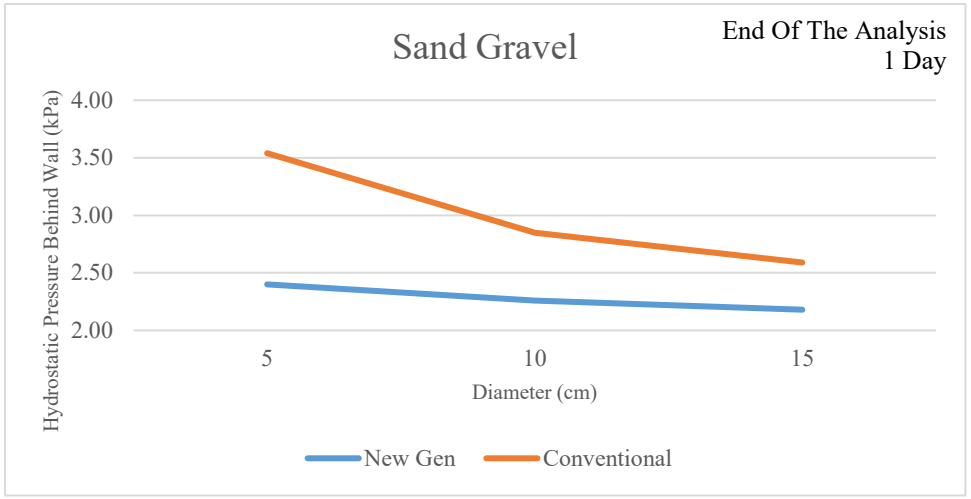
In contrast, it is observed that the two systems yield very similar results in the silty clay material with the lowest permeability. The fact that hydrostatic pressure ratios vary within the range of 90–96% indicates that both systems exhibit similar behavior under these conditions. This suggests that system performance depends not only on the type of weep hole but also on rainfall intensity and soil type. Overall, it was concluded that the new system offers superior performance, particularly under high rainfall intensity.

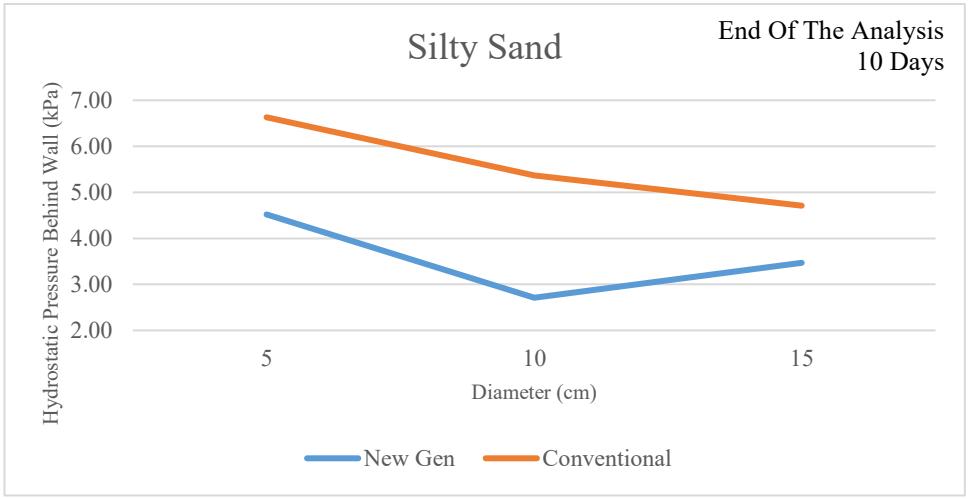
To enable a comparison of the same parameters across all soil types, the models were analyzed under free drainage conditions, without taking the effect of rainfall intensity into account. To more effectively evaluate drainage behavior based on the permeability characteristics of the soils, the analysis periods were set at 1, 10, 20, and 30 days for the sand-gravel, silty sand, graywack and silty clay models respectively, in descending order of permeability. Analyses were conducted for two different types of weep holes for each soil model, and the hydrostatic pressures behind the wall obtained at the end of the analysis periods were compared. Using the results obtained, the effects of changes in weep hole type and diameter on drainage performance were evaluated. The analysis parameters and results for each soil type are presented in **Table 4** and **Figure 4**.

Table 5 shows the pore water pressure ratio for the new generation weep hole compared to the conventional weep hole for each soil type at different diameters. For example, in the new generation 5 cm diameter weep hole model on sand-gravel material, the ratio of the pore water pressure behind the wall to the water pressure behind the wall obtained in the conventional



weep hole model is 0.678. In other words, the obtained pore water pressure in the new generation weep hole model is lower than conventional one.

Table 4. Properties of Analysis Models



Diameter (cm)	Soil Type	Weep Hole Type	Pore Water Pressure (kPa)	Duration (Day)

Figure 4. Comparison of Conventional and New Generation Weep Hole Results, (a. Sand Gravel, b. Silty Sand, c. Graywack, d. Silty Clay)

In sand-gravel soil with high permeability, it is observed that as the weep hole diameter increases, the hydrostatic pressure values behind the wall decrease in both systems. In the new gen weep holes, the hydrostatic pressure value, calculated as 2.40 kPa for a 5 cm diameter, drops to 2.18 kPa for a 15 cm diameter; in the conventional weep holes, the same values were obtained as 3.54 kPa and 2.59 kPa, respectively. The results show that drainage performance in highly permeable soils is significantly affected by the weep hole diameter and that the new generation system provides more effective drainage by producing lower hydrostatic pressure values across all diameters. However, it is observed that the performance difference between the two systems decreases as the diameter increases.

In the silty sand model, increasing the weep hole diameter from 5 cm to 10 cm in both systems resulted in significant reductions in hydrostatic pressure values. However, in the new generation system, the value of 2.71 kPa obtained at a 10 cm diameter rise to 3.47 kPa at a 15 cm diameter. Similarly, while the downward trend continued in the conventional system, the increase in performance was observed to gradually decrease. This indicates that drainage performance depends not only on the weep hole cross-sectional area but is also influenced by the flow regime within the soil and the geometric characteristics of the drainage zone. Under the conditions examined, it was determined that the 10 cm diameter weep hole in the new generation system provided the lowest hydrostatic pressure value.

The effect of changes in weep hole diameter on drainage performance was observed more clearly on the graywack. In the new generation weep holes, the hydrostatic pressure value was 7.40 kPa at a 5 cm diameter, while it decreased to 4.55 kPa at a 10 cm diameter and to 4.43 kPa at a 15 cm diameter. In the conventional system, the values obtained were 9.08 kPa, 6.89 kPa, and 7.43 kPa, respectively. In particular, it was observed that the new generation generated hydrostatic pressure approximately 40% lower than the conventional system at a 15 cm diameter. The results show that the drainage efficiency of the new gen system becomes more pronounced in soils with medium permeability and that it can provide greater benefits than an increase in diameter.

In the silty clay model, the effect of an increase in the weep hole diameter on hydrostatic pressure was more limited compared to other soil types. In the new generation system, hydrostatic pressure values decreased from 8.50 kPa to 8.05 kPa, while in the conventional system, they decreased from 9.34 kPa to 8.55 kPa. Due to low permeability, the movement of water within the soil is restricted, and drainage performance is largely controlled by the soil's hydraulic conductivity. Therefore, while increasing the weep hole diameter provides a certain improvement in drainage capacity, its effect on system performance remains limited.

When all soil types are considered together, it is observed that the new generation weep holes produces lower hydrostatic pressure values compared to the conventional weep holes across all diameters and soil conditions examined. The advantage provided by the system varies depending on soil permeability and becomes particularly pronounced in soils with moderate permeability, such as graywack and silty sand. In contrast, in low-permeability soils such as silty clay, where drainage performance is largely controlled by soil properties, the effect of the diameter of weep hole and type is more limited. These results demonstrate that focusing solely on increasing the diameter in weep hole design is insufficient; rather, soil properties and weep hole geometry must be evaluated together.

Abstract. Expansive clays are commonly encountered in semi-arid regions where seasonal moisture variations alter matric suction and induce swelling–shrinkage behavior. Because their mechanical response is strongly suction-dependent, conventional constitutive models that neglect unsaturated soil behavior may not adequately represent field conditions. The Barcelona Basic Model (BBM) incorporates suction effects into stress–strain behavior and is widely used for unsaturated expansive soils; however, its calibration generally requires extensive laboratory testing, which limits its routine engineering application. This study evaluates the sensitivity of BBM parameters on the predicted upward movement of a single pile embedded in expansive Çubuk–Ankara clay using numerical analyses performed in RS2 finite element software. The reference BBM parameter set was obtained from soil water retention curve measurements together with saturated and unsaturated mechanical tests. Sensitivity analyses were conducted for $\lambda(0)$, κ, r, β, p_c, k, and M by varying each parameter individually while keeping the remaining parameters constant. The pile response was evaluated using normalized pile movement, u_p/L_e, where L_e is the embedded pile length in clay. The results show that κ, representing the slope of the unloading–reloading line, is the most influential parameter controlling pile movement, followed by $\lambda(0)$, the slope of the virgin compression line. The parameters r and M also produced noticeable effects, whereas p_c, β, and k had comparatively limited influence. These findings indicate that BBM calibration for pile-heave simulations should prioritize parameters controlling stiffness and compressibility.

Keywords: Expansive clay; Barcelona Basic Model; unsaturated soil mechanics; pile heave; finite element analysis

1 Introduction

Expansive clays are problematic geomaterials because their volume-change behavior is governed by variations in water content and matric suction. In semi-arid regions, seasonal wetting and drying cycles may lead to repeated swelling and shrinkage, which can cause ground heave, differential movement, and distress in lightly loaded structures [1,2]. The response of foundations constructed in such soils is therefore not controlled only by conventional strength and stiffness parameters, but also by the hydraulic state of the soil and its suction-dependent deformation behavior [3, 4].

Pile foundations are commonly used in expansive clay deposits to transfer structural loads below the active zone [5,6], where seasonal moisture changes are expected to be less significant [7]. However, the portion of the pile located within the active zone may be subjected to upward shaft forces during wetting [8-10]. The final pile response depends on the swelling potential of the clay, the depth of the active zone, the pile-soil interface behavior, the anchorage length below the active zone, and the deformation characteristics of the surrounding unsaturated soil

[8,9]. For this reason, realistic numerical modelling of pile behavior in expansive clays requires a constitutive framework that can account for suction-dependent stress–strain response [3,11-13]. The conceptual mechanism of swelling-induced pile movement considered in this study is illustrated in Fig. 1. During wetting, suction decreases and the expansive clay in the active zone swells, producing upward shaft forces and pile movement, while the lower embedded portion provides resistance through shaft interaction.

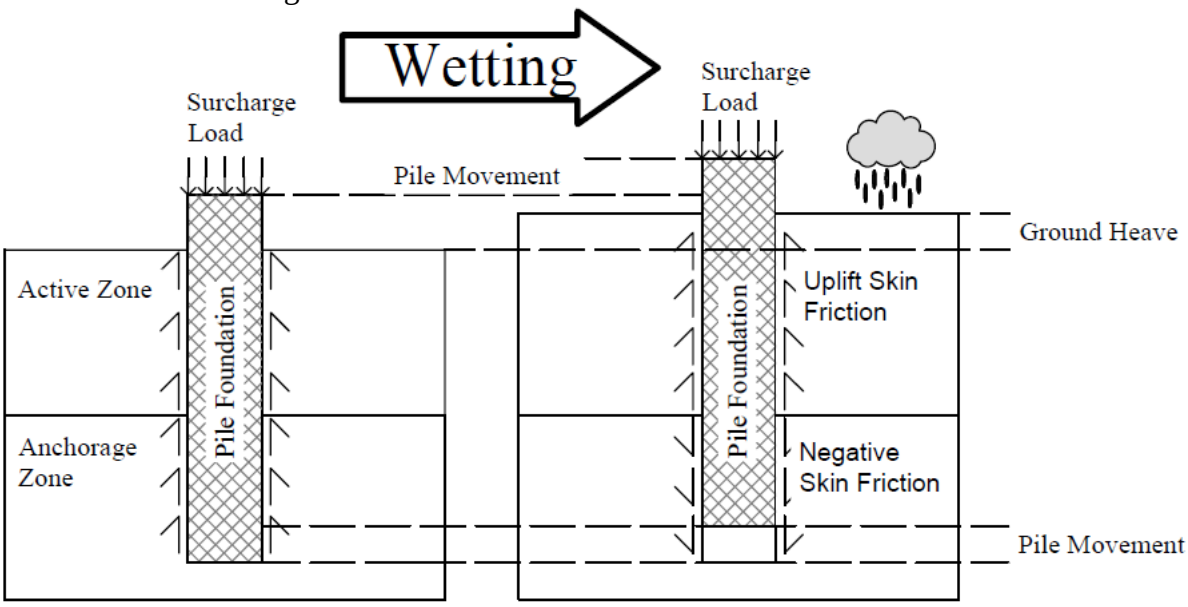

Fig. 1. Conceptual representation of swelling-induced pile movement in expansive clay during wetting [4-6, 9].

The Barcelona Basic Model (BBM) is one of the most widely used constitutive models for unsaturated soils because it incorporates matric suction as an independent stress-state variable. The model provides a theoretical framework for representing suction-dependent stiffness, yielding, and volumetric behavior [11-16]. Despite this advantage, the practical application of the BBM remains challenging because its parameters are not always easy to determine. A complete calibration procedure may require soil water retention curve measurements, saturated and unsaturated consolidation tests, triaxial tests, and suction-controlled testing [3,17,18]. These requirements can make the use of the model time-consuming and experimentally demanding in routine geotechnical practice [11,13,16].

For engineering applications, it is therefore important not only to calibrate BBM parameters, but also to understand which parameters most strongly affect the numerical prediction of the problem of interest. A parameter that has a strong influence on pile movement should be determined with greater care, whereas parameters with limited influence on the same response may be treated with a lower calibration priority. However, the importance of individual BBM parameters may depend on the type of analysis considered. For example, the parameters controlling pile heave may not necessarily be the same as those governing shear strength, post-yield behavior, or failure mechanisms.

This study investigates the sensitivity of selected BBM parameters on the predicted upward movement of a single pile embedded in expansive Çubuk–Ankara clay. The analyses were performed using an axisymmetric finite element model in RS2. The reference BBM parameter set was obtained from previous laboratory-based calibration work involving soil water retention behavior, saturated and unsaturated mechanical tests, and swelling-related characterization of the expansive Ankara clay [4,19]. In the sensitivity analyses, the parameters $\lambda(0)$, κ, r, β, p_c, k, and M were varied individually while the remaining parameters were kept constant.

The main objective of this study is to identify the relative influence of these BBM parameters on swelling-induced pile movement and to establish a practical calibration priority for this specific numerical problem. The scope of the study is limited to the upward displacement response of a single pile under the investigated modelling conditions. Therefore, the sensitivity ranking presented in this paper should not be interpreted as a general ranking for all BBM applications, particularly for analyses focused on shear strength, failure, or large-strain post-yield behavior.

2 Materials and Methods

2.1 Study Material and Reference Data

The analyses were performed for expansive Ankara clay, which is a highly plastic natural clay exhibiting significant suction-dependent volume-change behavior. The experimental database used for defining the reference numerical model included index property tests, mineralogical characterization, swelling tests, soil water retention curve measurements, saturated and unsaturated consolidation tests, triaxial compression tests, concrete–clay interface shear tests, and laboratory-scale single pile tests [4].

The clay was previously identified as an expansive soil containing smectitic and illitic clay minerals together with non-clay minerals such as quartz and calcite. This mineralogical composition, combined with the high plasticity of the soil, indicates a strong potential for swelling upon wetting [19]. Therefore, the Barcelona Basic Model (BBM) was selected to represent the suction-dependent mechanical response of the clay in the numerical analyses.

2.2 Reference BBM Parameter Set

The reference BBM parameter set was established from laboratory test results obtained on the same clay. The saturated compression parameters $\lambda(0)$ and κ were derived from one-dimensional consolidation behavior. Suction-dependent compressibility parameters were evaluated using unsaturated consolidation results, while the critical state parameter M was defined based on triaxial compression tests. The soil water retention curve was used to relate water content and matric suction during the calibration process.

The experimental basis used for determining each BBM parameter and the reference BBM parameters adopted in the numerical model are given in Table 1. This parameter set represents the baseline condition against which the sensitivity analyses were evaluated.

Table 1. Reference BBM parameters used in the numerical analyses [4].

Parameters	Description	Experimental basis	Reference value
$\lambda(0)$	Slope of the virgin compression line at zero suction	Saturated 1-D consolidation test	0.084
κ	Slope of the unloading–reloading line	Saturated 1-D consolidation test	0.0198
r	Parameter controlling suction-dependent compressibility	Unsaturated 1-D consolidation tests and SWRC	0.8909
β	Parameter controlling suction-dependent stiffness variation	Unsaturated 1-D consolidation tests and SWRC	0.0011
p_c	Reference pressure parameter	1-D consolidation and LC curve calibration	7.9

k	Parameter related to suction-induced cohesion increase	Unsaturated triaxial and SWRC	0.56
M	Critical state stress ratio	Saturated CD triaxial	0.67

2.3 Numerical model

The numerical analyses were carried out using RS2 finite element software. An axisymmetric model was adopted to represent the laboratory-scale single pile system. The clay domain was modelled using the BBM, while the concrete pile was represented as a linear elastic material. The pile–soil interaction was simulated using interface elements along the pile shaft, with interface properties defined from concrete–clay direct shear test results [20].

The boundary conditions were selected to represent the laboratory model configuration. The bottom boundary was restrained in both horizontal and vertical directions, whereas the outer vertical boundary was restrained horizontally and allowed to move vertically. The top surface was kept free to allow swelling-induced deformation. The axis of symmetry was restrained in the horizontal direction.

The wetting condition was represented through suction change in the expansive clay based on the soil water retention behavior. The reference analysis was first performed using the calibrated BBM parameter set. The upward vertical displacement of the pile obtained from this reference model was then used as the baseline response for the sensitivity analyses.

2.4 Sensitivity analysis procedure

The sensitivity analyses were conducted to evaluate the influence of selected BBM parameters on the predicted upward movement of the single pile. The investigated parameters were $\lambda(0)$, κ, r, β, p_c, k, and M. A one at a time sensitivity approach was used. In each analysis, only one parameter was varied, while all other parameters were kept constant at their reference values.

The response parameter used for comparison was the upward vertical displacement of the pile. Therefore, the sensitivity ranking presented in this study is specific to swelling-induced pile movement. It does not represent a general BBM sensitivity ranking for all possible geotechnical problems. For analyses governed by shear strength, bearing capacity, or post-yield failure mechanisms, a different parameter ranking may be obtained.

The influence of each parameter was assessed by comparing the calculated pile displacement with the reference model response. Parameters causing larger changes in upward pile movement were interpreted as having higher calibration priority for BBM based pile-heave simulations in expansive clays.

3 Results and Discussion

3.1 Normalized Pile Movement Response

The sensitivity analyses were evaluated using the upward movement of the pile as the response variable. In order to express the displacement in a dimensionless engineering form, the calculated pile movement was normalized by the embedded pile length in the clay. The embedded pile length was 50 mm; therefore, the normalized pile movement was calculated as:

$$\frac{u_p}{L_e}(\%) = \frac{u_p}{50} \times 100 \quad (1)$$

where u_p is the upward movement of the pile and L_e is the embedded pile length. This normalization allows the magnitude of pile movement to be interpreted relative to the pile length embedded in the expansive clay, rather than comparing the BBM parameters directly on the basis of their numerical ranges.

The variations of normalized pile movement with the investigated BBM parameters are shown in Fig. 2. The corresponding range of normalized pile movement for each parameter is summarized in Table 2 and Fig. 3. The results indicate that the calculated pile movement is most sensitive to the parameters controlling the compressibility and stiffness response of the clay.

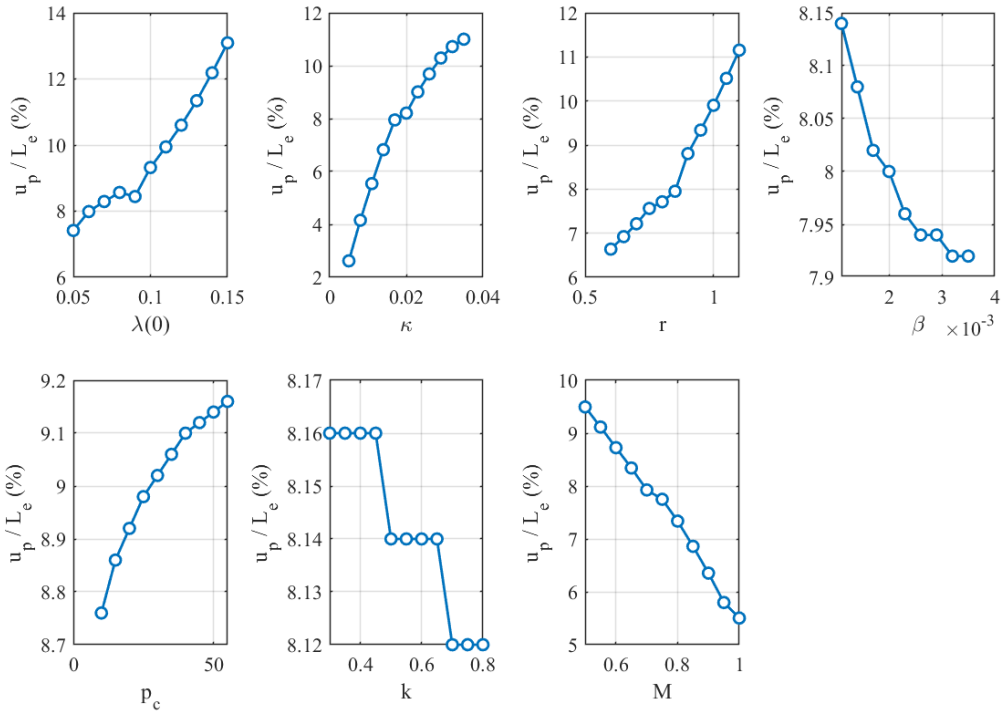

Fig. 2. Variation of normalized pile movement with BBM parameters.

Table 2. Range of normalized pile movement obtained from the BBM parameter sensitivity analyses.

Parameters	**Investigated range**	**Normalized pile movement range, (u_p/Le) (%)**	**Range, (Δu_p/Le) (%)**	**Relative effect**
κ	0.005–0.035	2.62–11.00	8.38	Highest
λ(0)	0.050–0.150	7.42–13.09	5.68	Very high
r	0.600–1.100	6.64–11.15	4.52	High
M	0.500–1.000	5.50–9.50	4.00	High
p_c	10–55	8.76–9.16	0.40	Low
β	0.0011–0.0035	7.92–8.14	0.22	Very low
k	0.300–0.800	8.12–8.16	0.04	Negligible

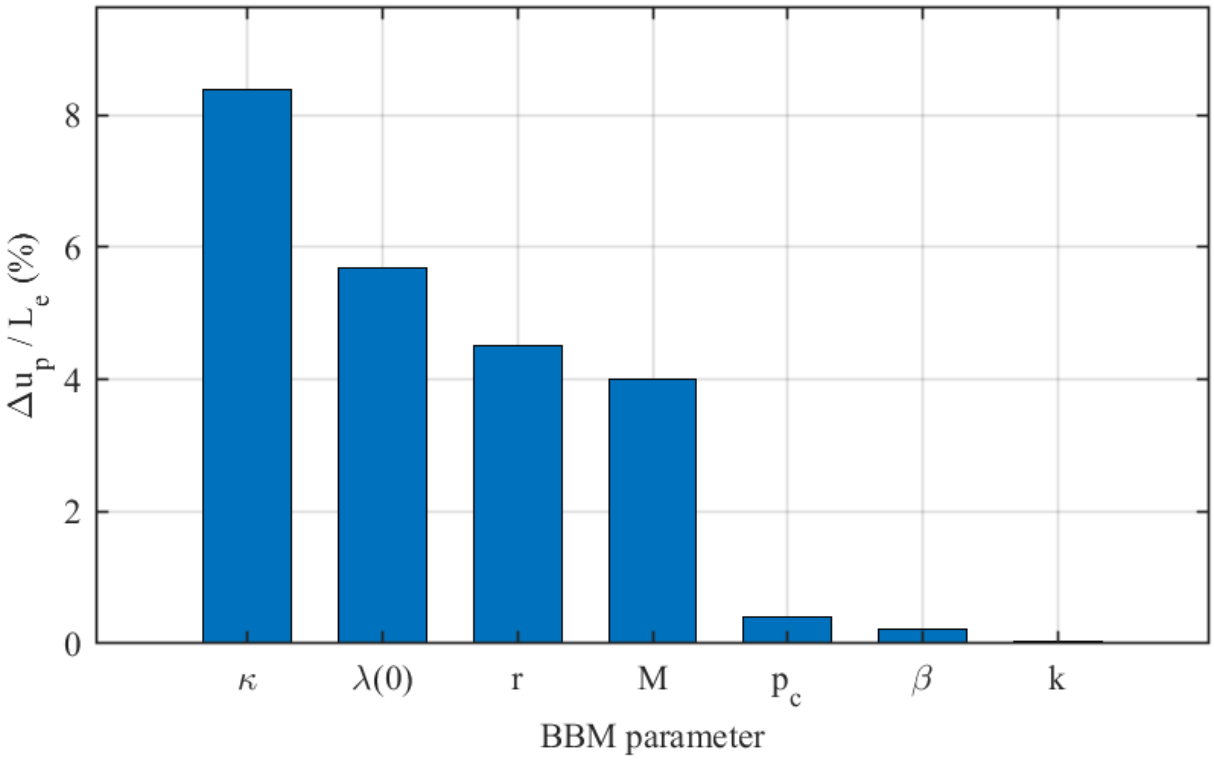

Fig. 3. Sensitivity ranking of BBM parameters based on the range of normalized pile movement.

3.2 Effect of κ and λ(0)

The parameter κ produced the largest variation in normalized pile movement within the investigated parameter range. As κ increased from 0.005 to 0.035, the normalized pile movement increased from 2.62% to 11.00% of the embedded pile length. This corresponds to a total normalized movement range of 8.38%, which was the highest among all parameters examined. Since κ represents the slope of the unloading–reloading line, this result indicates that the elastic volumetric stiffness of the clay has a major influence on the swelling-induced pile displacement.

The parameter λ(0) was the second most influential parameter. The normalized pile movement increased from 7.42% to 13.09% as λ(0) varied between 0.050 and 0.150, giving a total normalized movement range of 5.68%. This parameter defines the slope of the virgin compression line at zero suction and controls the compressibility of the soil skeleton. The strong influence of λ(0) is consistent with the displacement-controlled nature of the problem, since pile heave is governed primarily by the volumetric deformation of the surrounding expansive clay.

The results therefore show that the BBM parameters governing compression and unloading–reloading behavior are the dominant parameters for predicting upward pile movement. For this reason, κ and λ(0) should be treated as primary calibration parameters in BBM-based pile-heave simulations.

3.3 Effect of r and M

The parameter r also had a considerable effect on the calculated pile movement. The normalized pile movement increased from 6.64% to 11.15% as r increased from 0.600 to 1.100, corresponding to a normalized movement range of 4.52%. Since r controls the suction-dependent evolution of compressibility in the BBM formulation, its influence on pile movement is expected in a wetting-induced swelling problem. Although its effect was lower than those of κ and λ(0), r remained an important parameter for the predicted pile response.

The critical state parameter (M) showed a decreasing trend with increasing parameter value. The normalized pile movement decreased from 9.50% to 5.50% as M increased from 0.500 to 1.000, giving a total normalized range of 4.00%. This indicates that M has a noticeable influence on the pile movement response, although the investigated problem is mainly governed by swelling-induced deformation rather than shear failure. Therefore, M should not be considered negligible for the present analysis. However, its role may become even more significant in problems involving bearing capacity, shaft resistance failure, or large post-yield deformation.

3.4 Effect of p_c, β and k

The parameters p_c, β, and k produced comparatively small changes in normalized pile movement within the investigated ranges. The normalized pile movement increased only from 8.76% to 9.16% as pc varied from 10 to 55, corresponding to a movement range of 0.40%. This indicates that pc had a limited effect on the predicted pile heave for the selected modelling conditions.

The influence of β was even smaller. As β increased from 0.0011 to 0.0035, the normalized pile movement slightly decreased from 8.14% to 7.92%, giving a total range of only 0.22%. The parameter k showed an almost negligible effect, with normalized pile movement varying only between 8.12% and 8.16%. These results suggest that uncertainty in p_c, β, and k has a much lower influence on pile movement than uncertainty in κ, λ(0), r, and M for the present pile-heave simulation.

3.5 Overall sensitivity ranking and calibration priority

The sensitivity results were compared using the range of normalized pile movement, u_p/Le, where u_p is the calculated upward pile movement and Le is the embedded pile length in clay. The response curves in Fig. 2 show that the pile movement is mainly affected by κ, λ(0), r, and M, while the variations caused by p_c, β, and k are relatively small. The same trend is more clearly observed in Fig. 3, where the normalized movement ranges are compared directly.

Based on this ranking, κ produced the largest change in pile movement, followed by λ(0), r, and M. This indicates that the parameters controlling volumetric stiffness, compressibility, suction-dependent compressibility, and critical state response have the greatest influence on the predicted pile-heave behavior under the investigated conditions. In contrast, p_c, β, and k had limited influence on the selected response variable.

These results suggest that BBM calibration for swelling-induced pile movement should prioritize κ and λ(0), followed by r and M. However, this priority is specific to the upward displacement of a single pile embedded in expansive clay. For analyses focused on shear strength, bearing capacity, or post-yield deformation, the relative importance of the BBM parameters may be different.

4 Conclusions

This study evaluated the sensitivity of selected Barcelona Basic Model (BBM) parameters on the predicted upward movement of a single pile embedded in Ankara expansive clay. The sensitivity analyses were performed using an axisymmetric finite element model in RS2, and the pile response was evaluated in terms of normalized pile movement, (u_p/L_e), where (L_e) is the embedded pile length in clay.

The following conclusions can be drawn from the analyses:

1. The predicted pile movement was most sensitive to κ, which controls the unloading–reloading stiffness of the soil. Within the investigated range, κ produced the largest variation in normalized pile movement.

2. The parameter $\lambda(0)$, representing the slope of the virgin compression line, was the second most influential parameter. This confirms that the compressibility characteristics of expansive clay have a major effect on swelling-induced pile heave.
3. The parameters r and M also produced noticeable changes in the predicted pile movement. Therefore, these parameters should not be neglected when calibrating the BBM for pile-heave simulations.
4. The effects of p_c, β, and k were comparatively limited within the investigated parameter ranges. Their influence on the selected response variable was much smaller than that of κ, $\lambda(0)$, r, and M.
5. The results indicate that BBM calibration for swelling-induced pile movement should prioritize the parameters controlling volumetric stiffness and compressibility. However, the sensitivity ranking obtained in this study is specific to upward pile displacement. A different ranking may be obtained for analyses focused on shear strength, bearing capacity, or post-yield failure behavior.

Abstract. Accurate determination of pile bearing capacity is critical for deep foundation design in large-scale infrastructure. Conventional static load testing presents significant limitations for high-capacity piles exceeding 10–20 MN, requiring complex reaction systems and large workspaces. The Osterberg Cell (O-Cell) bidirectional load testing method offers a superior alternative by embedding a hydraulic jack within the pile itself, creating a self-reacting system that eliminates external reaction infrastructure. This study presents a comprehensive review of O-Cell methodology, including working principles, instrumentation systems (Linear Vibrating Wire Displacement Transducers, telltale extensometers, strain gauges, pressure gauges, and automated data loggers), and loading protocols. The method automatically separates skin friction from end-bearing resistance with direct measurements at multiple levels. Two field case studies demonstrate practical applications: (1) the Anadolu Highway Viaduct in Turkey, where O-Cell testing verified a 1.85 m diameter rock-socketed pile at twice the design load with only 0.3% normalized settlement, and (2) the Flame Towers Project in Baku, where a 1.2 m diameter, 36 m deep bored pile yielded an equivalent top-down capacity of 15.4 MN. Key advantages include high loading capacity (up to 320 MN, world record), no external reaction systems, automatic component separation, pile reuse after grouting, minimal workspace requirements, and enhanced safety. The O-Cell method is particularly advantageous for test loads exceeding 10 MN and has been applied in over 900 projects across 32 countries.

1 Introduction

The design of deep foundations represents one of the most complex challenges in geotechnical engineering, particularly in large-scale projects where structural loads far exceed the capacity of shallow foundation systems [1]. In such cases, bored piles (drilled shafts) are employed to transfer superstructure loads to deeper, more competent soil or rock strata. The reliable determination of pile bearing capacity is therefore of paramount importance for ensuring structural safety, optimizing foundation design, and achieving economic efficiency.

Pile bearing capacity can be estimated through theoretical and empirical analytical methods, dynamic testing approaches, and full-scale static load testing. Among these, static load testing remains the most reliable and direct method, as it replicates actual field loading conditions at prototype scale. However, conventional top-down static load testing presents significant practical and economic constraints, particularly when high-capacity piles with test loads in the range of 10–20 MN or greater are involved [2]. The construction of appropriate reaction

systems (anchor piles, ground anchors, or kentledge platforms) demands considerable workspace, time, material resources, and introduces non-trivial safety hazards.

The Osterberg Cell (O-Cell) bidirectional load testing method, developed by Dr. Jorj O. Osterberg of Northwestern University and introduced to the construction industry in 1991, represents a paradigm shift in pile load testing technology [3]. By embedding a hydraulic jack within the pile itself, the O-Cell method exploits the pile's own resistance components as a self-reacting system, thereby circumventing the need for external reaction infrastructure. Since its introduction, the method has been applied in over 900 projects across 32 countries by 2009, with test loads reaching a world record of 320 MN in 2010.

This paper presents a systematic review of O-Cell testing principles, instrumentation, test execution methodology, comparison with conventional methods, and analysis of two significant field case studies conducted in Turkey and Azerbaijan.

2 Background: Deep Foundations and Pile Load Testing

2.1 Deep Foundation Systems

Piles are structural members of timber, concrete, or steel that transfer superstructure loads to deeper soil or rock strata through a combination of shaft friction and end bearing. They are employed when shallow foundations cannot provide adequate bearing capacity, when excessive settlements are anticipated, or when uplift, lateral, or moment loads must be resisted. Pile types are classified by material (timber, steel, reinforced concrete, composite), installation method (driven, bored/cast-in-place, CFA, screw), and load transfer mechanism (friction, end-bearing, combined).

The total axial capacity of a pile is expressed as:

$$Q_f = Q_b + Q_s = q_b.A_b + f_s.A_s \quad (1)$$

where Q_f is the ultimate bearing capacity, Q_b is the end-bearing resistance, Q_s is the total shaft friction resistance, q_b is the unit end-bearing stress, f_s is the unit skin friction stress, A_b is the pile tip cross-sectional area, and A_s is the pile shaft surface area.

2.2 Conventional Pile Load Testing Methods

Static pile load tests are conducted using one of three principal loading configurations: axial compression (ASTM D1143), axial tension/uplift (ASTM D3689), and lateral loading (ASTM D3966) [4]. In axial compression testing, load is applied to the pile head via a hydraulic jack reacting against either a loaded platform (kentledge), anchor piles, or ground anchors, and pile head settlement is measured at specified load increments. Loading procedures include Slow Maintained Load (SML), Quick Maintained Load (QML), Constant Rate of Penetration (CRP), and Cyclic (Swedish) methods.

While these methods are well-established, their application to high-capacity large-diameter bored piles is severely constrained by the size and cost of the required reaction systems. For a 100 cm diameter test pile, ASTM D1143 requires anchor pile clear spacing of five pile diameters or minimum 2.0 m, resulting in workspace requirements of approximately 150 m² or greater. At test loads exceeding 10–20 MN, reaction system construction becomes a primary engineering challenge and cost driver.

3 The Osterberg Cell Method

3.1 Concept and Operating Principle

The Osterberg Cell (O-Cell) is a sacrificial, calibrated, hydraulic flat jack device embedded at or near the base of a bored pile during reinforcement cage assembly. When hydraulically pressurized after pile concreting and curing, the O-Cell expands bidirectionally: the upward reaction load mobilizes shaft friction along the pile segment above the cell, while the equal and

opposite downward reaction load mobilizes shaft friction and end-bearing capacity in the pile segment below the cell [5].

This self-reacting mechanism means that the pile itself serves as both the loading mechanism and the reaction system, eliminating the need for external reaction infrastructure. The O-Cell independently separates and quantifies the two primary resistance components of pile capacity, skin friction and end bearing, which cannot be directly distinguished in conventional top-down testing without supplementary instrumentation.

The O-Cell load value is determined by correlating the applied hydraulic pressure with the cell's load calibration curves provided by the manufacturer. The working principle satisfies the equilibrium condition:

$$P = F \text{ (skin friction above)} = Q \text{ (end bearing + skin friction below)} \quad (2)$$

3.2 Historical Development and Global Adoption

The O-Cell concept was developed and patented by Dr. Jorj O. Osterberg and introduced commercially through LOADTEST Inc. in 1991. The method gained rapid acceptance due to its technical advantages in high-capacity testing scenarios. Key milestones include [6]:

1991: Commercial introduction of O-Cell testing (LOADTEST)
2005: World record test load of 279 MN, Korea
2009: Over 900 O-Cell tests completed in 32 countries
2010: New world record of 320 MN, Missouri–Illinois Bridge (3.35 m diameter piers)
2011: LOADTEST reports over 2,000 test applications, with annual growth of 300–400 tests

Standard O-Cell dimensions and nominal capacities in common use are summarized in Table 1.

Table 1. Standard O-Cell Dimensions and Nominal Capacities (LOADTEST, 1991)

Nominal Diameter (mm)	Nominal Capacity (MN)
230	1.8
330	3.6
540	8.9
660	16.0
870	27.0

4 Instrumentation System

The O-Cell test relies on a comprehensive instrumentation package, all components of which are factory-calibrated and delivered with calibration certificates. The principal instruments are as follows:

4.1 Telltale Rod and Casing Extensometers

Two pairs of telltale rod-and-casing extensometers are installed: one pair extending from the O-Cell upper plate to the pile top (measuring compression of the upper pile segment), and a second pair extending from the O-Cell lower plate to the pile top (measuring compression and tip movement of the lower pile segment). Measurements are rounded to the nearest 0.01 mm.

4.2 Linear Vibrating Wire Displacement Transducers (LVWDT)

Three or four LVWDT units are placed between the upper and lower O-Cell bearing plates at 120° angular spacing to directly and continuously measure O-Cell expansion. Additional LVWDTs attached to telltale rods at the pile head measure upward pile movement relative to an independent reference beam.

4.3 Vibrating Wire Strain Gauges (VWSG)

Multiple strain gauge levels are installed along the pile shaft above and below the O-Cell to determine the distribution of mobilized unit skin friction with depth. Gauges are installed in diametrically opposed pairs at each instrumented level.

4.4 Bourdon Pressure Gauge and Pressure Transducer

A calibrated high-capacity Bourdon gauge measures hydraulic pressure in the pump supply line, while a high-resolution calibrated pressure transducer measures return line pressure for reference confirmation. These readings are used to calculate the applied O-Cell load via the manufacturer's calibration curves.

4.5 Automated Data Logger

All LVDTs, LVWDTs, and VWSGs are connected via multiplexers to an automated data logger interfaced with a laptop computer, enabling simultaneous readings at 0.5-minute intervals throughout the test. The data logger also records temperature readings at each instrumented level for thermal correction purposes.

5 Test Execution Methodology

5.1 Pile Preparation and O-Cell Assembly

Prior to pile installation, the O-Cell assembly (comprising the hydraulic jack, upper and lower bearing plates, LVWDTs, telltale casings, hydraulic supply lines, and strain gauge cables) is welded to the reinforcement cage at the predetermined depth. Temporary support welds maintain assembly integrity during lifting and installation. The cage is lowered into the borehole, verified for verticality (maximum deviation 1/50), and the O-Cell orientation is confirmed perpendicular to the pile axis (tolerance 1/100). Tremie concrete placement proceeds from the bottom up, with concrete strength verified through cube specimens tested at 7, 10, and 21 days.

5.2 Loading Protocol

Testing commences after the pile concrete achieves the minimum specified compressive strength (typically at 10 days). The standard loading program comprises [7]:

Loading phase: 12 equal load increments to maximum test load or O-Cell capacity

Hold criterion at each increment: Minimum 30 minutes OR until creep rate falls below 0.05 mm per 10 minutes (maximum hold time: 3 hours)

Unloading phase: 4 equal decrements with approximately 10-minute holds each

Zero load hold: Minimum 1 hour observation after full unloading

The test is terminated upon reaching the predetermined test load, the O-Cell maximum travel distance (150 mm), or the ultimate capacity of either the upper or lower pile segment.

5.3 Data Interpretation

The equivalent top-down load-settlement curve is constructed by combining the upward and downward displacement measurements from the O-Cell test, accounting for elastic pile compression and pile self-weight. If skin friction failure precedes end-bearing failure, a nominal static load can be applied at the pile top to continue testing for end-bearing capacity. After test completion, the O-Cell cavity is grouted, and the pile can be incorporated into the permanent foundation system.

6 Comparison with Conventional Methods

Table 2 presents a systematic comparison of the O-Cell method with conventional static load testing and dynamic load testing approaches.

Table 2. Comparison of Pile Testing Methods

Parameter	Conventional Static	O-Cell Bidirectional	Dynamic Testing
Maximum Test Load	~20 MN	>320 MN	Moderate
Workspace Required	Large (~150 m²)	Minimal	Small
Separate Components	No	Yes (automatic)	Indirect
Pile Reuse After Test	Possible	Yes (after grouting)	Yes

6.1 Key Advantages of O-Cell Testing

High loading capacity: Routinely achieves 27 MN per single O-Cell; multiple O-Cells enable loads exceeding 220 MN

No reaction system: Eliminates anchor piles, kentledge, and reaction frames

Automatic separation of skin friction and end-bearing components

Rock socket friction assessment: Direct loading of socket zone through targeted O-Cell placement

Pile reuse: Post-test grouting restores structural continuity

Reduced working load stress: Only half the test load acts on any pile cross-section

Minimal workspace: Applicable in confined environments, under structures, and offshore

Enhanced safety: No surface-level high-energy loading systems

6.2 Limitations

Test pile must be pre-designated before construction

Maximum applicable load limited by the lesser of upper skin friction or lower skin friction plus end bearing

Interpretation of results requires specialized expertise

Pile cap zone cannot be directly tested

7 Case Studies

7.1 Case Study 1: Anadolu Highway Viaduct (Gümüşova–Gerede, Turkey)

Project Context:

The Anadolu Highway V4 viaduct required verification of pile capacity in completely weathered meta-diorite rock.

Pile and Test Parameters:

Pile diameter: 1.85 m

Pile length: 12 m (embedded length in rock: 5.40 m)

Rock formation: Completely weathered meta-diorite

Test load achieved: 1,600 tons (2× design load)

Results:

At maximum test load, maximum pile settlement was 5.25 mm, equivalent to a normalized settlement of 0.3% of pile diameter, indicating that the entire axial load was carried by unit skin friction without mobilization of end-bearing failure. Back-analysis yielded an ultimate unit skin friction of $\tau_k = 0.524$ MPa, consistent with competent weathered rock socket performance.

Significance:

This case demonstrates the O-Cell method's capability to directly load a rock-socketed pile at twice the design load, achieving clear verification of capacity with minimal displacement, a result that would have required a very large and costly reaction system with conventional testing.

7.2 Case Study 2: Flame Towers Project, Baku, Azerbaijan

Project Context:

The Flame Towers Project in Baku comprises three high-rise towers with basement parking and retail levels. Given the high seismicity, wind loads, and complex soil profile at the site, piled raft foundations were adopted for each tower, with the Hotel Tower designed on 1.20 m diameter, 34.0 m deep bored piles with an allowable design load of Q_all = 1,150 tonnes.

Test Pile TP1 Configuration:

Nominal diameter: 1,200 mm

Total pile length: 36.0 m

O-Cell location: 11.90 m above pile base

O-Cell size: 2 × 405 mm diameter units, calibrated to 6.3 MN each

Test Execution and Results:

Testing was conducted on 23 October 2008 following preload cycling. The first six load increments yielded coherent and consistent data up to an O-Cell load of 5.71 MN (at 31.03 MPa pressure). At this load level, displacements above and below the O-Cell were 2.5 mm (upward) and 1.2 mm (downward), respectively. Equivalent top-down analysis demonstrated that the O-Cell load of 5.71 MN corresponds to an equivalent conventional top-down load of approximately 15.4 MN. Extrapolated settlement predictions indicated 9.2 mm at working load (11.0 MN) and 13.5 mm at 1.5× working load (16.5 MN), confirming satisfactory pile performance within design limits.

8 Conclusions

This study has presented a comprehensive technical review of the Osterberg Cell (O-Cell) bidirectional pile load testing method and its application in geotechnical engineering practice. The following principal conclusions are drawn:

The O-Cell method provides a reliable, accurate, and self-contained system for determining pile bearing capacity through bidirectional internal loading, automatically separating skin friction from end-bearing resistance without requiring external reaction infrastructure [8].

At test loads exceeding 10 MN, the O-Cell method demonstrates clear cost, safety, and logistical advantages over conventional top-down static load testing, with demonstrated capability up to 320 MN.

The comprehensive instrumentation package, comprising LVWDTs, telltale extensometers, vibrating wire strain gauges, pressure gauges, and automated data loggers, enables high-precision, multi-parameter characterization of pile behavior throughout the test.

Case Study 1 (Anadolu Highway Viaduct) confirmed successful capacity verification at twice the design load for a rock-socketed pile, with an ultimate unit skin friction of τ_k = 0.524 MPa and negligible pile settlement (0.3% D).

Case Study 2 (Flame Towers, Baku) demonstrated the method's effectiveness in a multi-layered soil profile, yielding an equivalent top-down capacity of 15.4 MN from an O-Cell load of 5.71 MN, and providing reliable settlement predictions within acceptable design limits.

Post-test grouting of the O-Cell cavity restores full structural integrity, enabling the test pile to be incorporated into the permanent foundation system, representing an additional economic advantage.

The O-Cell method has established itself as the preferred approach for high-capacity pile load testing worldwide and is expected to continue expanding its application in complex geotechnical environments, offshore foundations, and mega-infrastructure projects.

Acknowledgments

The author wishes to express his deepest gratitude and respect to the late Prof. Dr. Özcan Tan, whose scientific guidance, mentorship, and invaluable contributions laid the foundation for this work. Prof. Tan supervised the research during its development and provided essential

academic insight before his passing. His dedication to geotechnical engineering and his lasting influence on this study are gratefully acknowledged and respectfully remembered.

Abstract. This study investigates the potential use of granular shingle waste (GSW) as an alternative additive for improving the geotechnical properties of sandy soils. The waste material consists of mineral-based granular particles collected as a by-product during shingle production. Crushed sand was mixed with varying percentages of GSW, and laboratory tests were conducted to evaluate the changes in the engineering behavior of the mixtures. The experimental program includes grain size distribution analysis, specific gravity tests, liquid limit tests, standard Proctor compaction tests and direct shear tests. The influence of different GSW contents on the physical and mechanical properties of the sandy soil was assessed through comparisons of grain distribution, classification, liquid limit, maximum dry unit weight, optimum moisture content and shear strength parameters. Preliminary observations indicate that the inclusion of GSW alters the particle size distribution of the sand and may enhance shear strength characteristics depending on the additive ratio. Test results showed that the liquid limit decreased from 24.9 to 22.0, while specific gravity increased from 2.68 to 2.74 with increasing GSW. The maximum dry unit weight increased from 17.4 kN/m³ to a peak of 18.1 kN/m³ at 10% GSW, beyond which it decreased slightly to 17.3 kN/m³ at 20%, while the optimum moisture content increased steadily from 10.7% to 11.9%. Direct shear tests revealed a substantial increase in the internal friction angle, from 31.5° to 49.9°, accompanied by a decrease in cohesion from 17.8 kPa to 4.6 kPa, indicating a shift toward friction-controlled shear behavior at higher additive contents.

Keywords: Geotechnical index properties; Sandy soil; Shingle waste; Soil improvement

1 Introduction

Due to rapidly increasing population and urbanization, the necessity of constructing structures on and/or within soils that lack the engineering properties suitable for civil engineering applications is becoming an increasingly common issue. Cohesionless and loosely structured sandy soils are often unsuitable for direct use in many engineering projects due to problems such as low bearing capacity, insufficient shear strength, and excessive permeability. Binding materials such as cement, lime, or fly ash have traditionally been used to improve the engineering performance of such soils; however, the production processes of these materials are associated with high energy consumption and carbon emissions. For this reason, the investigation of alternative additive materials that are both economically and environmentally sustainable for soil improvement applications constitutes one of the current and significant research areas in geotechnical engineering [1–3].

In this context, the reuse of various industrial and domestic waste materials for soil improvement purposes has attracted considerable interest in recent years. The use of waste materials as soil additives reduces the consumption of natural resources while also providing

an environmental benefit by decreasing the volume of waste accumulating in landfills. It has been reported that traditional materials such as cement and lime are increasingly being replaced by waste materials such as stone slurry waste, coffee grounds, rice husk ash, crushed waste concrete and glass, natural fibers, sawdust, and waste tires, and that an appropriate amount of waste additive reduces the compressibility of the soil while increasing its maximum dry unit weight (MDU) and shear strength, thereby contributing to soil strengthening. The use of waste materials as additives is regarded as both an economically and ecologically beneficial soil improvement method, as it eliminates material costs and helps mitigate the waste disposal problem, which is often costly and problematic [4].

The literature contains numerous experimental studies supporting this approach. In one such study, plastic waste particles obtained from discarded plastic water bottles were mixed into sandy soil at various proportions (0, 0.5, 0.75, and 1.0% by weight), and direct shear and California bearing ratio (CBR) tests were conducted; it was determined that the addition of plastic waste particles improved the shear strength of the sandy soil due to the increased friction between the soil particles and the plastic waste [5].

The use of waste tires is another method frequently investigated in geotechnical engineering. In a study conducted in Algeria, rubber granules were mixed into sand from the Chlef River at proportions of 5, 10, 15, 20, and 30% by weight, and direct shear tests were performed at various relative density values; it was observed that the rubber granule content increased the shear strength properties of the sand-rubber granule mixtures. [6].

In a study investigating the effect of glass waste on the shear strength of sandy soils, crushed waste glass was mixed into sand at three different sizes and four different percentage ratios, and direct shear tests were performed. The results showed that the addition of crushed waste glass reduced the optimum moisture content (OMC) but had little to no effect on the MDU of the sand. It was reported that the addition of crushed waste glass increased the shear strength of the engineering sand at all ratios, that the highest shear strength was observed at a 5% sand-glass waste mixture across all glass sizes, and that the primary increase occurred in the internal friction angle of the sand [7]. In another study supporting this finding, natural sand was progressively replaced with fine-grained crushed waste glass, and the results revealed that the MDU increased and the OMC decreased; cohesion rose from 0 kPa to 5.7 kPa, while the internal friction angle increased from 41.5° to 44.4° [8].

In a study in which cement kiln dust was used in layers to increase the bearing capacity of sandy soil, factors such as cement kiln dust layer thickness, number of layers, and layer position were evaluated, and a method was proposed in which the optimum cement kiln dust layer position was determined through direct shear testing [9]. Furthermore, in a recent study in which a geopolymer material produced from paper sludge ash was used for the stabilization of loose and poorly graded sands, the effects of curing time, alkali solution concentration and type, and the addition of different paper sludge ash ratios on the strength improvement of the stabilized sandy soil were investigated [10].

When these studies are evaluated as a whole, a wide variety of waste materials, including plastic, rubber, glass, industrial ash, and construction-demolition waste, have the potential to improve the physical and mechanical properties of sandy and other soil types. However, based on the comprehensive literature review conducted, no study has been found in which GSW, a mineral-based granular material generated during roofing (shingle) production, has been used to improve the geotechnical properties of soils. This points both to a significant research gap regarding the utilization of this waste material in geotechnical engineering and to the original contribution of the present study.

GSW has mostly been addressed in literature within the context of shingle (asphalt roofing material) production and recycling processes, in application areas other than soil improvement. Shingle granules are small, mineral-coated particles produced from crushed stone or mineral

blends and coated with ceramic pigments, which cover the surface of asphalt roofing materials; they function to protect the asphalt layer from ultraviolet radiation, thereby extending the service life of the roofing, providing fire resistance, and increasing surface traction during walking. In a study noting that the direct use of recycled asphalt shingle waste as fill material is limited due to its high compressibility, the potential use of recycled asphalt shingle as structural fill material in highway embankments or behind retaining walls was evaluated, and it was stated that, owing to its high compressibility, recycled asphalt shingle was instead selected as a granular additive to improve the mechanical properties of bottom ash and foundry slag. The same study also reported that approximately 11 million tons of asphalt roofing waste are generated annually in the United States, the majority of which is already being utilized by incorporation into hot mix asphalt. The use of shingle waste in the road construction sector is generally widespread as well; it is known that asphalt shingle recycling involves converting shingles into an additive for hot mix asphalt or into cold patches for filling road cracks and potholes. In addition, there are studies evaluating roofing granules as a fine aggregate substitute in concrete and tile production; in these studies, various waste materials such as rubber ash, sawdust, seashells, crumb rubber, pistachio shells, fly ash sand, stone dust, and copper slag have been partially used in place of fine aggregate in roofing tile mortar [11–13].

This study investigates the potential use of GSW, a by-product generated during roofing (shingle) production with a mineral-based granular structure, as an alternative additive material for improving the geotechnical and shear strength properties of sandy soils. Within this scope, clean sand was mixed with GSW at different proportions (5, 10, 15, and 20%), and a comprehensive experimental program was carried out to determine the changes in the engineering behavior of the mixtures, consisting of grain size distribution analysis, specific gravity tests, liquid limit tests, standard Proctor compaction tests, and direct shear tests. The effect of different shingle waste proportions on the soil's grain size distribution, classification, liquid limit, MDU, OMC, and shear strength parameters was comparatively evaluated. This study is expected to contribute to sustainable waste management by reducing the disposal of this industrial waste in landfills, as well as to introduce into the literature the usage potential of a waste material that has not previously been evaluated in geotechnical engineering.

2 Materials and Methods

In this study, crushed sand was used as the base soil material. Crushed sand is a commercially available material that is widely preferred in fills and concrete production. The crushed sand used in the study was obtained from a commercial source, and the geotechnical and mechanical properties of the material were determined prior to the start of testing. The characterization results obtained are presented in the following sections. The physical appearance of the crushed sand is shown in Figure 1a. The GSW used as the additive material in this study was obtained directly from a facility engaged in shingle production. The material was collected from the by-product waste accumulating beneath the production lines and was used without any pretreatment. Although GSW has a mineral-based granular structure, information regarding its grain size, specific gravity, and other physical properties is presented in detail in the experimental results section. The physical appearance of GSW is shown in Figure 1b.

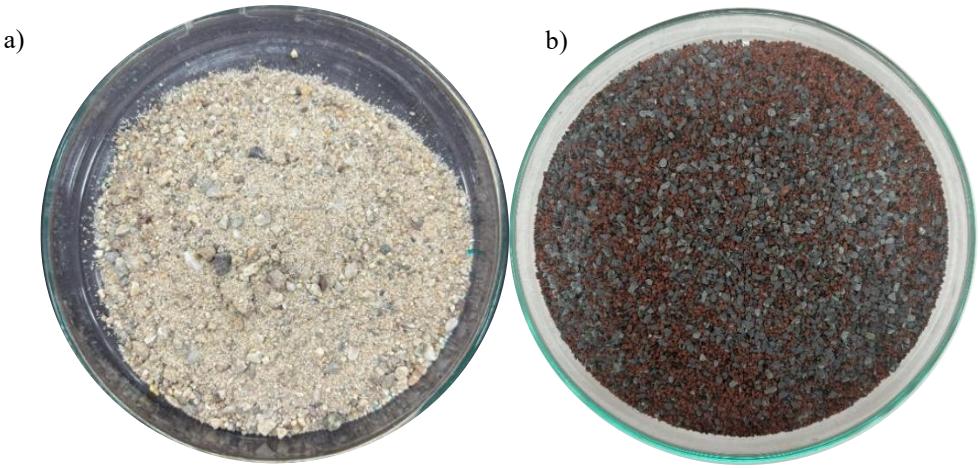

Fig. 1. Physical appearance of a) crushed sand, b) granular shingle waste.

Within the scope of the experimental program, crushed sand was mixed with GSW at proportions of 0, 5, 10, 15, and 20% of the total mixture weight. The 0% specimen was considered the reference soil, while the other proportions were determined to systematically evaluate the effect of increasing additive content on soil behavior. Dry sieve analysis tests were performed to determine the grain size distribution of the sand soil, the GSW, and mixtures based on the ASTM D6913 standard [14]. The specific gravity values of the sand soil, the GSW, and mixtures were determined using the pycnometer method in accordance with the ASTM D854 standard [15]. The liquid limit test using the cone penetration method was performed to evaluate the plasticity of the sand soil and mixtures. The test was conducted based on the BS 1377-2 standard [16]. Standard Proctor tests were performed to determine the compaction properties of the sand, the GSW, and mixtures. The tests were conducted in accordance with the ASTM D698 standard [17]. Direct shear tests were performed to determine the shear strength parameters of the sand, the GSW, and mixtures. The tests were conducted based on the ASTM D3080 standard using a 60 mm × 60 mm shear box [18]. Specimens for each mixture proportion were prepared at the MDU and OMC values obtained from the standard Proctor test. The tests were performed under three different normal stresses of 49, 98, and 196 kPa, with the shear rate kept constant at 0.5 mm/min in all tests. The mixing ratios and sample abbreviations used in the experiments are listed in Table 1.

Table 1. The mixing ratios and sample abbreviations.

Abbreviation	GSW Ratio (%)
S-0SW	0
S-5SW	5
S-10SW	10
S-15SW	15
S-20SW	20

3 Experimental Results

The particle size distribution curves for the addition of GSW at different proportions are shown in Figure 2. It is observed that the general character of the curves is preserved with the addition of GSW; however, the coarse grain fraction increases progressively with increasing additive content. This change has resulted in a limited shift of the particle size distribution curves toward

the coarser grain direction, while no significant difference has occurred in the granulometric properties of the mixtures at the additive proportions examined.

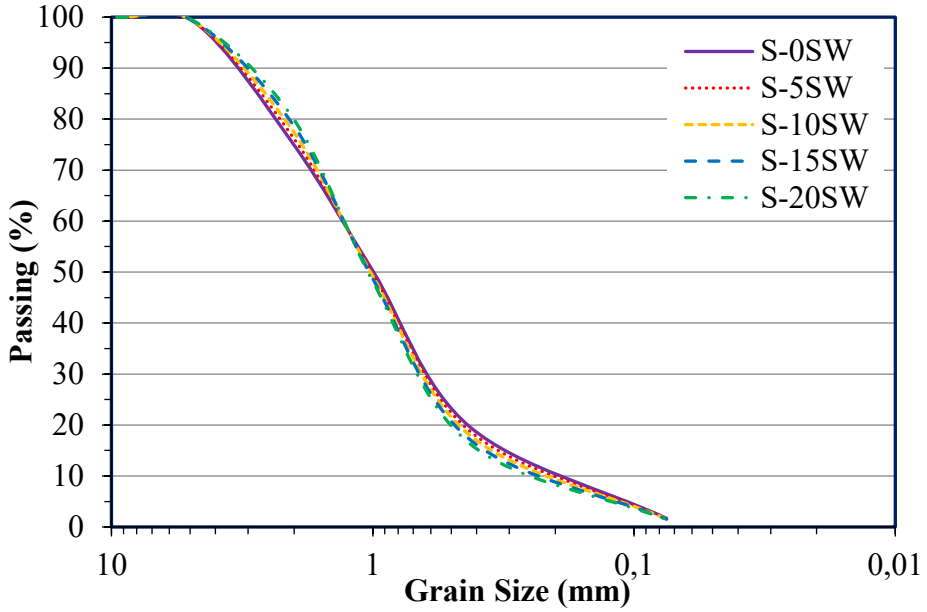

Fig. 2. Grain size distribution curves of sand - GSW mixtures.

Figure 3 shows the effect of the addition of GSW at different proportions on the liquid limit and specific gravity values of the soil. A consistent decrease in liquid limit values occurred with increasing GSW content. The liquid limit value, determined as 24.9 for the sand, was found to be 23.9, 23.4, 23.3, and 22.0 with the addition of 5, 10, 15, and 20% GSW, respectively. At the highest additive proportion, the liquid limit value decreased by approximately 11.6% compared to the initial specimen. This decrease can be attributed to the reduced water retention tendency of the mixture due to the non-plastic nature of the GSW. When the specific gravity results are examined, a consistent upward trend was observed in parallel with the increase in GSW content. The specific gravity, determined as 2.68 for the unamended specimen, reached 2.74 with the addition of 20% GSW, while values of 2.70, 2.71, and 2.72 were obtained at the intermediate additive proportions, respectively.

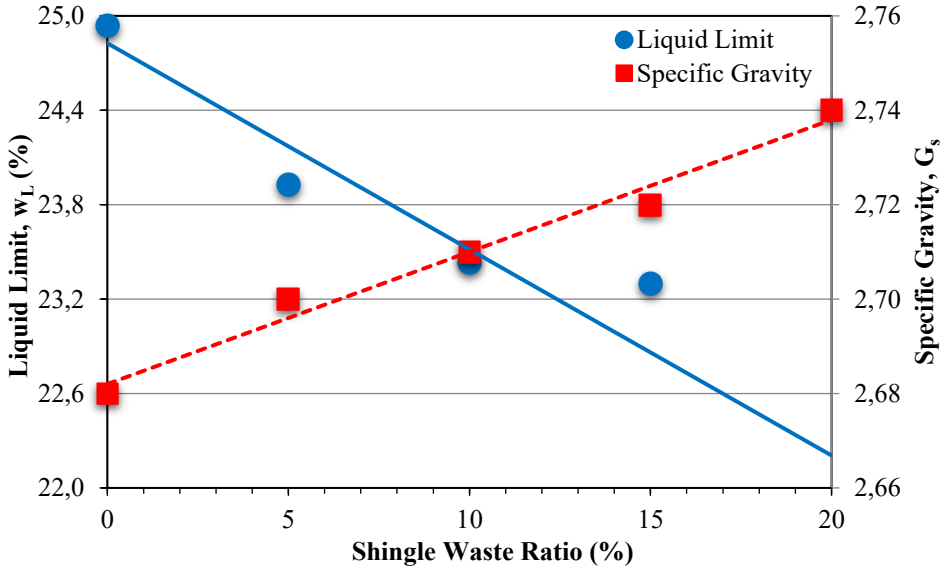

Fig. 3. Variation of liquid limit and specific gravity with GSW content.

The effect of the addition of GSW at different proportions on the MDU and OMC is presented in Figure 4. The test results reveal that the MDU first increases and then tends to decrease with increasing GSW content. The MDU, determined as 17.4 kN/m³ for the natural soil, reached its highest level of 18.1 kN/m³ with the addition of 10% GSW. However, when the additive proportion was increased beyond 10%, a limited decrease occurred in the MDU values, and the MDU was determined as 17.3 kN/m³ in the mixture containing 20% GSW. The findings obtained indicate that, in terms of MDU, a GSW content of approximately 10% provides the optimum compaction properties. When the OMC results are examined, a continuously increasing trend was observed depending on the increase in GSW content. The OMC, determined as 10.7% for the natural soil, increased to 11.9% with the addition of 20% GSW. This increase in OMC indicates that the mixture requires a higher water content to reach optimum compaction conditions in order to attain the MDU.

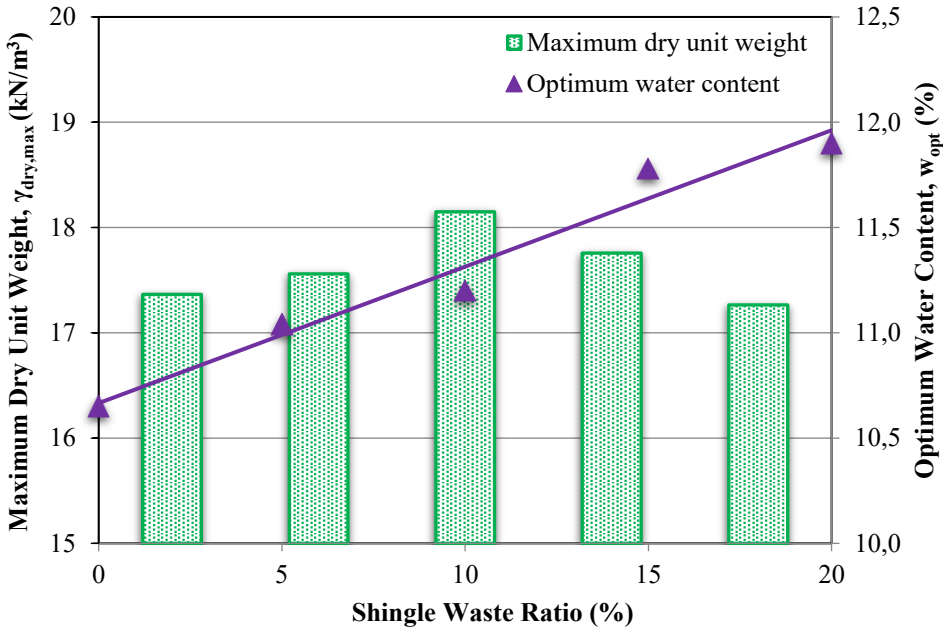

Fig. 4. Effect of GSW content on maximum dry unit weight and optimum moisture content.

Figure 5 presents the effect of the addition of GSW at different proportions on the internal friction angle (ϕ) and cohesion (c). The test results show that significant changes occur in the shear strength parameters with increasing GSW content. The internal friction angle, determined as 31.5° for the natural soil, increased continuously with the increase in GSW content and reached its highest value of 49.9° at 20% GSW content. The results obtained indicate that the addition of GSW significantly increases the frictional resistance of the soil. In contrast, a consistent decreasing trend was observed in cohesion values with increasing GSW. The cohesion, determined as 17.8 kPa for the natural soil, decreased to 4.6 kPa at 20% GSW. This decrease in cohesion can be attributed to the reduction of the binding effect between fine particles caused by the GSW. In contrast, the pronounced increase in the internal friction angle reveals that the shear strength behavior of the mixture increasingly exhibits friction-controlled behavior.

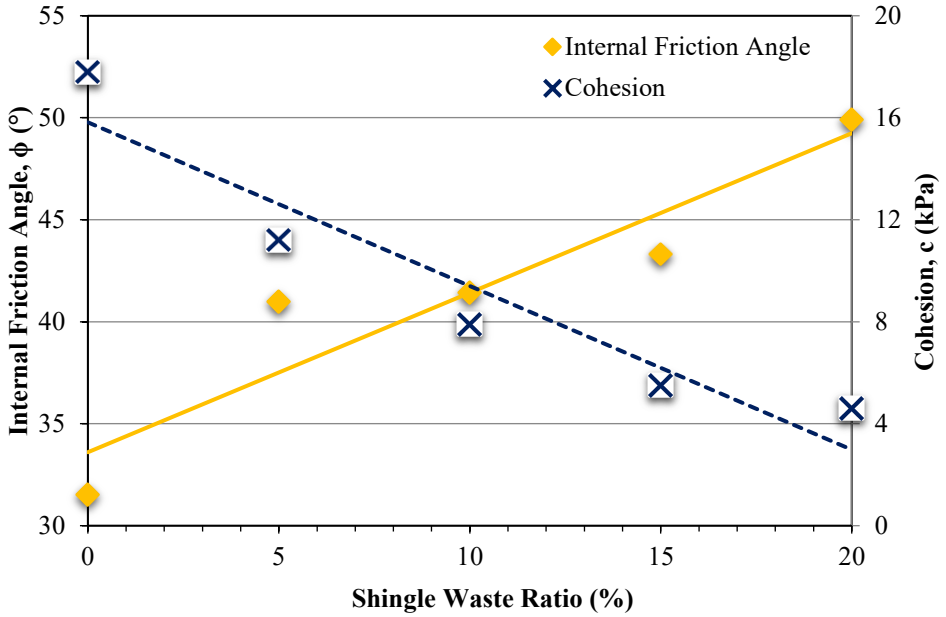

Fig. 5. Variation of cohesion and internal friction angle with GSW content.

4 Discussion

The addition of GSW resulted in noticeable changes in both the physical and mechanical properties of the sand soil. Although no major change was observed in the particle size distribution curves, the coarse grain fraction was found to increase progressively with increasing GSW content. While this did not significantly alter the overall granulometric character of the soil, it contributed to a reorganization of the grain skeleton and a change in the contact conditions between particles. The decrease observed in liquid limit values can be attributed to the non-plastic nature of the GSW. With the addition of GSW, the proportion of granular material in the mixture increased, thereby reducing the influence of fine particles and limiting the consistency change of the soil in the presence of water. In contrast, the increase in specific gravity values can be explained by the fact that GSW has a higher particle density than natural sand. Considered together, these findings suggest that the addition of GSW altered the physical properties of the mixture, contributing to the formation of a denser grain structure and reducing the soil's sensitivity to water. The results obtained from the compaction tests indicate that the changes occurring in the physical properties are directly reflected in the compaction behavior. At low additive proportions, the granular shingle particles filled the voids between sand grains more effectively, resulting in a more regular grain arrangement and contributing to an increase in MDU. However, as the additive proportion increased, the excess amount of GSW partially disrupted the regularity of grain arrangement, causing a limited decrease in MDU. On the other hand, the continuous increase in OMC indicates that the altered grain skeleton requires more water to reach the optimum compaction level. These results indicate that an addition of approximately 10% shingle waste represents the most favorable proportion in terms of compaction. The direct shear test results show that the addition of GSW has a significant effect on the shear strength of the soil. The pronounced increase observed in the internal friction angle can be attributed to the more effective mechanical interlocking developing between the granular shingle particles and the sand grains, along with an increase in inter-particle frictional resistance. In contrast, the decrease occurring in cohesion values can be explained by the granular additive reducing the binding effect between fine particles. This indicates that as the GSW content increases, the contribution of cohesion to the shear strength of the soil diminishes, while inter-particle friction becomes more decisive. Consequently, the addition of GSW increased the shear strength of the soil and contributed to behavior characterized by higher

frictional resistance. Overall, the addition of GSW altered the physical properties of the sand soil and positively affected its compaction and shear strength behavior. In particular, the improvements obtained up to an additive proportion of approximately 10% indicate that GSW can enhance engineering performance when used in an optimum amount. However, the limited changes observed in some properties at higher additive proportions reveal that determining the optimum additive proportion is important for soil improvement applications [19–20].

5 Conclusions

This study investigated the potential use of GSW, a mineral-based by-product generated during roofing (shingle) production, as an alternative additive material for improving the geotechnical properties of sandy soils. Crushed sand was mixed with GSW at proportions of 0, 5, 10, 15, and 20% by weight, and the effects of these mixtures were evaluated through a comprehensive experimental program comprising grain size distribution analysis, specific gravity, liquid limit, standard Proctor compaction, and direct shear tests. Based on the experimental findings, the following conclusions can be drawn:

- The addition of GSW did not substantially alter the overall character of the particle size distribution curves; however, the coarse grain fraction increased progressively with increasing additive content, indicating a limited shift toward coarser gradation and a reorganization of the grain skeleton.
- Liquid limit values decreased consistently with increasing GSW content, from 24.9 for the unamended soil to 22.0 at 20% GSW content, an effect attributed to the non-plastic nature of the additive and the corresponding reduction in the influence of fine particles.
- Specific gravity values increased steadily with increasing GSW relative to natural sand.
- Compaction behavior was found to be sensitive to additive content: the MDU increased from 17.4 kN/m³ to a peak of 18.1 kN/m³ at 10% GSW content, before decreasing slightly to 17.3 kN/m³ at 20% GSW content. The OMC increased continuously with additive content, from 10.7% to 11.9%, indicating that the modified grain skeleton required more water to achieve optimum compaction. These results identify approximately 10% GSW as the most favorable proportion in terms of compaction characteristics.
- Direct shear test results demonstrated a marked improvement in shear strength with increasing GSW. The internal friction angle increased substantially, from 31.5° for the natural soil to 49.9° at 20% GSW content, attributable to enhanced mechanical interlocking and inter-particle friction between the angular shingle particles and sand grains. In contrast, cohesion decreased from 17.8 kPa to 4.6 kPa over the same range, reflecting the reduced binding effect between fine particles as the proportion of granular additive increased. These trends indicate a progressive shift toward friction-controlled shear behavior with increasing GSW content.
- Overall, the incorporation of GSW was found to improve the compaction and shear strength characteristics of sandy soil, particularly at additive proportions up to approximately 10%, beyond which some properties exhibited limited or reversing trends. This underscores the importance of identifying an optimum additive proportion for practical soil improvement applications.

The findings of this study demonstrate, for the first time, the technical feasibility of utilizing GSW as a soil-improvement additive, thereby introducing a previously unexplored waste material into the geotechnical engineering literature. Beyond its technical merits, this approach offers a sustainable pathway for the reuse of an industrial by-product that is otherwise directed to landfill disposal, contributing to both waste minimization and resource efficiency. Future research is recommended to further investigate the long-term durability, environmental

leaching behavior, and field-scale applicability of shingle-waste-stabilized sandy soils, as well as their performance under cyclic and dynamic loading conditions.

Abstract. Soil–structure interaction (SSI) plays a critical role in determining the seismic response of structures. However, conventional structural design approaches often idealize the foundation system as fixed, neglecting the influence of soil flexibility. This study presents an experimental investigation aimed at comparatively evaluating the seismic behavior of a fixed-base structural model and a system incorporating soil–structure interaction. The experimental program was conducted using a uniaxial shaking table and a soil container made of plexiglass, specifically designed to simulate SSI conditions. The scaled structural model was tested under two different boundary conditions: (i) a fixed-base configuration, in which the structure was rigidly attached to the shaking table, and (ii) an SSI configuration, in which the structure was embedded within a granular soil. Acceleration data were recorded using accelerometers installed at different story levels of the structure. Following data processing and filtering procedures, displacement responses were obtained through numerical integration. Based on the experimental results, response parameters such as acceleration and displacement amplitudes, as well as dynamic characteristics, were evaluated. The findings indicate that the fixed-base assumption may lead to significant discrepancies in estimating both acceleration and displacement demands when compared to the SSI model. Furthermore, variations in natural frequency and damping ratio were observed due to energy dissipation mechanisms within the soil. These results highlight the importance of incorporating soil–structure interaction effects in the seismic performance assessment of structures, particularly those founded on granular soils. The study aims to contribute to the development of more realistic modeling approaches for seismic analysis.

Keywords: Soil–structure interaction; Shaking table; Plexiglass; Seismic behavior

1 Introduction

The seismic performance of civil engineering structures is governed not only by the characteristics of the structural system but also by the interaction between the structure, its foundation, and the supporting soil. During earthquake excitation, soil deformability modifies the dynamic properties of the coupled soil–foundation–structure system by altering its stiffness, damping capacity, and vibration characteristics. Consequently, the conventional fixed-base assumption, which is widely adopted in structural design and analysis, may not accurately represent the actual seismic response of structures founded on deformable soils (Wolf 1985; Kramer 1996; Mylonakis and Gazetas 2000).

Over the past several decades, soil–structure interaction (SSI) has become one of the most extensively investigated topics in earthquake engineering. Previous analytical and numerical studies have demonstrated that SSI may significantly influence natural frequencies, modal damping ratios, acceleration demands, displacement responses, and foundation settlements

depending on the relative stiffness of the soil and structure, foundation conditions, and earthquake characteristics (Stewart et al. 1999; Mylonakis and Gazetas 2000; Kausel 2010). In particular, the flexibility of the supporting soil may either amplify or reduce structural demands, indicating that neglecting SSI may lead to inaccurate estimation of seismic performance.

Although advances in computational methods have considerably improved the capability of finite element and finite difference analyses to simulate coupled soil–structure systems, the nonlinear behavior of soils and the complexity of wave propagation mechanisms continue to present significant challenges. Therefore, experimental investigations remain essential for understanding the actual dynamic behavior of soil–structure systems and for validating numerical simulation techniques. Among available experimental approaches, shaking table testing provides one of the most effective methods for reproducing earthquake loading under controlled laboratory conditions while simultaneously capturing the coupled response of the soil and the superstructure (Gajan et al. 2005; Rayhani and El Naggar 2008; Pitilakis et al. 2014).

Recent experimental studies have consistently reported that soil flexibility alters the distribution of structural acceleration and displacement demands, modifies modal characteristics, and affects the dynamic amplification mechanism throughout the structural height (Pitilakis et al. 2014; Tabatabaiefar et al. 2014; Liu et al. 2020). Nevertheless, relatively few experimental investigations have directly compared the seismic responses of identical structural models tested under both fixed-base and soil–structure interaction conditions using the same structural configuration, instrumentation layout, and earthquake excitation. Such comparative studies provide a more reliable assessment of the influence of soil flexibility by eliminating uncertainties associated with variations in structural properties and experimental conditions.

In this context, the present study experimentally evaluates the dynamic behavior of a scaled structural model under both fixed-base and soil–structure interaction conditions using a uniaxial shaking table. Initially, the dynamic characteristics of the fixed-base model were identified through experimental modal analysis using the Enhanced Frequency Domain Decomposition (EFDD) and Stochastic Subspace Identification (St-SSI) techniques. Subsequently, shaking table tests were carried out using the east–west component of the 1992 Erzincan earthquake record as the input ground motion. The structural responses were evaluated in terms of acceleration and displacement time histories, and the influence of soil flexibility on the seismic behavior of the structural system was investigated. The experimental results provide a valuable benchmark for validating numerical SSI models and contribute to a better understanding of the dynamic behavior of soil–foundation–structure systems subjected to earthquake loading.

1.1 Experimental Modal Characterization and Seismic Response of the Fixed-Base Structural Model

The reference dynamic behavior of the structural model was established through shaking table tests performed under fixed-base boundary conditions. The experimental setup consisted of a uniaxial shaking table, the structural model, and the data acquisition and measurement system. To simulate fixed-base conditions, the structural model was rigidly connected to the shaking table through threaded rod connections anchored to the base plate, thereby ensuring a stable and high-stiffness boundary condition throughout the tests. To characterize the dynamic properties of the structure and monitor its seismic response, accelerometers were installed at the top, middle, and bottom story levels (Fig. 1). Experimental modal identification was carried out using the Enhanced Frequency Domain Decomposition (EFDD) and Stochastic Subspace Identification (St-SSI) methods. The identified natural frequencies and modal damping ratios are summarized in Table 1, while the first two mode shapes obtained from the modal analyses are presented in Fig. 2. The mode shapes identified by both modal identification techniques

exhibit a high degree of agreement, demonstrating the consistency of the experimental modal analysis. Furthermore, owing to the square plan geometry of the structural model, the first two natural frequencies were found to be very close to each other. As presented in Table 1, the natural frequencies and damping ratios obtained from the EFDD and St-SSI methods are in excellent agreement, confirming the reliability and robustness of the experimental modal identification procedure. Following the identification of the dynamic characteristics of the structural model under fixed-base boundary conditions, its seismic response was investigated through shaking table tests. For this purpose, the east–west component of the ground motion recorded during the 1992 Erzincan earthquake was adopted as the input excitation. The acceleration time histories obtained under earthquake excitation are presented in Fig. 3. A consistent increase in acceleration amplitudes from the bottom story to the top story was observed under earthquake excitation. Under the 50% scaled Erzincan earthquake excitation, the measured acceleration responses remained relatively limited. These findings indicate that seismic demands were progressively amplified along the height of the structure, resulting in the largest acceleration responses at the upper stories. The displacement time histories corresponding to the east–west component of the 1992 Erzincan earthquake are presented in Fig. 4. The displacement time histories presented in Fig. 4 indicate that the displacement amplitudes consistently increase from the bottom story to the top story under the 50% scaled Erzincan earthquake excitation. In addition, the peak displacement responses at the upper stories occur with a noticeable time lag relative to those at the lower stories. This behavior can be attributed to the phase difference associated with the dynamic response of the structure and the propagation of structural vibrations along its height.

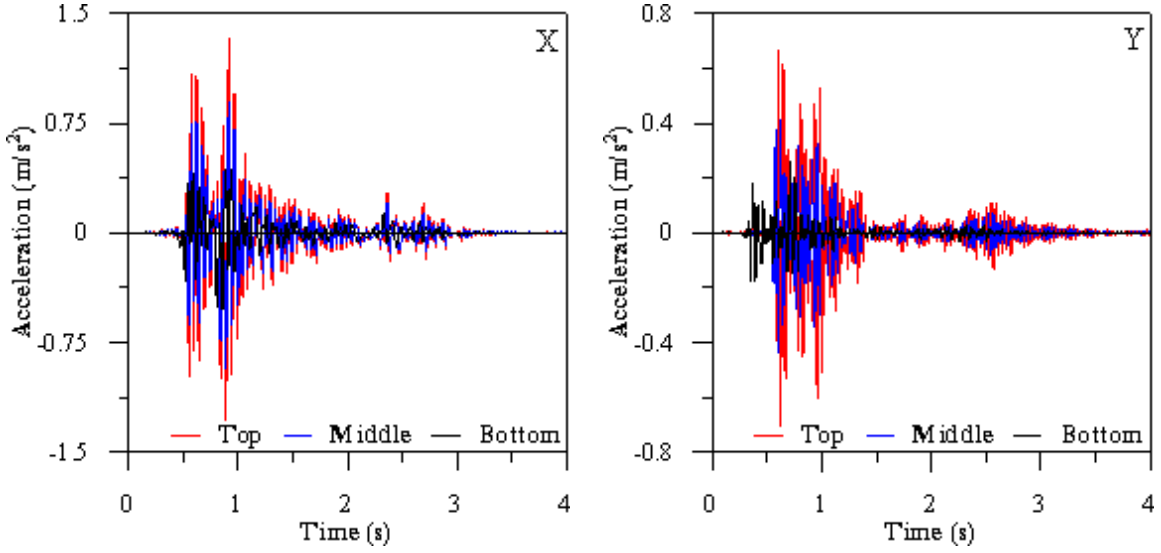
1.2 Shaking Table Tests of the Soil–Structure Interaction Model

Following the completion of the fixed-base experiments, the shaking table test setup was reconfigured to investigate soil–structure interaction (SSI). For this purpose, the plexiglass soil container was rigidly attached to the shaking table using threaded rod connections. The soil container was filled with sand to a height of 30 cm, and test were conducted at a relative density of 20%. To capture the dynamic response of the structural model, accelerometers were installed at the top, middle, and bottom stories in both horizontal directions, following the same sensor configuration adopted in the fixed-base experiments. In addition, an extra accelerometer was mounted at the top story in the vertical direction to monitor the vertical settlements induced by seismic loading. The experimental setup developed for the SSI tests, together with representative photographs of the shaking table experiments, is presented in Fig. 5.

Figure 6 presents the acceleration time histories obtained at a relative density of 20% under the 50% scaled earthquake excitation. The results demonstrate a consistent increase in acceleration amplitudes from the bottom story to the top story in both horizontal directions. In the X direction, the measured peak accelerations were 0.644, 0.972, and 1.332 m/s² at the bottom, middle, and top stories, respectively, corresponding to increases of 50.93% between the bottom and middle stories and 37.04% between the middle and top stories. A similar trend was observed in the Y direction, where the recorded accelerations were 0.258, 0.438, and 0.708 m/s², yielding increases of 69.77% and 61.64% between successive story levels. In the vertical direction, the acceleration recorded at the top story was 0.105 m/s². These results indicate that seismic acceleration demands progressively amplify along the structural height, reaching their maximum values at the upper stories. The observed response is indicative of a pronounced dynamic amplification mechanism within the soil–structure system.

Figure 7 presents the displacement time histories obtained at a relative density of 20% under the 50% scaled earthquake excitation. The maximum displacements measured in the X direction were 1.619, 1.611, and 1.445 mm at the top, middle, and bottom stories, respectively. In the Y direction, the corresponding displacement values were 0.044, −0.052, and 0.024 mm, while a vertical displacement of 0.099 mm was recorded at the top story.

The results indicate that the displacement response in the X direction generally increased with structural height, reflecting greater seismic demand at the upper stories. The difference between the top and middle stories was relatively small (0.5%), whereas the displacement increased by 11.5% between the middle and bottom stories. In contrast, the displacement



response in the Y direction remained considerably smaller and exhibited a less uniform distribution. This behavior is primarily attributed to the fact that the earthquake excitation was applied in the X direction, causing the structural response to be dominated by motion along this axis. The displacement differences between the top and middle stories and between the middle and bottom stories in the Y direction were calculated as 15.4% and 116.7%, respectively.

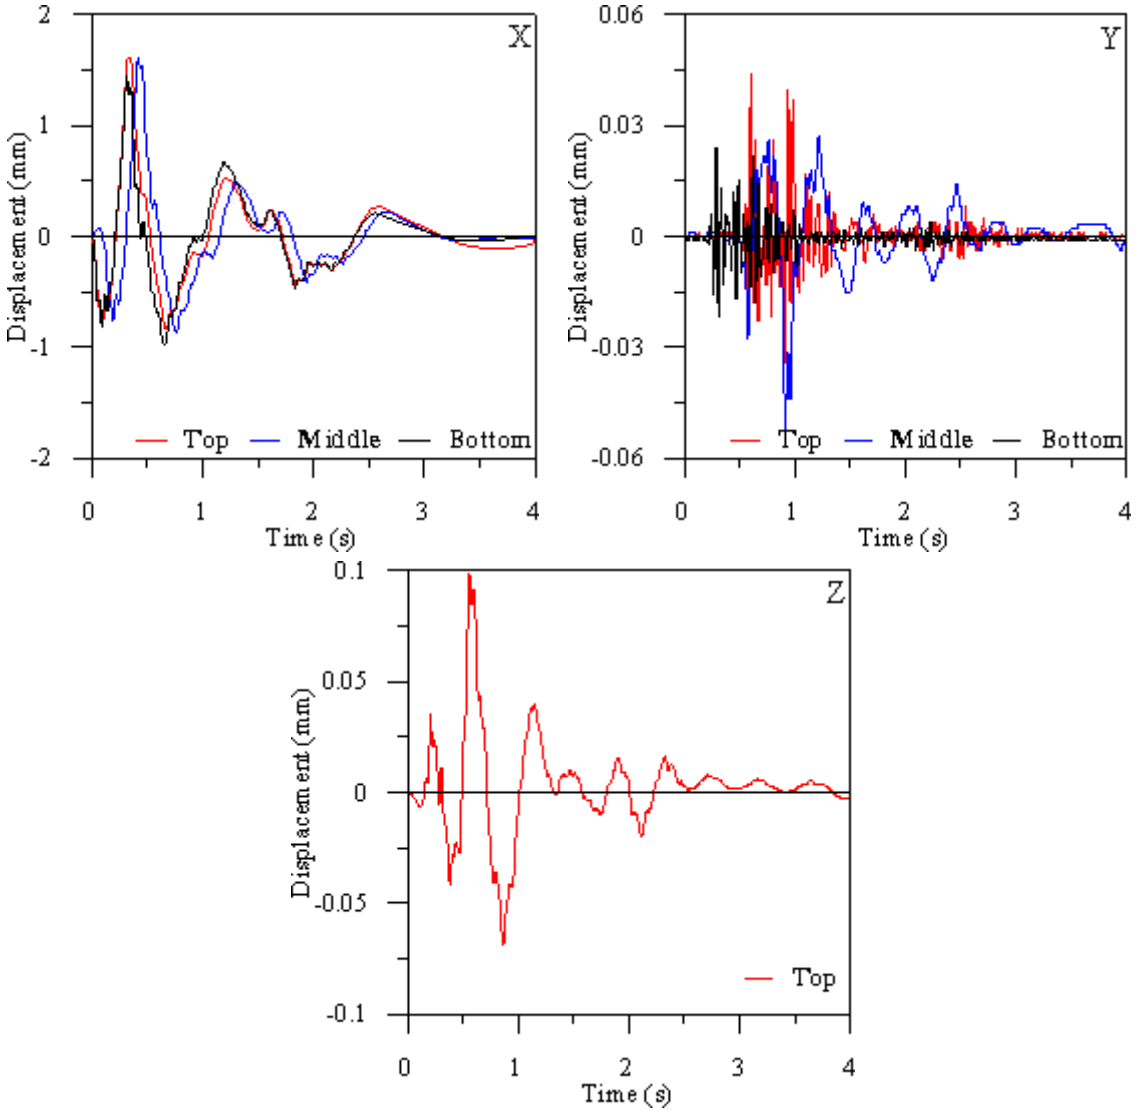

Fig. 7. Displacement time histories at 20% relative density under the 50% scaled earthquake excitation

2 Conclusion

This study experimentally investigated the dynamic characteristics and seismic behavior of a scaled structural model under both fixed-base and soil–structure interaction (SSI) conditions using shaking table tests. The experimental modal analysis demonstrated excellent agreement between the Enhanced Frequency Domain Decomposition (EFDD) and Stochastic Subspace Identification (St-SSI) methods in terms of the identified natural frequencies, modal damping ratios, and mode shapes, confirming the reliability of the adopted modal identification procedure. The shaking table experiments revealed that both acceleration and displacement responses increased progressively from the bottom story to the top story, indicating a pronounced dynamic amplification mechanism along the structural height. Under soil conditions with a relative density of 20%, a similar response trend was observed; however, the presence of the supporting soil modified the distribution of seismic demands throughout the structural system. Furthermore, the structural response was found to be predominantly governed by the direction of the applied earthquake excitation, resulting in considerably larger responses in the loading direction than in the transverse direction. Overall, the experimental findings demonstrate that soil flexibility significantly influences the dynamic behavior of the coupled soil–foundation–structure system and should therefore be considered in realistic seismic performance assessments. The experimental data obtained in this study provide a reliable benchmark for the calibration and validation of numerical soil–structure interaction models and contribute to a better understanding of the seismic behavior of soil–foundation–structure systems subjected to earthquake loading.

Abstract. In this study, the effects of polypropylene (PP) and copolymer (CP) fiber inclusions on the consolidation and swelling behavior of low (CL) and high (CH) plasticity clay soils were investigated. Within this scope, one-dimensional oedometer tests were conducted on specimens prepared by adding PP and CP fibers to both soil types at 0.25%, 0.50%, and 0.75% by dry weight. Based on the obtained stress–void ratio (e–log σ′) curves, the free swell percentage, compression index (Cc), recompression index (Cr), and coefficient of consolidation (cv) of the mixtures were determined. The findings indicate that the fiber type and inclusion ratio significantly affect the volumetric behavior of the soils. Fiber inclusion systematically reduced the free swell percentage, with reductions of up to 42% in the CH soil at 0.75% PP content and up to 44% in the CL soil at 0.75% CP content. The compression and recompression indices decreased moderately with increasing fiber content, while the coefficient of consolidation increased, indicating a faster dissipation of excess pore water pressures in the reinforced mixtures. The study comparatively demonstrates the extent to which fiber inclusion controls swelling—particularly in high plasticity clays—and how it modifies the compressibility characteristics. The results suggest that PP and CP fibers can be used as a sustainable and effective stabilization method for improving problematic clays in geotechnical engineering applications.

Keywords: Low plasticity clay, High plasticity clay, Oedometer test, Consolidation, Swelling, Fiber

1 Introduction

Expansive and compressible clayey soils are among the most problematic geomaterials encountered in transportation infrastructure, shallow foundations, and earth structures. Seasonal moisture fluctuations in such soils cause repeated swelling and shrinkage cycles, whereas long-term loading leads to excessive consolidation settlements; both mechanisms are responsible for severe distress in pavements and lightly loaded structures [1, 2]. In conventional practice, weak subgrade soils are excavated and replaced with granular fill; however, excavation, hauling, and material costs make this approach economically and environmentally unattractive, and in-situ improvement of the existing soil is generally the most cost-effective alternative [1].

A wide range of stabilization techniques has been proposed for problematic clays, including chemical additives, compaction control, prewetting, surcharge loading, and reinforcement with geosynthetics [2, 3]. In recent years, the inclusion of randomly distributed discrete fibers has

attracted particular attention because it is simple to apply, does not require curing, does not alter the soil chemistry, and mobilizes tensile resistance isotropically within the soil mass [3, 4]. Previous investigations have shown that discrete polymeric fibers increase the tensile and shear strength of clays [4], restrain crack development [4], and reduce the swelling potential of expansive soils [5–7]. Al-Akhras et al. [6] reported that both the swell percentage and the swelling pressure of a clayey soil decreased significantly as the fiber content increased, while Phanikumar and Singla [7] observed that fiber reinforcement reduced both the heave and the compression index of an expansive clay. Similar improvements in the swell–consolidation response of expansive soils reinforced with polypropylene fibers were reported by Puppala and Musenda [3], Viswanadham et al. [5], and Malekzadeh and Bilsel [8]. Fibers have also been combined with cementitious and pozzolanic additives such as cement and lime, where they mitigate the brittleness introduced by chemical stabilization [9, 10].

Although the strength behavior of fiber-reinforced clays has been studied extensively [4, 9, 11, 12], comparatively fewer studies have addressed the one-dimensional consolidation and swelling response of clays reinforced with different fiber types, and the influence of fiber content on the consolidation parameters (Cc, Cr, cv) is not yet fully clarified. In a previous study by the authors [13], the compaction, unconfined compression, California Bearing Ratio (CBR), and cyclic triaxial behavior of the same CH and CL soils reinforced with polypropylene (PP), copolymer (CP), and virgin homopolymer polypropylene fibers was investigated, and it was shown that fiber inclusion improves both the static strength and the cyclic softening resistance of the mixtures. The present study extends that experimental program to the volumetric behavior of the same soil–fiber combinations. One-dimensional oedometer tests were performed on CH and CL soils reinforced with PP and CP fibers at contents of 0.25%, 0.50%, and 0.75% by dry weight, and the free swell percentage, compression index, recompression index, and coefficient of consolidation of each mixture were evaluated and compared with the available literature.

2 Materials

2.1 Soils

Two natural clayey soils were used in the experimental program, identical to those employed in the companion study [13]. According to the Unified Soil Classification System (ASTM D2487) [14], Soil-I is classified as a high plasticity clay (CH) and Soil-II as a low plasticity clay (CL). Atterberg limit tests indicate that Soil-I has considerably higher plasticity than Soil-II, and hydrometer analyses show that Soil-I also has a higher clay fraction. The index properties of both soils are summarized in Table 1.

Table 1. Index and compaction properties of the soils tested [13].

Property	Soil-I	Soil-II
Liquid limit, LL (%)	78	41
Plastic limit, PL (%)	28	23
Plasticity index, PI (%)	50	18
Gravel (%)	0	0
Sand (%)	3	2
Silt (%)	27	53
Clay (%)	70	45
Optimum water content (%)	27	26

Property	Soil-I	Soil-II
Maximum dry unit weight (kN/m^3)	15.04	15.32
USCS class	CH	CL

2.2 Fibers

Two types of commercially available synthetic fibers were used: fibrillated polypropylene (PP) fibers and monofilament copolymer (CP) fibers. These fibers are primarily marketed for the reinforcement of concrete in accordance with ASTM C1116 [15], where they are used to control plastic and settlement shrinkage cracking. Both fibers exhibit excellent acid and alkali resistance and a specific gravity of 0.91. Prior to mixing, the fibers were cut to a uniform length of 6 cm, consistent with the companion study [13]. The physical properties of the fibers are given in Table 2.

Table 2. Physical properties of the fibers used in the experimental program [13].

Property	PP	CP
Color	White	Gray
Form	Fibrillated fiber	Monofilament fiber
Acid/alkali resistance	Excellent	Excellent
Specific gravity	0.91	0.91
Tensile strength (MPa)	570	758
Length used in tests (cm)	6	6

3 Experimental Program and Testing Procedure

The experimental program was carried out at the Soil Mechanics Laboratories of Işık University and İstanbul Aydın University. Each soil was oven-dried, pulverized, and mixed with PP or CP fibers at contents of 0%, 0.25%, 0.50%, and 0.75% by dry weight of soil. The fibers were added gradually during dry mixing to obtain a uniform, random distribution and to avoid balling of the fibers, after which the required amount of water was added. In total, fourteen mixtures (two plain soils and twelve soil–fiber combinations) were prepared. All specimens were compacted at the maximum dry unit weight and optimum water content obtained from standard Proctor tests (ASTM D698) [16] on the corresponding mixtures.

One-dimensional consolidation tests were performed in fixed-ring oedometers in accordance with ASTM D2435 [17] on specimens 50 mm in diameter and 20 mm in height. Following assembly, the specimens were inundated under a seating pressure of 7 kPa and allowed to swell freely until the swell deformation stabilized; the free swell percentage was computed as the ratio of the swell deformation to the initial specimen height, following the one-dimensional swell procedure of ASTM D4546 [18]. The specimens were subsequently loaded incrementally to 25, 50, 100, 200, 400, and 800 kPa, with each increment maintained for 24 h, and then unloaded in steps back to 25 kPa. Dial gauge readings were recorded at standard time intervals during each increment. The compression index (Cc) was determined from the slope of the virgin portion of the e–log σ′ curve, the recompression index (Cr) from the unloading branch, and the coefficient of consolidation (cv) using Casagrande's logarithm-of-time fitting method for the 100–200 kPa increment.

4 Results and Discussion

4.1 Stress–Void Ratio Response

Representative e–log σ′ curves for the plain and fiber-reinforced CH and CL soils are presented in Fig. 1 and Fig. 2, respectively. For both soils, the addition of fibers shifts the virgin compression line to a flatter slope and reduces the rebound upon unloading, indicating that the fiber network restrains both the compression of the soil skeleton and its elastic recovery. This behavior is consistent with the observations of Phanikumar and Singla [7] and Estabragh et al. [11], who attributed the reduced compressibility of fiber-reinforced clays to the mobilization of tensile stresses along the fiber–clay interfaces, which carry part of the applied load and restrict the rearrangement of clay particles.

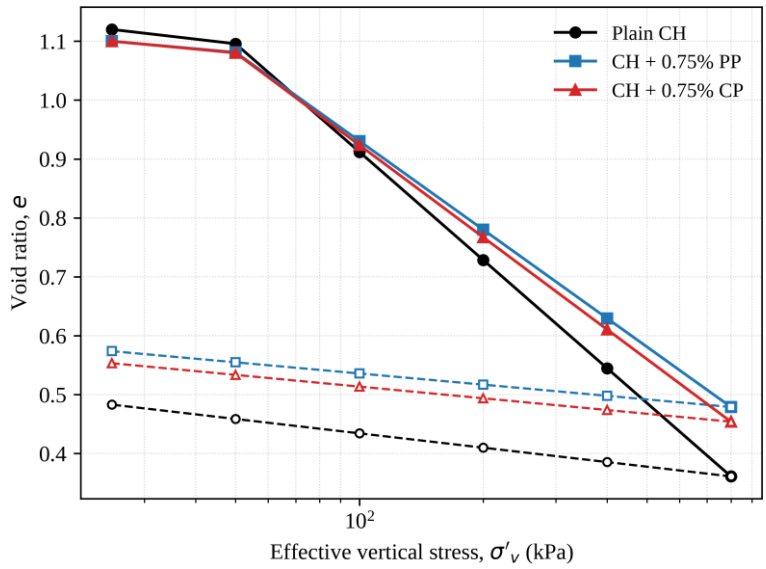

Fig. 1. e–log σ′ curves for plain and fiber-reinforced CH soil (solid lines: loading; dashed lines: unloading).

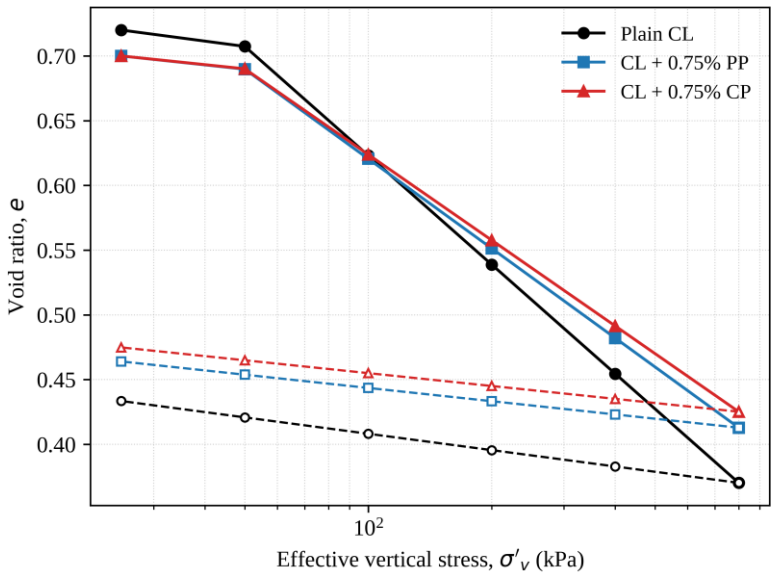

Fig. 2. e–log σ′ curves for plain and fiber-reinforced CL soil (solid lines: loading; dashed lines: unloading).

4.2 Swelling Behavior

The free swell percentages measured upon inundation are listed in Tables 3 and 4 and plotted against fiber content in Fig. 3. The plain CH soil exhibited a free swell of 10.6%, more than twice that of the plain CL soil (4.3%), consistent with its higher plasticity index and clay fraction. The inclusion of both fiber types reduced the swell percentage monotonically over the range of contents investigated. For the CH soil, the free swell decreased to 6.1% at 0.75% PP content (a 42% reduction) and to 6.8% at 0.75% CP content (a 36% reduction). For the CL soil, the corresponding values were 2.8% for PP (35% reduction) and 2.4% for CP (44% reduction).

The reduction in swelling can be attributed to two complementary mechanisms reported in the literature. First, the fibers replace part of the active clay mass, slightly reducing the total swelling potential per unit volume. Second, and more importantly, as the clay minerals hydrate and tend to expand, tensile stresses are mobilized along the fiber–soil interfaces; the randomly oriented fiber network therefore acts as a three-dimensional internal restraint against heave [5–7]. It is noteworthy that the fibrillated PP fibers were somewhat more effective in the high plasticity CH soil, whereas the monofilament CP fibers produced the largest swell reduction in the CL soil. A similar dependence of the optimum fiber type on soil plasticity was observed in the strength results of the companion study [13], where the highest CBR improvement of the CL soil was obtained with 0.75% CP fiber. The fibrillated structure of the PP fibers provides a larger effective interface area, which appears to be mobilized more efficiently by the stronger swelling drive of the CH soil, while the stiffer monofilament CP fibers interact more effectively with the siltier CL matrix.

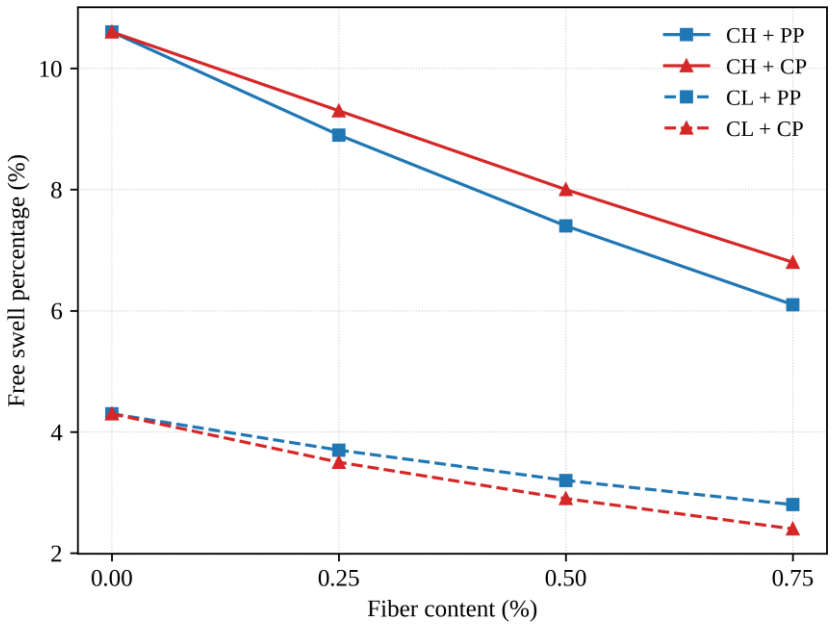

Fig. 3. Variation of free swell percentage with fiber content for CH and CL soils.

4.3 Compressibility and Consolidation Parameters

The consolidation parameters obtained for all fourteen mixtures are summarized in Table 3 for the CH soil and Table 4 for the CL soil. The compression index of the plain CH soil (C_c = 0.61) agrees closely with the empirical correlation $C_c = 0.009(LL - 10)$ proposed by Terzaghi and Peck [19], which yields 0.61 for LL = 78; the plain CL value (C_c = 0.28) is likewise consistent

with the correlation. With increasing fiber content, Cc decreased gradually to 0.50 (PP) and 0.52 (CP) for the CH soil and to 0.23 (PP) and 0.22 (CP) for the CL soil at 0.75% content, corresponding to reductions of about 15–21%. The recompression index followed the same trend, decreasing by roughly 20% at the highest fiber content. These reductions are of the same order as those reported by Phanikumar and Singla [7] for polypropylene fiber-reinforced expansive clays and by Estabragh et al. [11] for fiber–clay composites, and they imply proportionally smaller primary consolidation settlements of reinforced subgrades under embankment and pavement loading.

Table 3. Results of oedometer tests for the CH soil.

No	Mixture	Free swell (%)	C_c	C_r	c_v ($\times 10^{-4}$ cm^2/s)
1	Plain soil (CH)	10.5	0.63	0.084	0.43
2	99.75% CH + 0.25% PP	8.8	0.58	0.075	0.56
3	99.50% CH + 0.50% PP	7.3	0.55	0.069	0.64
4	99.25% CH + 0.75% PP	6.2	0.52	0.063	0.73
5	99.75% CH + 0.25% CP	9.1	0.59	0.073	0.51
6	99.50% CH + 0.50% CP	8.1	0.54	0.069	0.59
7	99.25% CH + 0.75% CP	6.7	0.51	0.063	0.68

Table 4. Results of oedometer tests for the CL soil.

No	Mixture	Free swell (%)	C_c	C_r	c_v ($\times 10^{-4}$ cm^2/s)
1	Plain soil (CL)	4.2	0.27	0.043	0.83
2	99.75% CL + 0.25% PP	3.6	0.26	0.037	1.04
3	99.50% CL + 0.50% PP	3.1	0.24	0.035	1.13
4	99.25% CL + 0.75% PP	2.8	0.23	0.034	1.28
5	99.75% CL + 0.25% CP	3.4	0.25	0.039	1.05
6	99.50% CL + 0.50% CP	2.8	0.23	0.037	1.23
7	99.25% CL + 0.75% CP	2.3	0.22	0.034	1.38

The coefficient of consolidation increased consistently with fiber content for both soils, as shown in Fig. 4. For the CH soil, c_v increased from 0.40×10^{-4} cm^2/s for the plain soil to 0.71×10^{-4} cm^2/s at 0.75% PP content (a 78% increase), while for the CL soil it increased from 0.85×10^{-4} to 1.35×10^{-4} cm^2/s at 0.75% CP content (a 59% increase). Two mechanisms contribute to this acceleration of consolidation. First, the fiber–clay interfaces provide preferential drainage paths that locally increase the permeability of the composite; second, the reduction in volume compressibility (m_v) directly increases c_v, since c_v is proportional to the ratio of permeability to volume compressibility. Comparable increases in the rate of consolidation of fiber-reinforced clays were reported by Malekzadeh and Bilsel [8] and Estabragh et al. [11]. From a practical standpoint, a higher c_v implies that primary settlements of fiber-reinforced subgrades are completed in a shorter time, which is advantageous for staged construction of highway embankments.

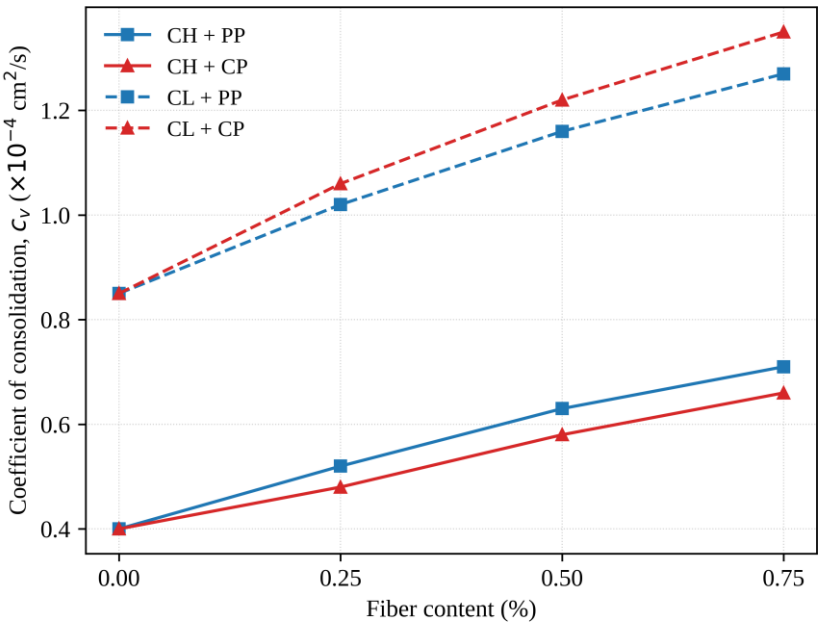

Fig. 4. Variation of the coefficient of consolidation with fiber content for CH and CL soils.

5 Conclusions

This study investigated the one-dimensional consolidation and swelling behavior of high (CH) and low (CL) plasticity clays reinforced with fibrillated polypropylene (PP) and monofilament copolymer (CP) fibers at contents of 0.25%, 0.50%, and 0.75% by dry weight. Based on the results of the oedometer tests, the following conclusions can be drawn:

(1) Fiber inclusion systematically reduced the free swell percentage of both clays over the entire range of contents investigated. The largest reductions were obtained at 0.75% fiber content, reaching 42% for the CH soil with PP fibers and 44% for the CL soil with CP fibers. Fiber reinforcement is therefore an effective means of controlling heave in expansive clay subgrades, particularly in high plasticity soils.

(2) The compression index and recompression index of both soils decreased moderately (by about 15–21%) with increasing fiber content, indicating that the randomly distributed fiber network restrains the compression of the soil skeleton and reduces expected primary consolidation settlements.

(3) The coefficient of consolidation increased by up to 78% for the CH soil and 59% for the CL soil at 0.75% fiber content, implying a faster dissipation of excess pore water pressures and shorter consolidation times for reinforced subgrades.

(4) The fibrillated PP fibers were more effective in the high plasticity CH soil, whereas the monofilament CP fibers gave the best performance in the CL soil, in agreement with the strength results of the companion study on the same soils.

Within the range investigated, the swelling and compressibility parameters improved continuously up to 0.75% fiber content, and no optimum content could be identified from the swelling aspect. In future work, the experimental program should therefore be extended to other fiber percentages (e.g., 1.0%, 1.25%, and intermediate contents) in order to determine the optimum fiber content from the swelling point of view, and the mixtures should also be combined with alternative additives such as fly ash and lime to develop stronger and more volumetrically stable soil combinations.

Acknowledgments

The authors would like to thank the technical staff of the Soil Mechanics Laboratories of Işık University and İstanbul Aydın University for their assistance during the experimental program.

Abstract. Three-dimensional (3D) soil modeling significantly supports decision-making processes-particularly in geotechnical engineering, urban planning, infrastructure, transportation, and mining engineering projects-by accurately depicting the spatial variation of the subsurface environment. Traditional two-dimensional geological maps and cross-sections cannot adequately represent the continuity of soil stratification or the complex subsurface structure. In particular, conducting new soil investigations in city centers with dense development and archaeological preservation areas is often limited by technical and legal constraints. In this study, a 3D soil model was created using Netcad NetPro/Mine software based on existing borehole data from the Karagümrük neighborhood in the Fatih district of Istanbul, an area subject to similar constraints. Within the scope of the model, lithological units and the groundwater level were evaluated in a shared database to develop a digital subsurface information system. The model enables a reduction in the need for new drilling, the effective use of existing data in areas where drilling is not possible, and rapid access to subsurface conditions. It is anticipated that this study will provide a data infrastructure serving as a decision support system for municipalities and engineering applications.

Keywords: 3D soil modeling, Netcad NetPro/Mine, drilling data, underground information system, Fatih.

1 Introduction

3D soil modeling is one of the fundamental components of modern engineering applications, enabling the numerical representation of the stratigraphic and geological characteristics of the subsurface environment. With the advancement of geographic information systems, digital modeling techniques, and improved data acquisition methodologies, soil data obtained from various sources can be integrated into a single platform, allowing for the high-accuracy modeling of subsurface structures. These models not only enable the 3D visualization of soil layers but also allow for the assessment of the spatial distribution of lithological continuity, groundwater levels, and other geotechnical parameters [1-3]. Today, 3D soil models are effectively used in many fields, including foundation design, tunnel and subway projects, infrastructure investments, urban renewal projects, disaster risk analyses, groundwater management, and mine site analyses. However, conducting new soil investigations in historic city centers is often limited due to dense development, confined work areas, existing infrastructure lines, and archaeological preservation requirements [2, 4]. For this reason, the integrated evaluation of borehole data collected in previous years and their conversion into three-dimensional digital models is of great importance. In this context, the approach of

establishing an integrated city-scale borehole database and generating 3D models has been addressed in only a few independent studies in the literature. In Chennai, India, approximately 175 boreholes from various sources were compiled to create a GIS-based 3D model [1], in Rome, over 800 boreholes were referenced to develop a 3D subsurface model [2], and in Thessaloniki, a database containing over 600 boreholes was used for decision support [5]. The Historic Peninsula of Istanbul is an area where conducting traditional soil investigations is quite challenging due to dense development, narrow transportation corridors, protected cultural heritage sites, and its status as an archaeological site. Furthermore, drilling operations conducted at various depths pose a risk of damaging historic structures and face significant time and cost constraints due to legal permitting processes and archaeological restrictions. For this reason, geotechnical-based 3D modeling approaches-which reduce the need for drilling and can provide continuous data over large areas-are of great importance in determining the region's soil structure. The numerous boreholes drilled at various times throughout the district, when integrated using appropriate methods, form a comprehensive data source representing the region's subsurface structure [6]. In this study, existing drilling data for the Fatih district were converted into a 3D soil model using Netcad NetPro/Mine software; an integrated subsurface information system was created by digitally modeling lithological units and the groundwater level. The developed model is intended to help reduce the need for new drilling, enable the effective use of existing data in areas where drilling is not possible, and allow municipalities and engineering firms to access subsurface information quickly and reliably. Additionally, the data infrastructure created is intended to serve as a foundation for future geotechnical analyses, infrastructure projects, and city-scale digital subsurface information systems.

2 Material and Method

The study area encompasses the Karagümrük neighborhood in the Fatih district, located within the boundaries of Istanbul's Historic Peninsula (Fig. 1). The Karagümrük neighborhood is bordered by Edirnekapı and Topkapı to the north, the Molla Gürani and İskenderpaşa neighborhoods to the east, the Aksaray area to the south, and Silivrikapı and neighborhoods near the city walls to the west. The area has a high population density due to its location along the transportation corridors of the Historic Peninsula.

Fig. 1. The Karagümrük neighborhood in the Fatih district, located within the boundaries of Istanbul's Historic Peninsula

The Karagümrük neighborhood is one of the oldest settlements on Istanbul's Historic Peninsula; due to its dense stock of historic buildings, registered cultural assets, narrow street layout, and archaeological protection status, it is one of the areas where conducting new geotechnical drilling studies is particularly challenging [7, 8]. The urban form of the Historic Peninsula bears layered traces from the Roman, Byzantine, Ottoman, and Republican periods; therefore,

subsurface modeling must also account for a multi-period and heterogeneous subsurface structure [7]. The Karagümrük neighborhood is one of the residential areas with high conservation priority due to its location adjacent to the Theodosius Walls and the numerous registered cultural assets and historic structures in its vicinity. The area is surrounded by historic structures such as the Kariye (Chora) Church, the Tekfur Palace, the Mihrimah Sultan Mosque, and Edirnekapı. Soil investigation surveys and drilling studies to be conducted as part of legal regulations aimed at preserving the mosques, dervish lodges, fountains, cemeteries, and registered examples of civil architecture located in the neighborhood and its immediate surroundings are subject to the approval processes of the relevant preservation boards. Furthermore, due to the existing building density, utility lines, and transportation constraints, drilling is technically impossible at many locations [9]. While this situation limits direct investigation of the subsurface environment, it necessitates an integrated evaluation of drilling data collected in previous years for various purposes. A 3D soil model developed within this framework combines existing drilling data on a single digital platform, enabling reliable predictions of lithological continuity and subsurface conditions in areas where drilling is not possible. Thus, the model contributes to the preservation of historic structures while also serving as an effective decision-support system that reduces the need for new drilling for municipalities, engineering firms, and conservation efforts. For these reasons, as part of this study, a large database has been compiled based on existing geotechnical drilling data obtained from engineering surveys previously conducted by public institutions and private firms. The drilling database includes drilling coordinates, soil elevations, lithological descriptions, stratigraphic boundaries, groundwater levels, and drilling depths, as well as the mechanical properties (stiffness and strength) of the soils. Prior to the 3D modeling process, all drilling records from 2018 to 2026 were reviewed, standardized, and transferred to a common digital database. The first stage of the data transfer process involved the systematic organization of drilling data in Microsoft Excel. In this context, three separate datasets were prepared, each of which was specifically configured for use in the Netcad NetPro/Mine software. The first dataset, the drilling file, contains the X, Y, and Z coordinates for each borehole, along with the total drilling depths (Fig. 2). This file is essential for defining the spatial distribution of the boreholes within the study area and for properly aligning the model with the reference coordinate system. The second dataset, the angle file, contains the initial depth, inclination values, and azimuth information for the boreholes (Fig. 3). This information provides the geometric input necessary to accurately model the borehole axis in three-dimensional space, particularly for inclined or deviated boreholes.

The third dataset, the lithology file, contains the start and end depths, interval thicknesses, and corresponding soil types (e.g., fill, clay, sand, claystone) for the lithological units identified along each borehole (Fig. 4). This file serves as a critical component for the thematic

classification of lithological units, the creation of surfaces, and the construction of the volume model.

Fig. 4. Lithology dataset

These three data tables (Fig. 2, Fig. 3, Fig. 4) ensured the comprehensive preparation of the spatial, geometric, and lithological information required for the Netcad NetPro/Mine platform to fully process the modeling procedures. The digitization of the data has significantly facilitated the management and analysis of geotechnical data. As a result, data mining and statistical analyses can be performed on large datasets, making it possible to examine the spatial distribution and correlations of soil properties. Specifically, for the Karagümrük neighborhood, 3D modeling studies were conducted for the antic fill, clay, and sand units' dominant in the field using 41 lithological data points (Fig. 5).

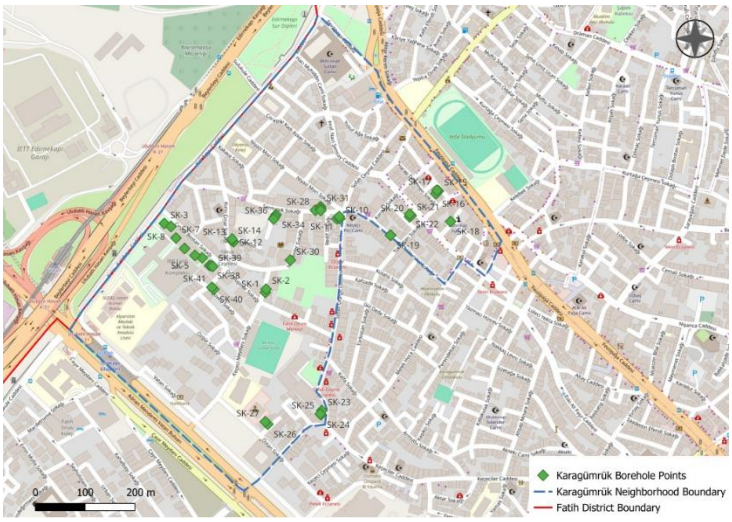

Fig. 5. Soil investigation data points

The 3D subsurface model was developed using Netcad NetPro/Mine software. Once data import was complete, the boreholes were displayed in 3D on the Netcad NetPro/Mine screen. At this stage, the software generated each borehole axis based on its location, inclination, and azimuth, thereby enabling the identification of lithological intervals in terms of both vertical and horizontal continuity. The use of thematic colors to represent these intervals enabled a rapid and analytical assessment of lithological differences and the distribution of strata on a borehole-by-borehole basis. This visualization stage serves as a crucial intermediate step for accurately defining the lithological boundaries required for surface modeling and for conducting correlation analyses between boreholes.

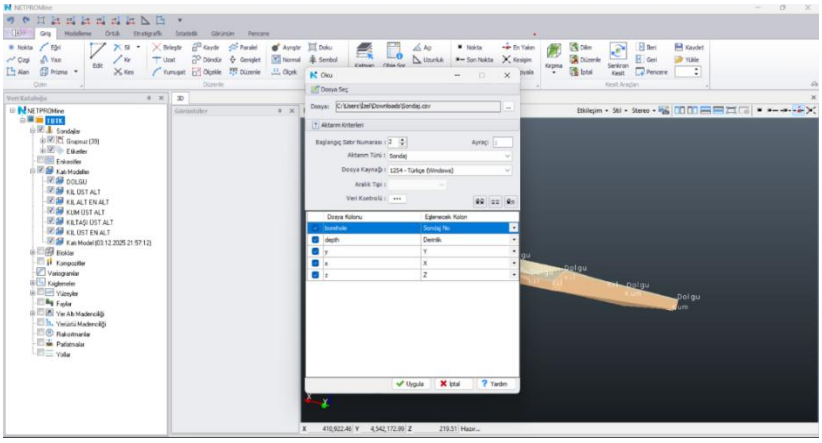

Fig. 6. Visualization of boreholes in a three-dimensional environment

The datasets prepared in Microsoft Excel were loaded into the Netcad NetPro/Mine software in sequence during the second step of the modeling process. First, by importing the borehole file into the system, the software identified the spatial distribution of the boreholes within the study area and established a geometric framework on a three-dimensional coordinate system. Subsequently, upon loading the angle file, Netcad NetPro/Mine calculated the spatial orientation of each borehole, thereby accurately representing the geometric configuration of the borehole axes. With the introduction of the lithology file into the system, the software identified the lithological boundaries for each borehole interval; these boundaries were then visualized using thematic colors and patterns. This made it possible to evaluate the continuity and variation characteristics of lithological units across boreholes. In this context, Fig. 2.6 presents the definition of borehole locations and lithology, while Fig. 2.7 presents the definition of groundwater characteristics and measurement points.

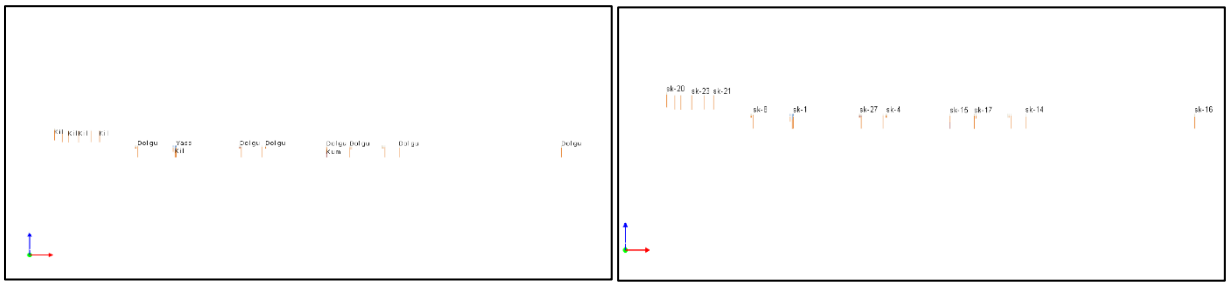

Fig. 2.6: Drilling locations and lithological description

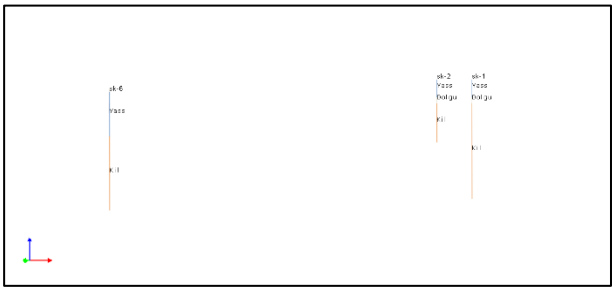

Fig. 2.7: Groundwater monitoring stations

Following the delineation of drilling data in a three-dimensional environment, upper and lower boundary surfaces were created for the lithological units identified in the study area. The Netcad NetPro/Mine software performed surface interpolations for each unit, using the start and end depths of the lithological intervals as references. Within the scope of this study, surface models were generated for three main lithological units (antic fill, sand, clay) and groundwater. The relevant units are presented in Fig.s 2.7-2.14. These surfaces define the spatial continuity of lithological boundaries across the study area and enable the interpretation of horizontal and vertical variations in geological strata.

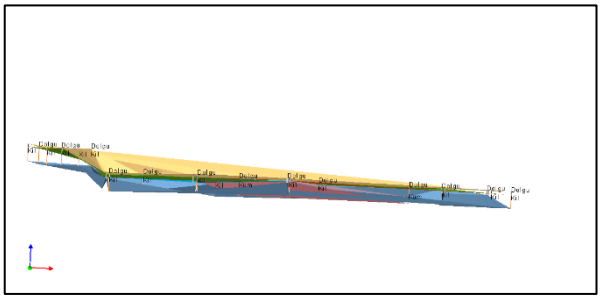

Fig. 2.14: Top view of the surface model of groundwater, showing the fill, clay, and sand units

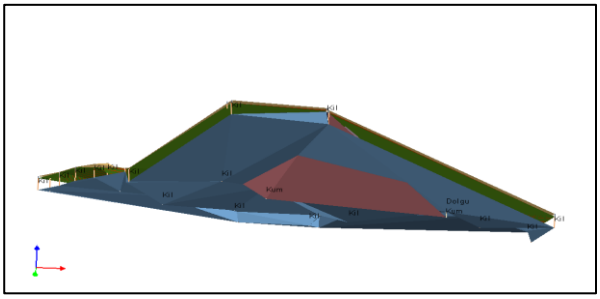

Fig. 2.15: A bottom view of the surface model of groundwater using fill, clay, and sand units

Following the creation of surface models, the lithological units were defined volumetrically. Netcad NetPro/Mine generated three-dimensional solid models for each lithological unit by closing surface pairs. Thus, the volumetric distribution of the fill, clay, and sand units, as well as the layer representing groundwater, within the study area was represented by precise geometric boundaries. Solid models play a fundamental role in geotechnical evaluations because they provide a realistic volumetric representation of soil units, both visually and analytically. Within the scope of this study, solid models were generated for three primary lithological units, and the resulting models are presented in Fig.s 2.15–2.22.

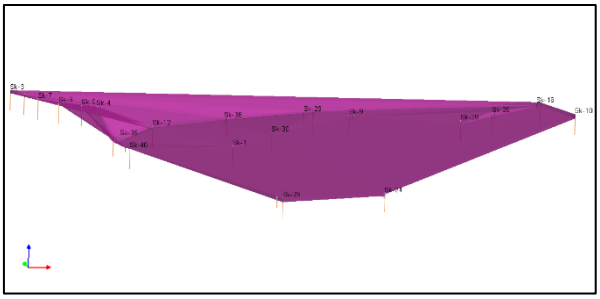

Fig. 2.15: Solid model of the filling unit

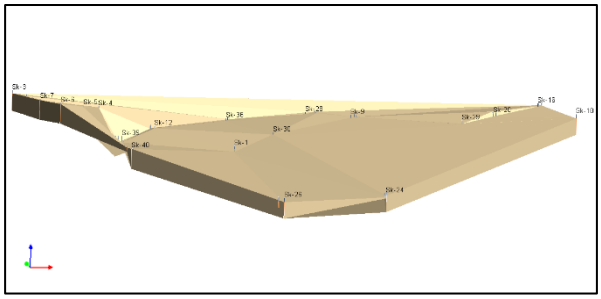

Fig. 2.16: Solid model of the clay unit

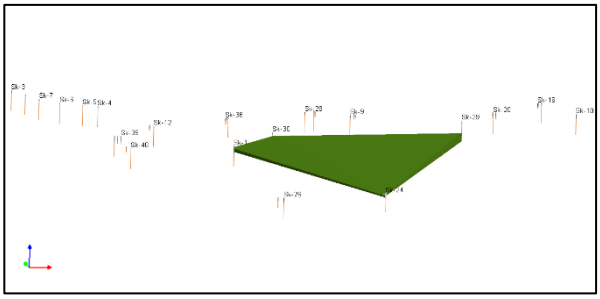

Fig. 2.17: Solid model of the sand unit

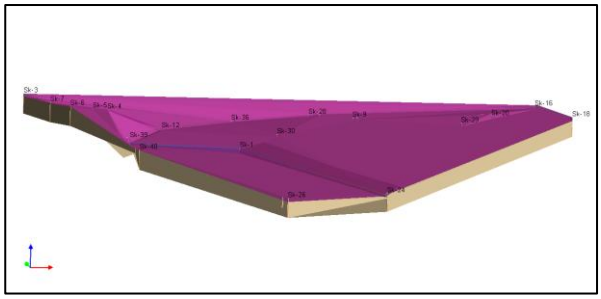

Fig. 2.21: Top view of a solid model representing fill, clay, sand, and groundwater

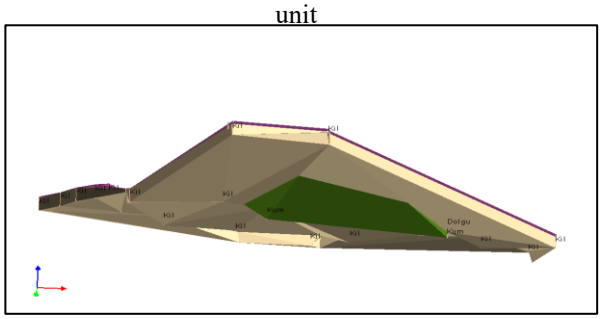

Fig. 2.22: Bottom view of a solid model representing fill, clay, sand, and groundwater

The final stage of the modeling process consisted of block modeling. In this stage, lithological layer models were divided into isometric blocks at a specific resolution; each block was linked to the relevant surface and solid models and classified according to the lithological unit to which it belonged. Thanks to Netcad NetPro/Mine's block modeling module, a structured, numerical, and three-dimensional data structure for the study area was obtained. This block model made a significant contribution to the numerical representation of the spatial distribution of lithological characteristics within the scope of the study. Visualizations of the block modeling work conducted in this context are presented in Fig.s 2.23–2.30.

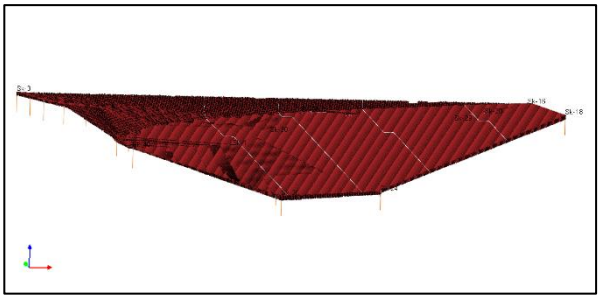

Fig. 2.23: Block model of the filling unit

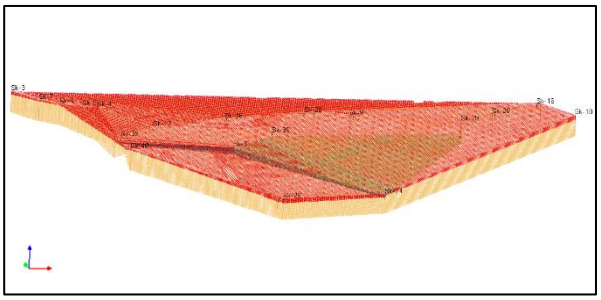

Fig. 2.29: Top view of a block model of groundwater, showing fill, clay, and sand units

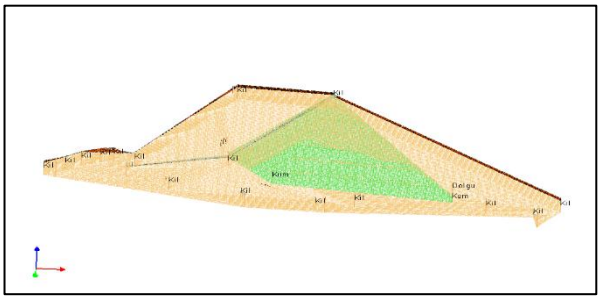

Fig. 2.30: Bottom view of the block model of groundwater, showing the fill, clay, and sand units

As a result of this comprehensive process, the three-dimensional structure of the fill, clay, and sand units in the study area was modeled with high accuracy; lithological boundaries were defined using surface and volume models; and the spatial distribution of soil units was numerically characterized through block modeling. This integrated modeling approach provided by the Netcad NetPro/Mine software has provided a scientific foundation for both the evaluation of field data and the creation of datasets to be used in advanced analyses.

3 Findings

As part of this study, data obtained from geotechnical borings conducted by various institutions in the Karagümrük neighborhood between 2018 and 2026 were consolidated into a single database, and a 3D soil model was successfully created using Netcad NetPro/Mine software. During the modeling process, borehole coordinates, lithological information, stratigraphic boundaries, and other geotechnical data were digitized, thereby enabling a three-dimensional visualization of the study area's subsurface structure. The model clearly reveals the spatial distributions, thickness variations, and interrelationships of the artificial fill, clay, and sand units commonly found in the study area. In particular, it was determined that the surface fill exhibits significant variations in thickness throughout the study area, which is attributed to the Historical Peninsula's long history of settlement, urban development activities, and anthropogenic filling processes. It was also determined that the clay and sand units underlying the fill layer generally exhibit continuity, although variations in thickness and elevation were observed in some areas between boreholes. The lithological surface models and volume models created in the Netcad NetPro/Mine environment have revealed not only the vertical variation of soil units but also their horizontal continuity. Compared to traditional two-dimensional geological cross-sections, the developed three-dimensional model has enabled a more accurate interpretation of the spatial relationships between lithological boundaries. Through the block modeling phase, the lithological units of the study area were represented as a regular grid of numerical cells, thereby creating an integrated subsurface data infrastructure that can be used in engineering analyses. One of the study's most significant findings is that it demonstrates how reliable subsurface data can be generated using existing borehole data in areas where new drilling is not possible due to dense historic development and archaeological preservation requirements. In areas with a high density of historic structures, such as the Karagümrük neighborhood, the ability to conduct new drilling is significantly limited by conservation board permits, existing development, utility lines, and narrow access corridors. Therefore, the three-dimensional model developed reduces the need for new drilling and enables the most effective evaluation of existing data. Through the digital subsurface information system that has been developed, drilling records, lithological units, and other subsurface data can be evaluated together on a single platform, allowing subsurface conditions at any desired location to be visualized quickly. This serves as a crucial decision-support tool, particularly for engineering projects involving foundation design, infrastructure projects, restoration work, urban renewal initiatives, disaster management, and risk analyses of mining sites.

4 Results

In this study, a three-dimensional soil model was created for the Karagümrük neighborhood, located within the boundaries of the Historic Peninsula of Istanbul, using existing geotechnical drilling data within the Netcad NetPro/Mine software environment. The main findings of the study are summarized below.

- Boring data collected by different institutions at various times have been successfully integrated by standardizing them in a common database.

- The three-dimensional spatial distributions, lithological continuities, and volumetric properties of artificial fill, clay, and sand units have been numerically modeled.
- The interpretation of the subsurface structure compared to traditional two-dimensional geological cross-sections.
- It has been demonstrated that reliable subsurface models can be created using existing drilling data in areas where new drilling is not feasible due to dense historical development, archaeological sites, and existing infrastructure.
- The developed model serves as a digital subsurface information system that can be used by municipalities, engineering firms, and public institutions, contributing to a reduction in the need for new drilling and accelerating engineering decision-making processes.

Consequently, the approach developed is not limited to the Karagümrük neighborhood alone but can also be applied to other historic city centers where sufficient drilling data is available. Through this 3D modeling strategy implemented under the TÜBİTAK UDAP 1001 project, it has become possible to develop city-scale digital subsurface information systems by integrating groundwater levels, SPT-N values, shear wave velocity (V_s), permeability, geotechnical parameters, and laboratory test results into the model. Consequently, a comprehensive decision-support system has been established that can be utilized in engineering applications such as earthquake-focused microzoning studies, foundation design, infrastructure planning, restoration projects, and disaster risk management.

Acknowledgments

This study was supported by the Scientific and Technological Research Council of Türkiye (TÜBİTAK) - UDAP under grant number 124M665 within the scope of the "TÜBİTAK- AFAD 1001-UDAP Joint Call for National Earthquake Research Program" and by the Istanbul University-Cerrahpaşa Scientific Research Projects Unit (IUC BAP) as a PhD Thesis Project under grant number 38685. The authors would like to express their gratitude to TÜBİTAK and IUC BAP for their support.

We would also like to extend our sincere thanks to geologicl engineer Cemal Reşit Pehlivanoğlu from YİKOB, AK Zemin, Netcad/Netpromine software team for their valuable contributions and support to the project.

Abstract. Soil liquefaction is one of the most crucial geotechnical hazards that affects the performance of foundations and structures under seismic loading. Standard Penetration Test (SPT)-based simplified procedures, as adopted in the Turkish Building Earthquake Code, remain widely used in engineering practice for evaluating liquefaction triggering potential due to their practicality and compatibility with routine site investigation data. Despite the availability of established methodologies and previously developed computational tools, their accessibility, usability, and dissemination to designers remain limited, often due to licensing constraints and restricted availability. This study presents the development of a web-based tool designed to perform energy-corrected SPT-based liquefaction assessment in a transparent and user-friendly environment. For the consideration of liquefaction potential, the computational framework is based on established simplified procedures, including SPT energy corrections, overburden stress normalisation, fines content adjustment, calculation of liquefaction resistance and earthquake-induced cyclic shear stress, and evaluation of the factor of safety against liquefaction. This tool allows users to input both seismic parameters (e.g., earthquake magnitude, short-period spectral acceleration) and layer-dependent soil properties (e.g., unit weight of soil, SPT-N values, and fine contents) that enables the analysis of single-layered and stratified soil profiles. The primary output provides an assessment of whether each soil layer within the profile satisfies the recommended factor of safety against liquefaction, with results presented in both graphical and tabular formats. The developed tool provides an accessible and practical platform for performing SPT-based liquefaction assessments without requiring specialised commercial software.

Keywords: Soil liquefaction, Standard penetration test, Energy correction, Cyclic resistance ratio, Earthquake-induced demand.

1 Introduction

Soil liquefaction is a major geotechnical concern in earthquake-prone regions due to its potentially severe effects on structures and infrastructures [1]. Loose, saturated cohesionless soils generally tend to densify under loading. During seismic loading induced by an earthquake, however, the essentially undrained response prevents the corresponding volume reduction, causing excess pore water pressure to progressively accumulate within the soil [2]. As excess pore water pressure continues to accumulate, the effective stress carried by the soil skeleton progressively decreases and may eventually approach zero, resulting in a state of liquefaction. The associated loss of shear strength and stiffness can cause substantial ground deformation and adversely affect the seismic performance of foundations, buildings, embankments, tunnels, bridges, and other infrastructures [3]. Consequently, extensive research has led to the development of various methods for evaluating earthquake-induced liquefaction potential,

which can broadly be classified as stress, strain, and energy-based approaches [1]. Among these methods, stress-based procedures have gained widespread acceptance in engineering practice, particularly those employing in-situ test data from the Standard Penetration Test (SPT) or Cone Penetration Test (CPT). The stress-based approach, originally introduced within the simplified procedure by Seed and Idriss [2], evaluates liquefaction triggering by comparing the cyclic stress induced by earthquake loading with the cyclic resistance of the soil.

In this study, a web-based tool was developed to implement the stress-based liquefaction assessment procedure specified in the Turkish Building Earthquake Code (TBEC) [4]. The application utilizes Standard Penetration Test (SPT) data, commonly obtained during routine site investigations, together with the relevant properties of the corresponding soil layers. The developed application provides a freely accessible and user-friendly platform for evaluating the liquefaction potential of both single-layered and stratified soil profiles.

2 Methodology

This paper presents a freely accessible web-based tool named GEOLIQA (Geotechnical Liquefaction Analysis) [5], developed to implement the stress-based liquefaction assessment procedure specified in the Turkish Building Earthquake Code. By integrating routinely available SPT data with the required soil and seismic parameters, GEOLIQA aims to facilitate the practical assessment of liquefaction triggering for layered soil profiles. Although the implementation of established liquefaction procedures in computational tools is not a new concept [6], GEOLIQA is intended to provide an openly accessible alternative that requires no commercial software or licensing [7]. More importantly, the platform has been developed with a flexible structure that allows additional liquefaction assessment methods and functionalities to be incorporated in future versions.

The computational procedure implemented in GEOLIQA begins with the definition of the soil profile and seismic input parameters. For each soil layer, the user provides the raw SPT N-value, saturated and unsaturated unit weights, soil type, and fines content, together with the required SPT correction factors such as C_N, C_R, C_S, C_B, and C_E. The groundwater table is defined for the soil profile, while the short-period design spectral acceleration (S_{DS}) and earthquake moment magnitude (M_w) are specified as seismic input parameters (Fig.1). The S_{DS} value should be determined specifically for the site, considering the local soil class and the selected earthquake ground-motion level, using the Türkiye Earthquake Hazard Maps Interactive Web Application provided by AFAD [8].

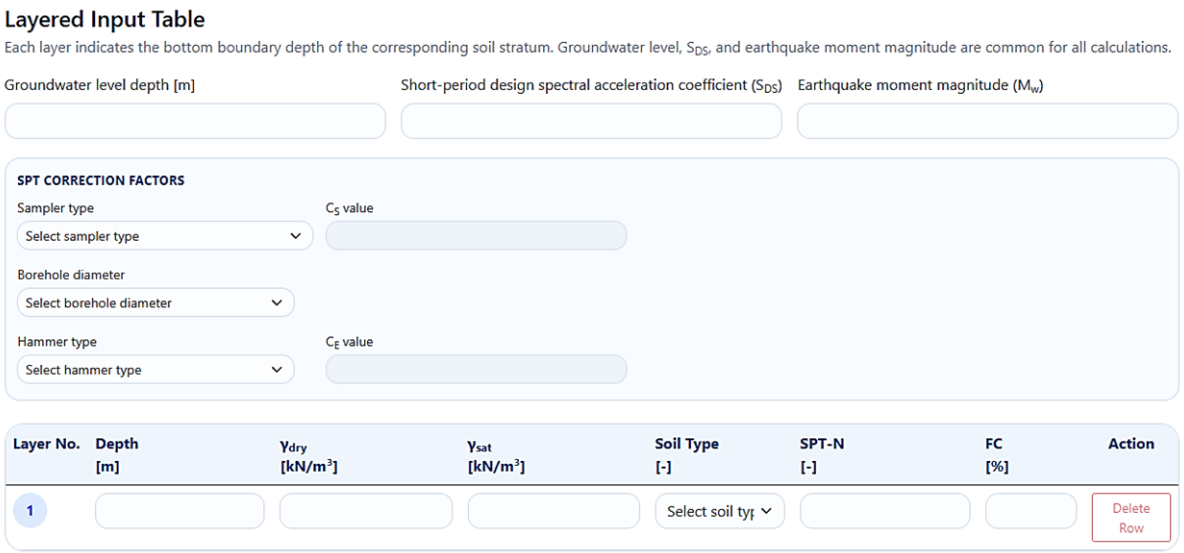

Fig. 1. GEOLIQA interface for defining input parameters and layered soil profiles.

Following the definition of the soil profile and input parameters, GEOLIQA performs the liquefaction assessment for each soil layer. The computational procedure includes correction of the measured SPT blow counts, calculation of total and effective stresses, evaluation of liquefaction resistance and earthquake-induced cyclic demand, and determination of the corresponding factor of safety. The main calculation steps and equations implemented in GEOLIQA in accordance with TBEC are summarized in Table 1.

Table 1. Computational steps and equations implemented in GEOLIQA for SPT-based liquefaction assessment.

Stages/Purposes	Equations/Procedures
Corrected SPT blow count: Correction of measured SPT blow count for field conditions and overburden stress.	$N_{1,60} = NC_N C_E C_B C_R C_S$
Total vertical stress: Determination of total vertical stress at the corresponding depth.	$\sigma_{v0} = \sum \gamma_i h_i$
Pore-water pressure: Determination of hydrostatic pore-water pressure below the groundwater table.	$U = \gamma_w (z - z_w)$
Effective vertical stress: Determination of effective overburden stress at the corresponding depth.	$\sigma'_{v0} = \sigma_{v0} - u$
Fines-corrected SPT blow count: Adjustment of $N_{1,60}$ according to fines content.	$N_{1,60f} = \alpha + \beta N_{1,60}$
Cyclic resistance ratio: Determination of $CRR_{M7.5}$ from the fines-corrected SPT value.	$CRR_{M7.5} = f(N_{1,60f})$
Magnitude correction factor: Adjustment of cyclic resistance according to earthquake magnitude.	$C_M = 10^{2.24}/M_w^{2.56}$
Liquefaction resistance: Determination of cyclic shear resistance of the soil.	$\tau_R = CRR_{M7.5} C_M \sigma'_{v0}$
Earthquake-induced demand: Determination of cyclic shear stress induced by earthquake loading.	$\tau_{earthq} = 0.65\sigma_{v0}(0.4S_{DS})r_d$
Factor of safety: Comparison of liquefaction resistance with earthquake-induced demand.	$FS = \tau_R/\tau_{earthq}$

Based on the calculated factor of safety (FS), GEOLIQA evaluates the liquefaction condition of each soil layer using predefined threshold values. Although a factor of safety higher than unity theoretically indicates that liquefaction triggering is not expected, factors of safety ranging from 1.1 to 1.3 are generally considered appropriate for building sites, with the selected value depending on the importance of the structure and the potential for ground displacement [9–11]. Accordingly, GEOLIQA adopts FS=1.1 as the minimum safety threshold while FS=1.3 is used as the upper threshold to provide a more conservative assessment. In summary, soil layers with FS<1.1 are classified as having high liquefaction potential, those with 1.1≤FS<1.3 are identified as being in a critical condition, while those with FS≥1.3 are classified as having low liquefaction potential.

3 Verification and Application

For verification of GEOLIQA, an example of previously published liquefaction analysis was selected from the literature as a reference case [6]. The input parameters reported in the reference study were introduced into GEOLIQA without modification, and the corresponding analysis was performed under the same conditions. The reference soil profile consists of ten layers extending to a depth of 15 m with a 1.5 m interval, with a groundwater table located at 4 m below the ground surface. The seismic input parameters were M_w=7.5, and S_{DS}=1.14, while the local soil class was defined as ZD. The SPT correction factors were taken as C_B=1.0,

C_E=1.2, and C_S=1.0. Layer-specific SPT-N values, unit weights, and fines contents were adopted directly from the reference study and entered GEOLIQA.

After the definition of the input parameters, the analysis was performed using GEOLIQA. The resulting total and effective vertical stresses and pore-water pressures are presented as depth-dependent profiles, together with the measured SPT-N values, as presented in Fig. 2. The groundwater table is also indicated to facilitate interpretation of the results.

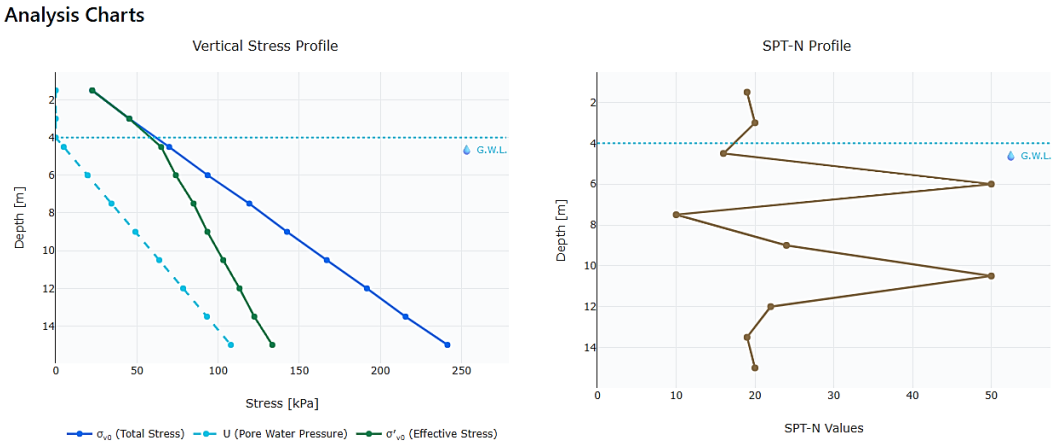

Fig. 2. Vertical stress and SPT-N profiles generated by GEOLIQA.

In addition to the graphical outputs, GEOLIQA provides a detailed layer-by-layer summary of the analysis results, as shown in Fig. 3. The table reports the numerical values of the input, intermediate, and final parameters involved in the calculation procedure, allowing users to directly examine each stage of the liquefaction assessment. This transparent presentation enables the calculated SPT corrections, stress components, liquefaction resistance and demand, and the resulting factor of safety to be readily traced for each soil layer.

Fig. 3. Detailed layer-by-layer analysis results generated by GEOLIQA.

For a more concise interpretation of the results, GEOLIQA also provides a summary table presenting the earthquake-induced demand (τ_{demand}), liquefaction resistance (τ_R), factor of safety (FS), and the corresponding liquefaction assessment for each soil layer (Fig. 4). This summary allows users to readily identify the layers that are potentially susceptible to liquefaction without examining the complete set of intermediate calculation parameters.

Brief Results Summary

Depth [m]	Soil Type [-]	τ_{demand} [kPa]	τ_R [kPa]	FS [-]	Evaluation [-]
1.50	SP	-	-	-	Liquefaction Not Expected
3.00	SP	-	-	-	Liquefaction Not Expected

10.50	SP	-	-	-	Liquefaction Not Expected
12.00	SP	48.50	68.37	1.41	Low Liquefaction Potential
13.50	SP	51.98	27.04	0.52	High Liquefaction Potential
15.00	SP	55.33	45.88	0.83	High Liquefaction Potential

Fig. 4. Summary of layer-based liquefaction assessment generated by GEOLIQA.

Finally, GEOLIQA provides a graphical layer-based assessment of the investigated soil profile, as shown in Fig. 5. The visualization combines the soil profile with the distribution of factor of safety (FS), indicating the position of each layer relative to the predefined assessment thresholds, and a direct comparison between earthquake-induced demand and liquefaction resistance. This integrated representation enables potentially susceptible layers to be readily identified and provides a comprehensive interpretation of the liquefaction response throughout the soil profile.

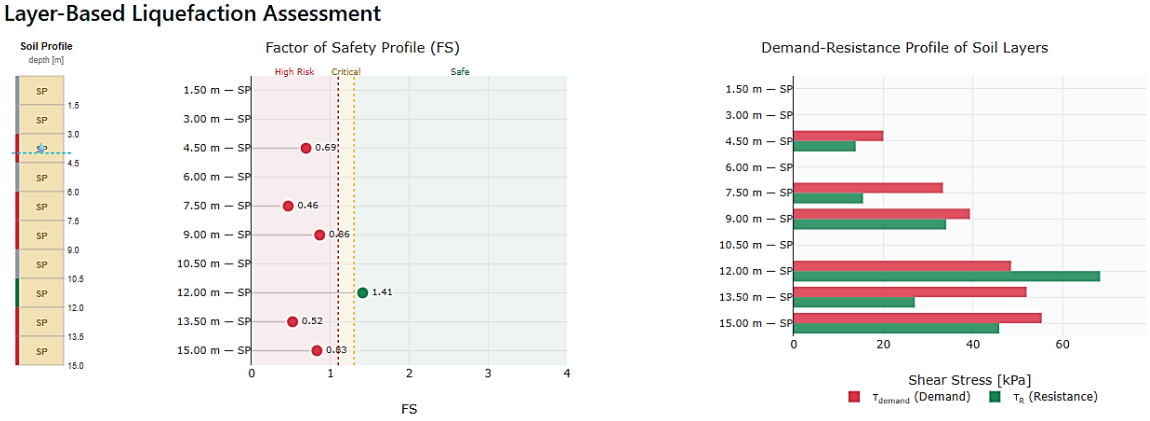

Fig. 5. Graphical layer-based liquefaction assessment generated by GEOLIQA.

It should be noted that GEOLIQA performs the liquefaction triggering assessment only for soil layers satisfying the applicability criteria specified in TBEC [4]. Accordingly, the assessment is applied to potentially liquefiable soils located below the groundwater table and within the upper 20 m of the soil profile, provided that the corrected SPT blow count ($N_{1,60}$) is less than 30 blows/30 cm. Potentially liquefiable soils are defined in TBEC as sand, gravelly sand, silty clayey sand, non-plastic silt, and silt–sand mixtures below the groundwater table. For layers that do not satisfy these criteria, GEOLIQA does not proceed with the liquefaction triggering calculations and reports the result as “Liquefaction Not Expected.”

4 Summary and Conclusions

This study presented GEOLIQA, a freely accessible web-based application developed for SPT-based liquefaction assessment in accordance with the procedure specified in the Turkish Building Earthquake Code (TBEC). The application integrates the required SPT corrections, stress calculations, liquefaction resistance and earthquake-induced demand calculations, and factor of safety assessment within a single computational environment.

The computational implementation was verified using a previously published liquefaction assessment example, in which the same soil profile and seismic input parameters were reproduced in GEOLIQA. The results obtained by GEOLIQA were consistent with the corresponding values reported in the reference study, confirming the correct implementation of the adopted calculation procedure. In addition to the numerical calculations, GEOLIQA provides detailed layer-by-layer results, concise liquefaction classifications, and graphical representations of the factor of safety and demand–resistance relationship throughout the soil profile.

The principal contribution of GEOLIQA is therefore not the introduction of a new liquefaction assessment methodology, but the implementation of an established code-based procedure in a transparent, freely accessible, and user-friendly web environment. By allowing the intermediate and final calculation parameters to be directly investigated, this web-based tool can facilitate both routine engineering assessment and educational use. Furthermore, its web-based structure provides a platform that can be continuously updated and extended as assessment procedures and regulatory requirements evolve.

Abstract. The behavior of buried flexible pipes under high fill loading depends on pipe stiffness, backfill properties, and soil–pipe interaction. This study numerically investigates the effect of EPS geofoam on the soil arching and deformation behavior of HDPE pipes with inner diameters of 0.60 m and 0.30 m. A PLAXIS 2D modelling approach calibrated using field measurements from the Deep Burial Project was used. The pipes, defined as HDPE-0.60 and HDPE-0.30, were analyzed under a 30 m fill height. Crushed stone, sand, and clay backfills were considered together with two different EPS geofoam configurations, namely EPS placed above the pipe crown and EPS placed around the pipe. The results were compared with the reference case without EPS. The comparison showed that the use of EPS geofoam increased positive soil arching and generally reduced the stresses transferred to the pipes. For the 0.60 m diameter pipe, at H/D ≈ 48, the vertical arching factor ranged from about 0.20 to 0.30 for granular backfills in the EPS models. For the 0.30 m diameter pipe, at H/D ≈ 96, the lowest vertical arching factor values for granular backfills decreased to approximately 0.15. The model in which the pipe was surrounded by EPS generally produced lower horizontal arching factors, whereas the model with EPS placed above the pipe crown provided vertical deflection ratios closer to zero in several cases. Overall, the results indicate that EPS geofoam configuration and backfill material type affect both stress redistribution and deformation behavior of small-diameter HDPE pipes under high fill conditions.

Keywords: EPS Geofoam; Small-Diameter HDPE Pipe; Soil Arching; High Fill Height

1 Introduction

The behavior of buried flexible pipes cannot be explained solely by the mechanical properties of the pipe material; it is the combined result of pipe stiffness, backfill properties, construction conditions, and soil–structure interaction developing around the pipe. In the calculation of vertical loads transferred to buried pipes, the weight of the soil prism above the pipe and the shear stresses mobilized between this prism and the adjacent soil zones are considered as the main components. This interaction produces soil arching depending on the relative settlement differences around the pipe and causes the load transferred to the pipe to differ from the direct weight of the overlying fill [1, 2]. In flexible pipes, deformation of the pipe section under

vertical loading may cause the soil prism above the pipe to settle more than the adjacent soil zones. In this case, positive soil arching develops; part of the overburden load is transferred to the adjacent soil zones, and the vertical stress acting at the pipe crown may become lower than the geostatic stress [3, 4].

In recent years, HDPE pipes have been widely used in buried infrastructure systems because of their light weight, corrosion resistance, and ease of installation. However, the flexible nature of these pipes makes pipe–soil interaction more important in design. The behavior of HDPE pipes under soil loading has been investigated by different researchers through field measurements, laboratory tests, and numerical analyses, and it has been shown that pipe stiffness, backfill properties, and compaction conditions can play important roles in pipe response [3, 4]. Studies on small-diameter corrugated HDPE pipes have shown that construction effects arising from the layer-by-layer placement and compaction of backfill significantly influence pipe deformation and the earth pressures developing around the pipe. These studies have demonstrated that pipe behavior cannot be explained solely by pipe diameter and pipe stiffness, but should be evaluated together with parameters such as the modulus of the sidefill soil, the degree and method of compaction, trench geometry, and the thickness and unit weight of the soil cover [5–7].

Under high-fill conditions, the earth loads acting on buried pipes increase, and the distribution of vertical and horizontal stresses around the pipe becomes an important design consideration. One method used to reduce these loads is the compressible inclusion approach, commonly referred to as the induced trench or imperfect ditch method. In this method, deformation of a compressible material placed above the pipe crown increases the relative settlement between the soil prism over the pipe and the adjacent soil zones. This increased relative settlement mobilizes shear stresses along the vertical boundaries of the soil prism and promotes positive soil arching, thereby transferring part of the overburden load to the adjacent soil and reducing the vertical load reaching the pipe [4, 8, 9]. EPS geofoam is one of the compressible materials used for this purpose because of its low stiffness and controlled compressible behavior. Previous experimental and numerical studies have shown that EPS geofoam panels can reduce vertical earth pressures acting on buried pipes and modify the horizontal–vertical stress distribution around the pipe [8, 9].

Studies conducted specifically on HDPE pipes have shown that the use of EPS geofoam not only reduces vertical stress but also affects pipe deformation by changing the pipe–soil interaction mechanism. Kılıç and Akınay [4] conducted full-scale laboratory tests on a 300-mm nominal-diameter corrugated HDPE pipe and reported that an EPS panel placed above the pipe crown significantly reduced the vertical stress at the pipe crown, the horizontal stress at the pipe springline, and pipe deflections. Akyelken and Kılıç [10] investigated buried HDPE pipes with EPS geofoam using PLAXIS 2D analyses supported by experimental measurements and showed that EPS geofoam configurations can reduce the vertical and horizontal stresses around buried HDPE pipes. Kılıç et al. [11] also investigated the effects of EPS geofoam configurations on the stress and deformation response of large-diameter thermoplastic pipes under high-fill conditions. In the present study, the investigation is focused on small-diameter HDPE pipes subjected to very high H/D ratios, considering different backfill materials and EPS geofoam configurations.

The numerical modelling approach used in this study was based on field data obtained from the Deep Burial Project, which was conducted to investigate the behavior of buried thermoplastic pipes under high-fill conditions [12]. Using the calibrated PLAXIS 2D modelling approach, small-diameter HDPE pipes with inner diameters of 0.60 m and 0.30 m were analyzed parametrically under a 30 m high fill.

2 Numerical Model and Analysis Program

In the field experiments conducted within the scope of the Deep Burial Project, large-diameter PVC and HDPE pipes were investigated under high fill loads. In these experiments, the vertical stresses acting at the pipe crown, the horizontal stresses acting at the pipe springline, and the horizontal and vertical pipe deflections were measured. These field test conditions were modelled in PLAXIS 2D, and the modelling approach was calibrated by comparing the stress and deflection results obtained from the numerical analyses with the field measurements [11-13].

A two-dimensional plane-strain approach was adopted in the numerical analyses. A medium-density finite-element mesh consisting of 15-node triangular elements was used, and the construction sequence was simulated using staged construction. The lateral boundaries were restrained in the horizontal direction while vertical displacement was allowed, whereas the bottom boundary was fixed in both the horizontal and vertical directions.

Following the calibration stage, parametric analyses were performed for small-diameter HDPE pipes that were not directly included in the field test program. In this study, two HDPE pipes with inner diameters of 0.60 m and 0.30 m were considered, and these pipes are referred to as HDPE-0.60 and HDPE-0.30, respectively. Therefore, the analyses should be considered as calibrated-model-based parametric numerical analyses rather than direct field validation for these specific pipe diameters. The properties of the small-diameter HDPE pipes used in the parametric analyses are given in Table 1. The pipe parameters were taken from the values reported by Bozkurt (2021) [13].

The HDPE pipes were modelled using the tunnel option in PLAXIS 2D, and their behaviour was considered elastic.

Table 1. Properties of the small-diameter HDPE pipes used in the parametric analyses.

Pipe code	Inner diameter, D (m)	Pipe stiffness (kN/m/m)	Moment of inertia, I (m^4/m)	Axial stiffness, EA (kN/m)	Flexural rigidity, EI (kNm^2/m)
HDPE-0.60	0.60	215	1.77×10^{-6}	7500	0.922
HDPE-0.30	0.30	378	4.886×10^{-7}	7032.41	0.1906

Note: The Poisson's ratio of both HDPE pipes was taken as $\nu = 0.46$.

The 30 m embankment fill was constructed in 30 stages by adding 1 m-thick fill layers. Three different backfill materials were considered: crushed stone, sand, and clay. The backfill soils were represented using the Hardening Soil (HS) model. These materials were selected to examine the influence of backfill stiffness and strength properties on stress redistribution, soil arching, and pipe deformation response. The backfill parameters used in the analyses are summarized in Table 2.

EPS geofoam with a nominal density of 15 kg/m³ (EPS15) was used as the compressible inclusion in the analyses. The EPS15 response was represented using a piecewise linear elastic formulation based on the uniaxial compression test data reported in the underlying numerical modelling study [11, 13]. An interface strength reduction factor of R_{inter}=0.67 was used for the pipe–backfill interface, whereas R_{inter}=1.00 was adopted for the pipe–EPS and EPS–backfill interfaces [13]. After the pipe and backfill properties were defined, three numerical model cases were considered to evaluate the effect of EPS geofoam configuration. The reference model represents the case without EPS geofoam.

Table 2. Material properties of the backfill soils used in the numerical analyses.

	Crushed stone	Sand	Clay
Natural unit weight, γ_n (kN/m^3)	22	17.70	20.4
Reference secant stiffness, E_{50}^{ref} (kN/m^2)	180000	9500	5210
Reference tangent oedometric stiffness, E_{oed}^{ref} (kN/m^2)	180000	9500	5210
Reference unloading-reloading stiffness, E_{ur}^{ref} (kN/m^2)	54000	28500	15630
Cohesion, c (kN/m^2)	-	-	34.5
Friction angle, φ (°)	40	37	15
Dilatancy angle, ψ (°)	5	7	-
Power for stress-level dependency, m (-)	0.8	0.5	0.5

In Model 1, EPS geofoam was placed above the pipe crown. In Model 2, EPS geofoam was placed around the pipe. These configurations were used to investigate how the location of the compressible inclusion affects stress redistribution, soil arching, and pipe deformation under high-fill loading [11, 13], as shown in Fig. 1.

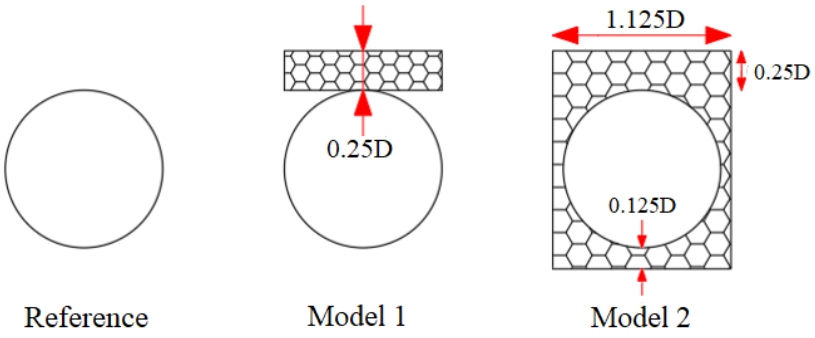

Fig. 1. Numerical model configurations used in the high-fill analyses: reference model, Model 1 with EPS geofoam above the pipe crown, and Model 2 with EPS geofoam around the pipe.

The stress redistribution around the pipe was evaluated using the vertical arching factor (VAF) and horizontal arching factor (HAF), defined as

$$VAF = \frac{W_e}{PL} = \frac{2N_{sp}}{P_L} \quad (1)$$

$$HAF = \frac{W_h}{PL} = \frac{N_c + N_i}{P_L} \quad (2)$$

where W_e and W_h are the total vertical and horizontal loads, respectively; P_L is the prism load; N_{SP} is the soil stress at the pipe springline; and N_c and N_i are the soil stresses at the pipe crown and invert, respectively [11].

The horizontal and vertical pipe deflection ratios were calculated as (Δx/D) x 100 and (Δy/D) x 100, respectively, where Δx and Δy are the changes in the horizontal and vertical pipe diameters and D is the initial inner diameter. Positive values indicate an increase in the corresponding diameter, whereas negative values indicate a decrease.

The results were evaluated in terms of H/D, where H is the embankment fill height and D is the inner pipe diameter.

3 Results and Discussion

The numerical results were evaluated by comparing the reference model with the EPS geofoam configurations for each pipe diameter and backfill material. The vertical arching factor and horizontal arching factor were used to assess the stress redistribution around the pipe, whereas the horizontal and vertical deflection ratios were used to evaluate the pipe deformation response. The results are presented separately for the HDPE-0.60 and HDPE-0.30 pipes in order to examine the influence of pipe diameter and H/D ratio under the same 30 m fill height.

Since the two pipes also have different pipe stiffnesses, the differences between their responses reflect the combined influence of pipe diameter, H/D ratio, and pipe stiffness rather than the isolated effect of H/D.

3.1 Effect of EPS Geofoam on Arching and Deflection Behavior

The variation of vertical and horizontal arching factors with H/D ratio for the HDPE-0.60 pipe is shown in Fig. 2.

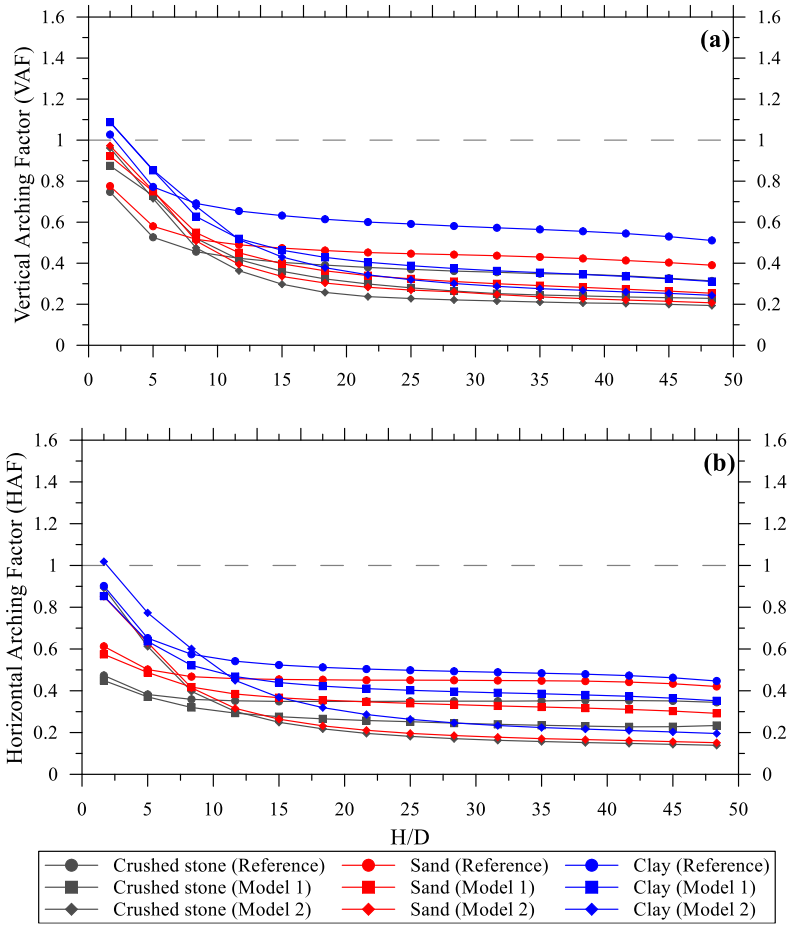

Fig. 2. Variation of arching factors for the HDPE-0.60 pipe under different backfill materials and EPS geofoam configurations: (a) vertical arching factor; (b) horizontal arching factor.

In Fig. 2(a), the vertical arching factor decreases with increasing H/D ratio for all backfill materials and model cases. The decrease is more pronounced at lower H/D values, whereas the curves show a flatter trend at higher H/D values. At the same H/D values, the vertical arching factors for the clay backfill generally remain the highest. Lower vertical arching factors are obtained for the crushed stone and sand backfills. Except at the lowest H/D values, the EPS models generally show lower vertical arching factors than the reference case.

Fig. 2(b) also shows a decreasing trend in the horizontal arching factor with increasing H/D ratio. The horizontal arching factors for the clay backfill generally remain higher than those for the crushed stone and sand backfills. When the EPS configurations are compared, Model 2, in which EPS is placed around the pipe, gives lower horizontal arching factors than Model 1 and the reference model in most cases.

The variation of horizontal and vertical deflection ratios for the HDPE-0.60 pipe is presented in Fig. 3. In Fig. 3(a), the horizontal deflection ratio increases with increasing H/D ratio in the reference cases. Among the reference cases, the highest horizontal deflection ratios are obtained for the clay backfill, followed by sand and crushed stone.

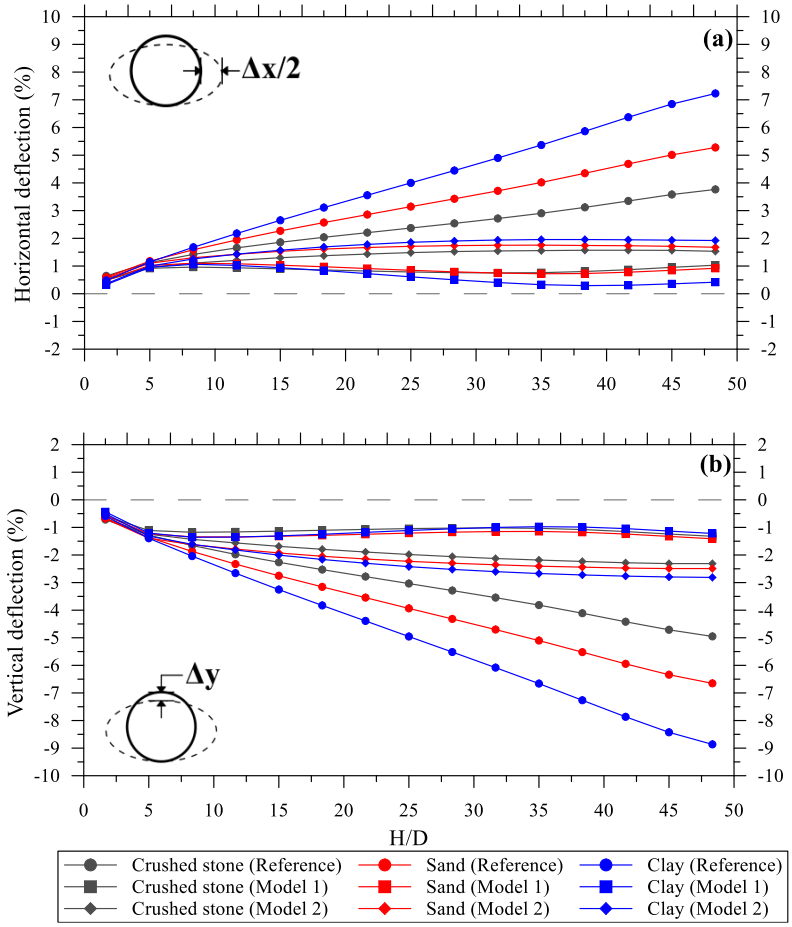

Fig. 3. Variation of pipe deflection ratios for the HDPE-0.60 pipe under different backfill materials and EPS geofoam configurations: (a) horizontal deflection ratio; (b) vertical deflection ratio.

In the EPS models, the horizontal deflection ratios are generally lower than those of the reference cases. Model 1 generally gives the lowest horizontal deflection ratios, whereas the values obtained with Model 2 remain higher than those of Model 1 but generally lower than the reference cases.

Fig. 3(b) shows that the vertical deflection ratios become more negative with increasing H/D ratio in the reference cases. The largest vertical deflection magnitudes are obtained for the clay backfill, followed by sand and crushed stone. Compared with the reference cases, the EPS models reduce the magnitude of vertical deflection for all backfill materials. This reduction is more pronounced for sand and clay backfills. Among the EPS configurations, Model 1 generally gives vertical deflection ratios closer to zero than Model 2.

The variation of vertical and horizontal arching factors with H/D ratio for the HDPE-0.30 pipe is shown in Fig. 4. Since the same 30 m fill height was applied to the smaller pipe diameter, the HDPE-0.30 pipe reached higher H/D values than the HDPE-0.60 pipe.

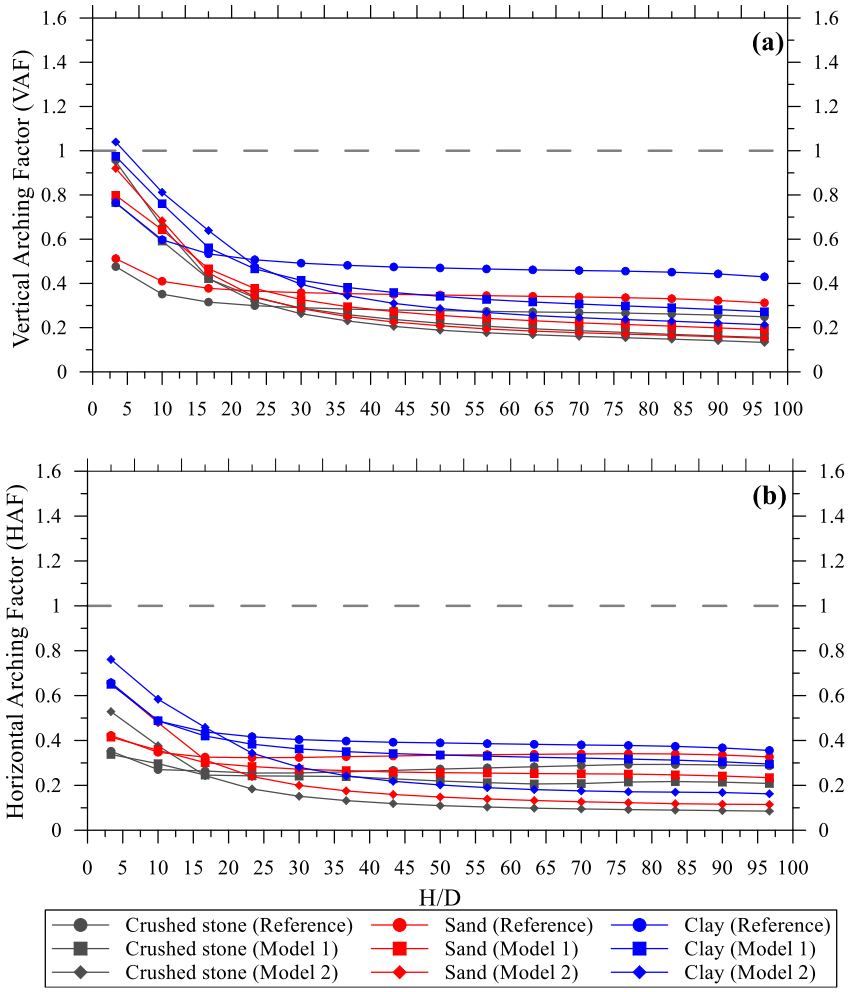

Fig. 4. Variation of arching factors for the HDPE-0.30 pipe under different backfill materials and EPS geofoam configurations: (a) vertical arching factor; (b) horizontal arching factor.

In Fig. 4(a), the vertical arching factor decreases with increasing H/D ratio for all backfill materials and model cases. The decrease is more pronounced at lower H/D values, whereas the curves become flatter at higher H/D values. At the same H/D values, the vertical arching factors for the clay backfill generally remain the highest. The crushed stone backfill generally gives the lowest vertical arching factors, while the sand backfill shows intermediate values. At higher H/D values, the EPS models generally give lower vertical arching factors than the reference case. Fig. 4(b) shows that the horizontal arching factor also decreases with increasing H/D ratio. Similar to the vertical arching factor, the decrease is more rapid at lower H/D values and becomes limited at higher H/D values. The horizontal arching factors for the clay backfill generally remain higher than those for the crushed stone and sand backfills. When the EPS configurations are compared, Model 2, in which EPS is placed around the pipe, generally gives the lowest horizontal arching factors. Model 1 also generally gives lower values than the reference case, but the reduction is generally smaller than that obtained in Model 2.

The variation of horizontal and vertical deflection ratios for the HDPE-0.30 pipe is presented in Fig. 5. In Fig. 5(a), the horizontal deflection ratio increases with increasing H/D ratio in the

reference cases. Among the reference cases, the highest horizontal deflection ratios are obtained for the clay backfill, followed by sand and crushed stone.

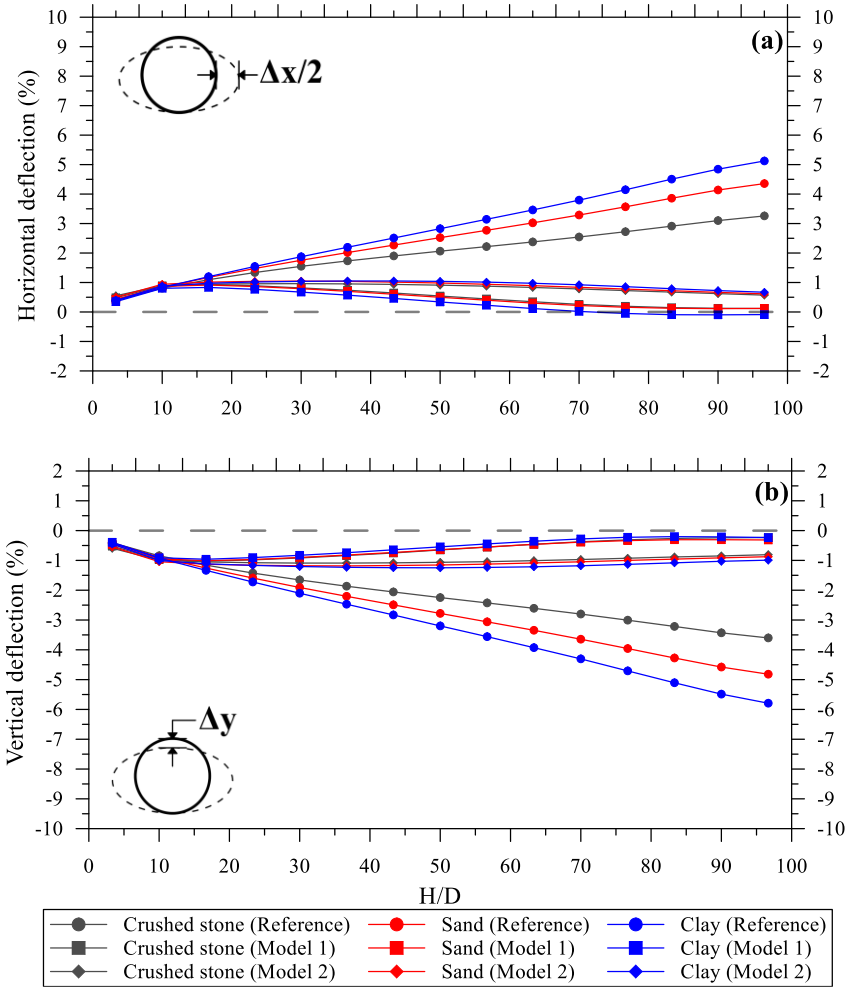

Fig. 5. Variation of pipe deflection ratios for the HDPE-0.30 pipe under different backfill materials and EPS geofoam configurations: (a) horizontal deflection ratio; (b) vertical deflection ratio.

In the EPS models, the horizontal deflection ratios are generally lower than those of the reference cases, with the differences becoming more pronounced as H/D increases. Model 1 generally gives the lowest horizontal deflection ratios and, at higher H/D values, values close to zero or slightly negative.

Fig. 5(b) shows that the vertical deflection ratios become more negative with increasing H/D ratio in the reference cases. The largest vertical deflection magnitudes are obtained for the clay backfill, followed by sand and crushed stone. Compared with the reference cases, the EPS models reduce the magnitude of vertical deflection for all backfill materials. This reduction is more evident at higher H/D values. Among the EPS configurations, Model 1 generally gives vertical deflection ratios closer to zero than Model 2.

3.2 Overall Evaluation of the Results

When the results for the HDPE-0.60 and HDPE-0.30 pipes are evaluated together, the models with EPS generally give lower arching factors than the reference cases. This trend is consistent with previous studies reporting that EPS geofoam, when used as a compressible inclusion, can reduce earth pressures acting on buried pipes by promoting positive soil arching [4, 9]. Similar

reductions in vertical and horizontal stresses around HDPE pipes with EPS geofoam were also reported by Kılıç and Akınay [4] and Akyelken and Kılıç [10].

The results also show that the backfill material affects both the arching factors and the deflection ratios. In the reference cases, clay backfill generally produced higher arching factors and larger horizontal and vertical deflection magnitudes than crushed stone and sand. In the EPS cases, the differences among the backfill materials were generally reduced and depended on the EPS configuration. This observation is in agreement with previous studies showing that pipe response is influenced by the stiffness and compaction characteristics of the surrounding soil, as well as by pipe diameter and pipe stiffness [5–7].

The comparison of EPS configurations indicates that stress reduction and deformation response do not always follow the same trend. Model 2, in which EPS is placed around the pipe, generally gives lower horizontal arching factors, whereas Model 1 provides vertical deflection ratios closer to zero in several cases. In Model 2, the compressible EPS zone along the sides of the pipe allows greater stress redistribution around the springline; compression of this lateral EPS zone contributes to the reduction in horizontal stresses acting on the pipe [11]. Therefore, EPS geofoam configuration should be evaluated by considering both stress redistribution and pipe deformation response.

4 Conclusions

This study investigated the effects of EPS geofoam configuration and backfill material type on the soil arching and deformation behavior of small-diameter buried HDPE pipes under a 30 m high fill. The analyses were performed using a PLAXIS 2D modelling approach calibrated based on field measurements from the Deep Burial Project. The following conclusions can be drawn:

The models with EPS geofoam generally produced lower vertical arching factors than the reference model. This trend was observed for both HDPE-0.60 and HDPE-0.30 pipes. Lower vertical arching factors were generally obtained with crushed stone and sand backfills than with clay backfill. In both pipe diameters, clay backfill generally resulted in higher arching factors than the granular backfills. EPS geofoam configuration affected the horizontal arching factor. Model 2, in which EPS surrounded the pipe, generally resulted in lower horizontal arching factors than Model 1 and the reference model.

The deflection results did not always follow the same trend as the arching factors. Although Model 2 generally produced the lowest horizontal arching factors, Model 1 generally resulted in smaller horizontal and vertical deflection magnitudes. Under the same 30 m fill height, the HDPE-0.30 pipe reached higher H/D values than the HDPE-0.60 pipe and generally exhibited a more pronounced soil-arching response. However, the differences between the two pipe sizes indicate that pipe diameter, H/D ratio, and pipe stiffness should be considered together. Overall, the results indicate that EPS geofoam configuration and backfill material type should be evaluated together when assessing stress redistribution and deformation behavior of small-diameter HDPE pipes under high-fill conditions.

Abstract. The 6 February 2023 Kahramanmaraş earthquake sequence caused extensive ground deformation and liquefaction-related damage in Gölbaşı, Adıyaman, emphasizing the influence of local soil conditions on seismic ground response. This study integrates physical and index soil properties, borehole observations, and Multichannel Analysis of Surface Waves (MASW) and Refraction Microtremor (ReMi) measurements to characterize the earthquake-affected deposits. The investigation program comprised ten investigation pits (AÇ-1–AÇ-10) and seven geotechnical boreholes (SK-1–SK-7). Active MASW and ReMi measurements were conducted at the ten AÇ locations, where soil samples were also obtained for physical and index testing, while the SK boreholes provided soil-profile information with depth, Standard Penetration Test (SPT-N) data, soil samples, and groundwater observations. The physical and index characterization presented herein is based on the currently available laboratory test results, as the broader laboratory testing program is ongoing. Based on these available data, USCS classifications show marked spatial variability: AÇ-1, AÇ-4, AÇ-5, and AÇ-7 are dominated by low-plasticity clay (CL), AÇ-2 and AÇ-3 by poorly graded sand (SP), and AÇ-8 and AÇ-9 by well-graded sand (SW), while AÇ-10 contains a predominantly sandy soil with approximately 13% fines. Plasticity index (PI) ranges from 9.1% to 25.6% among the fines-rich AÇ deposits, while relative density (Dr) ranges from approximately 27% to 91% among the granular samples. Measured SPT-N values in the SK boreholes range from 2 to 37, indicating pronounced spatial and depth-dependent variability in penetration resistance across the investigated deposits**.** Groundwater depths vary from 0.7 to 5.5 m. Inversion of the combined MASW- and ReMi-derived dispersion curves yielded V_{s30} values ranging from 159.9 to 210.2 m/s across the ten AÇ locations, with the lowest value at AÇ-7 and the highest at AÇ-8. The complete V_s–depth profiles exhibited pronounced vertical stiffness variations that are not fully represented by V_{s30} alone. The integrated results indicate that field-scale stiffness reflects the combined influence of soil type, plasticity, density state, penetration resistance, groundwater conditions, and vertical stratigraphy, providing a comprehensive basis for seismic site characterization of the Gölbaşı basin.

1. INTRODUCTION

The 6 February 2023 Kahramanmaraş earthquake sequence caused widespread structural damage and severe ground deformations across southeastern Türkiye. Gölbaşı district of Adıyaman was particularly affected, with post-earthquake investigations documenting sand boils, lateral spreading, settlement, ground cracking, foundation distress, and building tilting

associated with liquefaction-induced ground deformation [1–3]. In the alluvial portion of Gölbaşı, settlements locally reached approximately 40 cm [2]. The location of the study area, the epicenters of the earthquake sequence, and representative earthquake-induced damage are presented in Fig. 1.

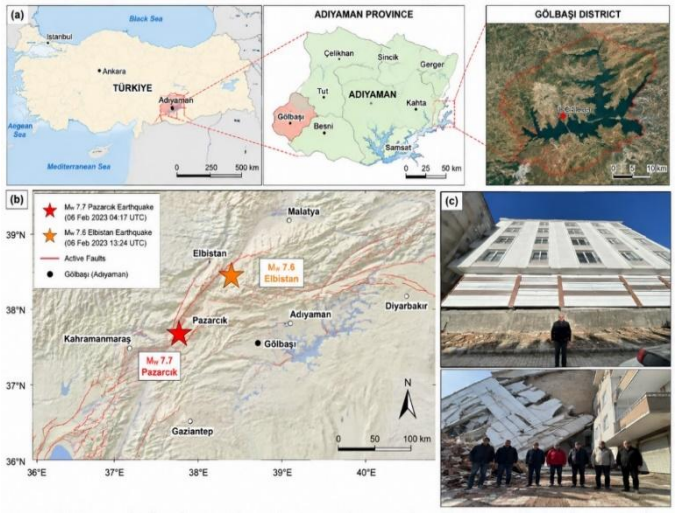

Figure 1. *Location of the Gölbaşı study area and representative earthquake-induced ground and structural damage observed following the 6 February 2023 Kahramanmaraş earthquake sequence.*

The severity of these ground failures is closely related to the geological and geotechnical setting of the Gölbaşı basin. The settlement area is underlain by heterogeneous Quaternary alluvial and marsh deposits comprising gravel, sand, silt, and clay, with locally organic-rich fine-grained sediments near Lake Gölbaşı. Groundwater is also shallow, locally approaching the ground surface [2]. Post-earthquake investigations attributed much of the observed ground failure to liquefaction and cyclic softening and emphasized the influence of local soil conditions on the spatial distribution of damage [3]. Liquefaction-susceptible sandy–silty layers and earthquake-induced strength degradation have also been associated with movements toward Lake Gölbaşı [4].

The earthquake-affected soils exhibit considerable physical variability and cannot be represented solely by clean sands. Fine-containing sands, silts, and low-plasticity clayey soils have also been identified among liquefied or ejected materials [5]. Consequently, grain-size distribution, fines content, natural water content, Atterberg limits, specific gravity, and density state are important for characterizing the heterogeneous deposits and interpreting their geotechnical response.

Geophysical investigations similarly indicate pronounced lateral and vertical variations in the stiffness structure of the Gölbaşı basin, with relatively low shear-wave velocities (V_s) particularly near Lake Gölbaşı [6]. These observations emphasize the importance of evaluating the complete V_s –depth structure rather than relying exclusively on an averaged parameter such as $V_{s\,30}$. Surface-wave methods provide an effective approach for such characterization. Active-source Multichannel Analysis of Surface Waves (MASW) utilizes Rayleigh-wave dispersion to evaluate the 1D shear-wave velocity (V_s) structure with depth [7], whereas Refraction Microtremor (ReMi) utilizes ambient vibrations and extends the investigation toward lower frequencies and longer wavelengths [8]. Their combined use can therefore provide broader dispersion-frequency coverage and improved constraints on one-dimensional V_s profiles.

However, geophysical measurements alone do not fully describe the composition and physical state of heterogeneous deposits, while laboratory index properties obtained from discrete samples cannot provide continuous field-scale stiffness information. Integrating physical soil properties, borehole observations, and surface-wave measurements therefore provides a more comprehensive basis for interpreting the heterogeneous subsurface conditions of Gölbaşı. Despite extensive post-earthquake reconnaissance and recent geotechnical and geophysical investigations, integrated characterization combining spatially distributed MASW–ReMi measurements with physical and index properties remains comparatively limited.

Accordingly, this study integrates geophysical and geotechnical data to characterize the earthquake-affected deposits of Gölbaşı. The investigation program comprised ten investigation pits (AÇ-1–AÇ-10) and seven geotechnical boreholes (SK-1–SK-7). Active MASW and passive ReMi measurements were conducted at the ten AÇ locations to obtain dispersion characteristics, one-dimensional V_s profiles, and V_{s30} values. Soil samples obtained from the AÇ pits and selected depths within the SK boreholes were used for physical and index characterization. Laboratory characterization included grain-size distribution, natural water content, Atterberg limits, specific gravity (Gs), and, for selected granular samples, limiting void ratios and relative density (Dr). SPT-N data and groundwater observations from the SK boreholes were additionally used to characterize depth-dependent subsurface conditions. The combined dataset is used to evaluate spatial and vertical variations in soil composition, physical state, and field-scale stiffness and to provide a basis for subsequent seismic site characterization of the Gölbaşı basin.

2. MATERIALS AND METHODS

2.1. Study Area and Investigation Program

The investigation program was designed to characterize the spatial and vertical variability of the earthquake-affected deposits in the Gölbaşı basin using integrated geotechnical and geophysical data. It comprised ten investigation pits (AÇ-1–AÇ-10), where MASW and ReMi measurements were conducted and soil samples were obtained, and seven geotechnical boreholes (SK-1–SK-7), which provided stratigraphic information, SPT-N data, soil samples, and groundwater observations (Fig. 2).

***Figure 2**. Distribution of the investigation locations in Gölbaşı, showing the AÇ-1–AÇ-10 investigation pits, where MASW–ReMi measurements were conducted, and the SK-1–SK-7 geotechnical boreholes.*

Groundwater depths at SK-1–SK-7 were 2.7, 2.2, 2.7, 1.2, 5.5, 0.7, and 0.8 m below ground surface, respectively, indicating spatially variable but generally shallow groundwater conditions. Measured SPT-N values across the seven boreholes ranged from 2 to 37, indicating considerable spatial and depth-dependent variability in penetration resistance. The lowest SPT-N value (N = 2) was recorded at SK-5 at a depth of 12.00–12.45 m, whereas the highest value (N = 37) was obtained at SK-6 at 19.50–19.95 m. These observations were evaluated together with the borehole stratigraphy and physical soil properties.

2.2. Geotechnical and Physical Soil Characterization

Laboratory testing of samples from the AÇ locations and selected SK borehole depths included natural water content (w), grain-size distribution, fines content, liquid limit (LL), plastic limit (PL), plasticity index (PI), and specific gravity (Gs). For selected granular samples, maximum and minimum void ratios (e_{max} and e_{min}), current void ratio (e), and relative density (Dr) were also evaluated. Grain-size distribution, natural water content, Atterberg limits, and specific gravity were determined in accordance with the applicable ASTM procedures [9–13],

while soils were classified according to the Unified Soil Classification System (USCS) [14]. For selected granular samples, maximum and minimum index densities and relative density were determined in accordance with ASTM D4253 and ASTM D4254 [15,16]. The plasticity index and relative density were calculated as:

$$PI = LL - PL \quad (1)$$

and

$$Dr = [(e_{max} - e)/(e_{max} - e_{min})] \times 100 \quad (2)$$

where LL and PL are the liquid and plastic limits, respectively, and e is the current void ratio. The laboratory results were interpreted together with borehole stratigraphy and SPT-N values to characterize variations in soil type, plasticity, and density or consistency with depth. Detailed physical and index results are provided in Appendix A.

2.3. MASW and ReMi Measurements

Surface-wave measurements were conducted at AÇ-1–AÇ-10 using MASW and ReMi techniques. Active-source MASW method uses Rayleigh-wave dispersion to estimate shear-wave velocity (V_s) with depth [7], whereas ReMi utilizes ambient seismic vibrations and provides complementary lower-frequency and longer-wavelength information to obtain deeper V_s structure [8].

For the MASW surveys, an impact source and a linear multichannel array equipped with 4.5 Hz vertical geophones were deployed, using geophone intervals ranging between 1 and 3 m with source offsets from 4 to 12 m. In contrast, passive surface wave (ReMi) measurements were collected using geophone spacings of 3 to 5 m to record ambient noise without a controlled source; at least eight 30-s records were acquired at each station for dispersion analysis. Representative MASW data acquisition and processing steps are illustrated in Fig. 3

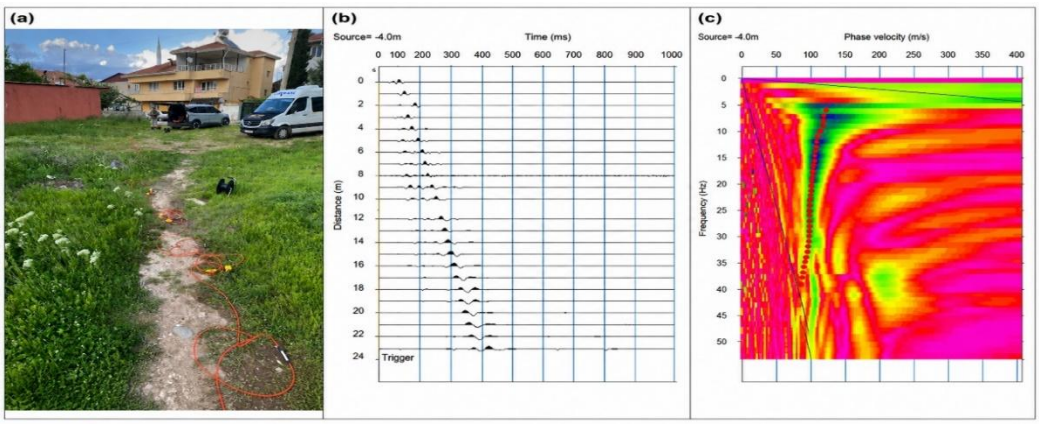

Figure 3. Representative MASW measurements at AÇ-4: (a) field acquisition configuration, (b) recorded multichannel shot gather, and (c) dispersion spectrum with the selected Rayleigh-wave dispersion curve.

2.4. Dispersion Analysis and V_s Profiling

Raw seismic records were initially transformed into the frequency–phase velocity (f–c) domain using distinct wavefield transformation techniques: the phase-shift method was applied to the active-source MASW shot gathers, whereas the τ–p transformation followed by Fourier transform was implemented for the passive ReMi ambient noise records. Fundamental-mode

Rayleigh-wave dispersion trends were subsequently identified and picked from the resulting energy spectra [7,8].

To resolve both near-surface details and deeper strata, high-frequency MASW data and low-frequency ReMi data were merged into a single broadband dispersion curve. A one-dimensional (1D) layered earth inversion was then conducted using the iterative Levenberg–Marquardt damped least-squares algorithm. This inversion scheme successfully resolved high-resolution 1D shear-wave velocity (V_s) profiles at AÇ-1–AÇ-10 [7,17].

The average shear-wave velocity of the uppermost 30 m (V_{s30}) was calculated as follows:

$$V_{s30} = 30/\Sigma(h_i/V_{si}) \quad (3)$$

where h_i and V_{si} are the thickness and shear-wave velocity of the ith layer, respectively, over a total depth of 30 m. V_{s30} values were interpreted together with the complete V_s–depth profiles, and site conditions were evaluated, where applicable, with reference to TBDY 2018 [18].

Finally, the MASW–ReMi-derived V_s profiles were evaluated together with grain-size distribution, fines content, Atterberg limits, water content, Gs, density-state parameters, SPT-N, and groundwater observations. Because laboratory samples represent discrete intervals whereas surface-wave inversion represents larger subsurface volumes, direct point-to-point equivalence was not assumed; instead, the datasets were integrated to assess relationships among soil composition, stratigraphy, physical state, groundwater conditions, and field-scale stiffness.

3. RESULTS AND DISCUSSION

3.1. Physical, Index, and Subsurface Characteristics of the Investigation Locations

The physical, index, and field investigation results demonstrate substantial lateral and vertical variability across the Gölbaşı deposits. The available dataset includes grain-size distribution, fines content, natural water content (w), liquid limit (LL), plastic limit (PL), plasticity index (PI), specific gravity (Gs), and, for selected granular soils, limiting void ratios and relative density (Dr). These results were interpreted together with SPT-N, stratigraphy, and groundwater observations from the SK boreholes. Representative samples and field sampling procedures are shown in Fig. 4.

(a) AC 10 (b) AC 2 (c) AC 6

Figure 4. *Representative field investigation procedures at the AÇ locations in the Gölbaşı study area: (a) disturbed soil sampling at AÇ-10, (b) measurement of the sampling depth at AÇ-2, and (c) measurement of the groundwater level at AÇ-6.*

Based on the USCS criteria [14], the investigated materials range from fines-dominated low-plasticity clayey soils to predominantly granular SP and SW soils. AÇ-1 contained 71.2% fines with LL = 45.6%, PI = 25.6%, w = 17.1%, and Gs = 2.60 and was classified as CL. The adjacent SK-1 similarly comprises predominantly fine-grained clayey and sandy-clayey layers, with generally low shallow SPT-N values and groundwater at 2.7 m. AÇ-4 also contained a high fines fraction (69.7%) but exhibited substantially lower plasticity (LL = 29.9%, PI = 9.1%) and was classified as CL. The adjacent SK-2 is predominantly fine-grained but contains a coarser interval where SPT-N reaches 22; groundwater occurs at 2.2 m. These results demonstrate that similar fines contents may be associated with considerably different plasticity characteristics.

AÇ-5, AÇ-6, and AÇ-7 are also fines-dominated low-plasticity clayey soils. AÇ-5 contains 51.3% fines and PI = 17.7%, whereas AÇ-6 contains approximately 61.84% fines with PI = 15.58%. AÇ-7 contains 54.0% fines and PI = 15.5%. AÇ-5 is adjacent to SK-4, where predominantly clayey and sandy-clayey deposits exhibit shallow SPT-N values of approximately 6–8 and groundwater at 1.2 m. AÇ-6 is adjacent to SK-6, which comprises clayey to sandy-clayey soils with SPT-N increasing from approximately 5–9 near the surface to 37 at greater depth; groundwater occurs at only 0.7 m. AÇ-7 is adjacent to SK-5, which contains clayey, sandy-clayey, and locally organic-bearing soils. SK-5 is characterized by particularly low SPT-N values of approximately 2–7 over several intervals, locally high water contents reaching approximately 68%, and a deeper groundwater level of 5.5 m.

The predominantly granular AÇ locations exhibit substantial variations in density state. AÇ-2 is classified predominantly as SP, with Dr decreasing from 63.71% at 1.50 m to 27.00% at 2.00 m. Its adjacent SK-3 contains shallow gravelly-sandy materials before transitioning to predominantly finer-grained soils below approximately 6 m; groundwater occurs at 2.7 m. AÇ-3 is also predominantly SP and exhibits a relatively dense state, with Dr = 74.95% at approximately 1.60 m.

AÇ-8 and AÇ-9 are predominantly SW and show pronounced variations in density state. AÇ-8 exhibits Dr values of 91.0% and 69.26% at 1.50 and 2.00 m, respectively, representing some of the densest investigated granular conditions. At AÇ-9, the 1.90-m sample contains approximately 10.50% fines, while Dr decreases from approximately 85% at 1.50 m to approximately 28% at 1.90 m. AÇ-10 shows depth-dependent variation in fines content, increasing from approximately 4.46% at 1.50 m to 12.98% at 1.90 m, while the corresponding Dr values are approximately 62% and 54%, respectively. These results demonstrate substantial spatial and vertical variability in packing state even among the predominantly granular deposits.

SK-7 provides additional subsurface information outside the paired AÇ–SK locations and contains predominantly fine-grained to sandy-clayey materials. Groundwater was encountered at approximately 0.8 m, further demonstrating the shallow and spatially variable groundwater conditions across the study area.

The measured SPT-N values across the seven boreholes ranged from 2 to 37, indicating considerable spatial and vertical variability in penetration resistance. Relatively low values were encountered in several shallow to intermediate-depth clayey and sandy–clayey intervals. The lowest measured value (N = 2) occurred in SK-5 at 12.00–12.45 m, whereas the highest

value (N = 37) was recorded in SK-6 at 19.50–19.95 m. In several boreholes, penetration resistance generally increased at greater depths, although the profiles remained heterogeneous rather than exhibiting a uniform depth-dependent trend.

Laboratory characterization of selected SPT samples further demonstrates the vertical variability within the SK boreholes (Table A2). The tested SPT samples exhibit substantial variations in grain-size distribution, natural water content, and plasticity, with predominantly granular materials containing variable fines contents and locally plastic fines. These results complement the depth-dependent SPT-N and borehole observations and further demonstrate that the subsurface conditions cannot be represented by a single soil type.

Overall, the paired AÇ–SK results demonstrate that shallow soil classification alone does not represent the complete subsurface sequence. The investigated deposits exhibit substantial variations in soil type, plasticity, density state, SPT resistance, groundwater conditions, and vertical stratigraphy. Among the granular AÇ samples, Dr ranges from approximately 27% to 91%, while groundwater across SK-1–SK-7 ranges from 0.7 to 5.5 m. Detailed grain-size distribution, natural water content, PI, and USCS classification results for the AÇ samples are presented in Table A1(a), while Gs and density-state parameters are given in Table A1(b). Grain-size distribution, natural water content, PI, and USCS classification results for selected SPT samples from the SK boreholes are presented in Table A2 in Appendix A.

3.2. MASW–ReMi Dispersion and Inversion Results

The MASW and ReMi measurements at AÇ-1–AÇ-10 exhibited complementary dispersion characteristics. MASW primarily constrained the higher-frequency response, whereas ReMi extended the usable information toward lower frequencies and longer wavelengths. Their combination therefore provided broader dispersion-frequency coverage for inversion. Representative MASW and ReMi dispersion curves and the resulting V_s–depth profile at AÇ-4 are presented in Fig. 5.

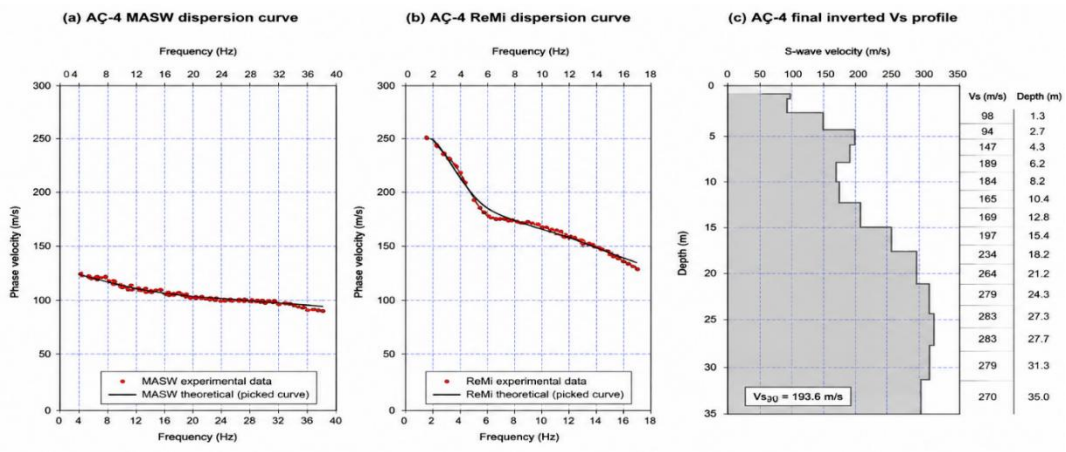

Figure 5. Representative surface-wave analysis at AÇ-4: (a) MASW dispersion curve, (b) ReMi dispersion curve, and (c) final inverted shear-wave velocity (Vs) profile obtained from the combined MASW–ReMi analysis.

Across the ten locations, final RMS misfits ranged from approximately 2.43 to 4.74 m/s (average 3.28 m/s), corresponding to normalized misfits of approximately 1.16–2.81% (average 1.64%). At AÇ-4, the RMS misfit decreased from 12.55 m/s (7.91%) for the initial model to 3.01 m/s (1.58%) for the final solution, indicating a satisfactory fit between the measured and

theoretical dispersion responses. The resulting profile exhibits distinct vertical velocity contrasts, including a shallow velocity reversal followed by a general increase in V_s at greater depths, and yields V_{s30} = 193.6 m/s.

The broad variability observed in the V_s profiles is consistent with the heterogeneous subsurface conditions identified from the nearby boreholes. Measured SPT-N values ranging from 2 to 37, together with alternating clayey, sandy, and mixed soil layers, indicate substantial spatial and depth-dependent variations in soil composition and penetration resistance. These borehole observations are consistent with the vertical stiffness variations revealed by the MASW–ReMi profiles and, together with the differences among investigation locations, highlight the heterogeneous nature of the Gölbaşı deposits. Because the AÇ and SK locations are not spatially coincident in all cases, these observations are interpreted as complementary evidence of subsurface heterogeneity rather than as a direct correlation between SPT-N and V_s.

3.3. V_s Profiles and V_{s30} Distribution

The inverted V_s profiles reveal pronounced lateral and vertical variability across AÇ-1–AÇ-10, including shallow low-velocity zones, velocity contrasts, and local velocity reversals (Fig. 6). V_{s30} ranges from 159.9 to 210.2 m/s. The values are 159.9 m/s at AÇ-7, 163.6 m/s at AÇ-10, 169.0 m/s at AÇ-3, 171.0 m/s at AÇ-6, 171.8 m/s at AÇ-1, 176.4 m/s at AÇ-5, 191.7 m/s at AÇ-9, 193.6 m/s at AÇ-4, 196.6 m/s at AÇ-2, and 210.2 m/s at AÇ-8.

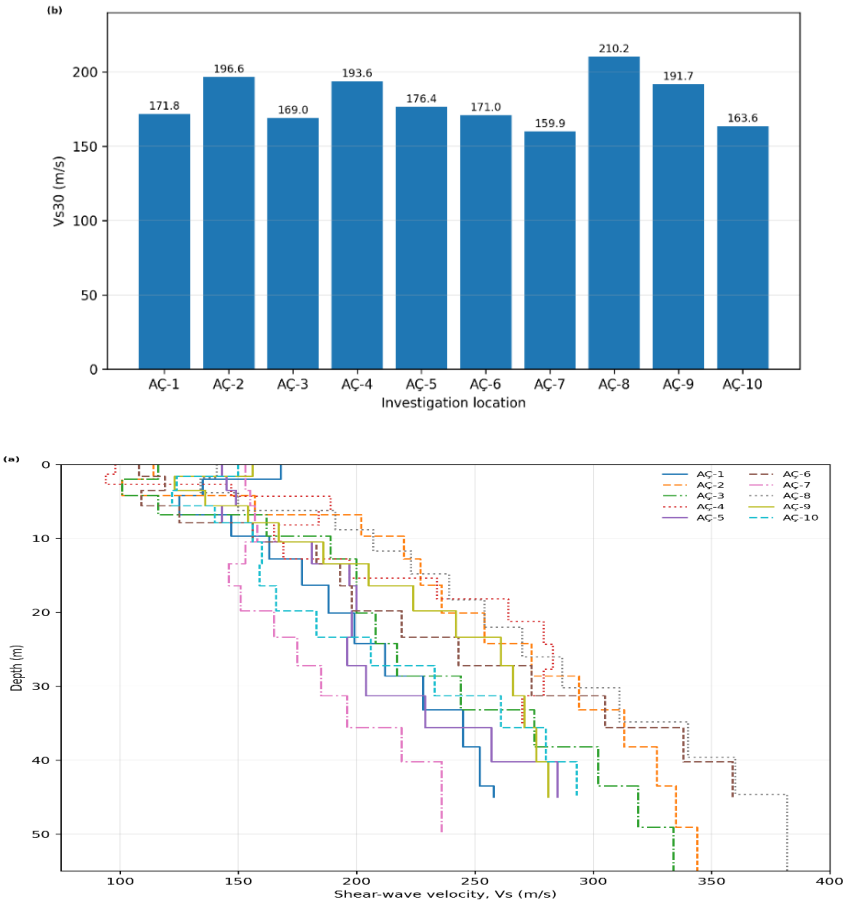

Fig. 6. Comparison of shear-wave velocity characteristics at the ten investigation locations: (a) inverted Vs–depth profiles obtained from the combined MASW–ReMi analyses and (b) corresponding Vs30 values.

Despite the relatively limited V_{s30} range, the complete V_s –depth profiles exhibit substantially greater vertical variability, indicating that V_{s30} alone may mask important differences in shallow stiffness and layer configuration.

3.4. Integrated Interpretation of Physical and Geophysical Characteristics

The integrated dataset indicates that spatial variability in V_s occurs within deposits characterized by variations in grain-size distribution, fines content, plasticity, density state, groundwater conditions, and stratigraphy, rather than being attributable to a single index parameter.

Among the granular locations, AÇ-8 exhibits Dr = 91.0% and 69.26% at 1.50 and 2.00 m, respectively, and the highest V_{s30} (210.2 m/s). AÇ-2 also has a relatively high V_{s30} (196.6 m/s), although Dr decreases from 63.71% at 1.50 m to 27.00% at 2.00 m. Similarly, at AÇ-9, Dr decreases from approximately 85% at 1.50 m to approximately 28% at 1.90 m, while the available gradation results indicate a predominantly granular SW soil with approximately 10.50% fines in the investigated sample; its V_{s30} is 191.7 m/s. In contrast, AÇ-10 contains approximately 12.98% fines, intermediate Dr values of approximately 62% and 54%, and a lower V_{s30} of 163.6 m/s. These comparisons demonstrate that V_{s30} represents the integrated stiffness of the upper 30 m rather than the density state of individual shallow layers.

The fines-rich locations show a similar complexity. AÇ-1 and AÇ-4 contain comparable fines contents of 71.2% and 69.7%, respectively, but differ markedly in PI (25.6% and 9.1%) and V_{s30} (171.8 and 193.6 m/s). Likewise, AÇ-5, AÇ-6, and AÇ-7 contain 51.3%, 61.84%, and 54.0% fines, respectively, with PI values of 17.7%, 15.58%, and 15.5% and V_{s30} values of 176.4, 171.0, and 159.9 m/s, respectively. Thus, fines content alone cannot explain the observed stiffness variations.

The borehole data provide further insight into the spatial and vertical heterogeneity identified by the surface-wave measurements. Across SK-1–SK-7, measured SPT-N values range from 2 to 37, indicating substantial variations in penetration resistance with location and depth. AÇ-7, which has the lowest V_{s30} (159.9 m/s), is located near SK-5, where low SPT-N values, reaching N = 2 at 12.00–12.45 m, together with locally high water contents and organic-bearing soils, indicate relatively soft subsurface conditions. In contrast, AÇ-2 (V_{s30} = 196.6 m/s) is located near SK-3, which contains relatively coarse gravelly-sandy materials within the profile, while AÇ-4 (V_{s30} = 193.6 m/s) is located near predominantly fine-grained SK-2, where SPT-N values locally reach 22. Groundwater conditions also vary considerably across the boreholes, with depths ranging from 0.7 to 5.5 m below ground surface and particularly shallow groundwater encountered at SK-4, SK-6, and SK-7. These observations are considered complementary evidence of subsurface heterogeneity rather than direct point-to-point correlations between SPT-N and V_s, because the AÇ and SK investigation locations are not spatially coincident.

Overall, the laboratory, borehole, and surface-wave datasets provide complementary descriptions of soil composition, physical state, penetration resistance, groundwater conditions, and field-scale stiffness. Their combined interpretation demonstrates pronounced spatial and depth-dependent heterogeneity across the investigated deposits. The results indicate that the MASW–ReMi-derived V_s structure should be interpreted together with physical and index properties, SPT-N measurements, groundwater conditions, and subsurface stratigraphy rather than as the response of a single homogeneous soil type. Detailed physical and index results are provided in Appendix A.

4. CONCLUSIONS

This study integrated laboratory physical and index testing, borehole and SPT observations, groundwater measurements, and combined MASW–ReMi analyses to characterize the earthquake-affected deposits of Gölbaşı, Adıyaman. The results demonstrate pronounced lateral and vertical heterogeneity in soil composition, density state, groundwater conditions, penetration resistance, and field-scale stiffness.

The investigated materials range from fines-dominated low-plasticity clayey soils to predominantly granular sandy deposits. Among the granular AÇ samples, relative density (Dr) varies from approximately 27% to 91%, while the SK boreholes reveal alternating fine- and coarse-grained layers and locally organic-bearing soils. Measured SPT-N values range from 2 to 37 across the seven boreholes, demonstrating substantial spatial and depth-dependent variability in penetration resistance. Groundwater depths range from approximately 0.7 to 5.5 m below ground surface.

Combined MASW–ReMi analyses provided V_s –depth profiles at ten locations, with V_{s30} ranging from 159.9 m/s at AÇ-7 to 210.2 m/s at AÇ-8. The complete profiles exhibit greater vertical variability than indicated by V_{s30} alone, including shallow low-velocity zones, velocity contrasts, and local velocity reversals.

The integrated results indicate that field-scale stiffness cannot be attributed to a single soil property. AÇ-8, with Dr values of approximately 91% and 69%, exhibits the highest V_{s30} (210.2 m/s), whereas AÇ-1 and AÇ-4 have similar fines contents (71.2% and 69.7%) but markedly different PI values (25.6% and 9.1%) and V_{s30} values (171.8 and 193.6 m/s). Furthermore, the lowest V_{s30} at AÇ-7 is consistent with the nearby SK-5 profile, where low SPT-N values, including a minimum measured value of N = 2, together with high-water-content and locally organic-bearing intervals indicate relatively soft subsurface conditions. These observations demonstrate the combined influence of soil composition, plasticity, density state, penetration resistance, groundwater conditions, and vertical stratigraphy on the measured V_s structure.

Overall, integrating the currently available physical and index properties with borehole stratigraphy, SPT-N measurements, groundwater observations, and MASW–ReMi-derived V_s profiles provides a more representative characterization of the heterogeneous Gölbaşı deposits than any individual dataset alone. Because the AÇ and SK investigation locations are not spatially coincident in all cases, the geotechnical and geophysical observations are interpreted as complementary evidence of subsurface heterogeneity rather than as direct point-to-point correlations between SPT-N and V_s. The integrated dataset provides a basis for subsequent seismic site characterization and site-response analyses aimed at evaluating the influence of local soil conditions on earthquake ground response in the Gölbaşı basin.

Abstract. Classical Rankine and Coulomb theories often fail to accurately represent stress distributions and failure mechanisms in cantilever retaining walls with cohesive-frictional backfills. To address this limitation, the present study investigates the geotechnical effect of adding a base shear key to this type of wall. A full-scale model of a 5.0 m high cantilever wall was developed in PLAXIS 2D, assuming a hardening soil Model for the backfill. A full-scale model of a 5.0 m high cantilever wall was developed in PLAXIS 2D, assuming a hardening soil Model for the backfill. A parametric analysis was then conducted to evaluate the influence of shear key's vertical height ($H_{shear\ key}$ ranging from 1 m to 1.5 m, corresponding to 0.2H to 0.3H) and its horizontal width ($B_{shear\ key}$ ranging from 0.5 m to 2.5 m). These configurations were tested under cohesive-frictional backfill with 10 kPa cohesion, an internal friction angle (ϕ= 30°) and unit weight (γ= 18 kN/m^3). Active limit states were triggered by applying incremental prescribed structural displacements. Finite element results show that the shear key effect that slip surfaces behind the wall and the earth pressure distribution. Furthermore, the geometry of the key has a meaningful influence on both total active thrust (Pa) and the shape of non-linear lateral pressure profile.

Keywords: Cantilever wall; Shear key; Cohesive-frictional backfill; Active earth pressure.

1 Introduction

Calculations related to lateral earth pressure problems have been carried out since the early 18th century. However, it was only several decades later that Coulomb [1] conducted the first major study of earth pressures, taking into account a rigid mass of soil sliding upon a shear surface. One of the methods that emerged from this study, known as Coulomb (1776), is still widely used today. Decades later, Rankine [2] proposed an alternative stress-field approach, and both methods remain widely used today for determining basic lateral earth pressures. Building upon these foundational theories to address more complex conditions, Shukla et al. [3] investigated an analytical expression for calculating the total active force on retaining walls for c-ϕ soil backfills, incorporating both horizontal and vertical seismic coefficients. Comparative analysis with earlier expressions reveals consistent trends in force variation. It's observed that the inclination of critical failure surfaces decreases with higher seismic coefficient values. The total active force rises with increasing horizontal seismic coefficient, while it decreases with escalating vertical seismic coefficient values, except for extreme horizontal values. Additionally, design charts are provided for practical estimation of total active force considering various seismic coefficients, cohesion, and angle of shearing resistance. Overall, this study enhances understanding and practical application of seismic considerations in retaining wall design [3].

For a c–ϕ backfill, the active pressure coefficient and pressure distribution depend on more than the effective friction angle. Analytical work has shown that cohesion, wall friction, wall

adhesion, unit weight, depth, and arching can influence active pressure behind a wall [4]. Tu and Jia [4] pointed out the shortcomings of traditional theories through an analysis of the active earth pressure, particularly in cohesive-frictional (c-ϕ) backfills. This was made possible through the inclusion of the effect of soil arching and continuous rotation of principal stress, proving through analytical means that the true lateral earth pressure is inherently non-linear in nature. It was additionally stressed that the cohesive nature of the soil is an essential factor in minimizing the active pressure of the soil towards the retaining wall.

The finite-element analyses indicate that active pressure is not mobilized at a certain displacement along the wall height. Mobilization depends on the behavior of the soil and the wall distortions at various depths. Also, it was found in the same study that a nonlinear soil model is better than an elastic-perfectly plastic soil model in order to avoid numerical instabilities in the analysis of soil-wall interaction [5].

This is especially relevant for cantilever retaining walls, where the stem of the wall is less restrained at the bottom and less stiff at the top. Thus, the rigid wall assumption may affect not only the magnitude but also the depth of active pressure [5, 6].

Pressure and wall friction were determined with the help of instrumented panels and load cells over the stem and base plate of a T-shaped wall. Wall friction was found on the vertical wall and upper surface of the base plate even with a horizontal surface of backfill. Wall friction interfered with the principal stress lines for a distance about equal to the wall height, and the test results were different from Coulomb, Terzaghi, and Peck solutions [7].

FE model should incorporate the proper law of friction and adhesion for stem-soil and base-soil contact instead of full bonding because, otherwise, there would be an error in the determination of pressure and sliding resistance [7].

Studies on calculations of soil pressure behind retaining walls has improved significantly over time, in addition to more advanced numerical and analytical modeling that considers arching action in cohesive-frictional backfills. Recent studies conducted by Sarfaraz et al. [8] was emphasis nonlinear stress distribution in sloped walls under static sliding conditions [8]. In another study, finite element method using PLAXIS 2D suggest that cohesion (c) lowers the area of failure zones by up to 40% and controls the shear strain to remain less than 8.5%, unlike the 20% in the case of cohesionless soil. Furthermore, the geometry of the failure surfaces is largely dependent on the heel width ratio (b/H) value [9].

An FE analysis of a 5.4 m flexible cantilever retaining wall with cohesive backfill under static and seismic loads mentions a reduction of up to 50% in seismic active pressure and 52% in total seismic thrust due to the presence of cohesion, along with a lowering of the location of the thrust load application point. However, the same study mentioned that some seismic code methods for estimating seismic active pressure were largely underestimated [10].

Despite these developments in modeling cohesive backfills, the exact geotechnical implications of introducing a shear key in the design of cantilever retaining walls are poorly investigated. In order to solve this problem, the current investigation aims at investigating the impact of the shear key geometry on the resultant active thrust force and non-linear distribution of lateral pressure on the cohesive-frictional backfills.

In the current investigation, an analytical approach will be introduced to estimate the active earth pressure of cohesive-frictional backfill supported by a cantilever retaining wall incorporating a shear key. In order to examine the effect of wall shear key geometry, a parametric matrix containing 9 cases was considered. The 2D finite element analyses were conducted through the PLAXIS 2D software to simulate the mobilization of the active earth pressure behind a cantilever retaining wall supporting a cohesive-frictional soil having a height of 5.0 m.

2 Numerical Modeling Procedure

A series of two-dimensional finite element simulations was conducted using PLAXIS 2D to investigate the mobilization of active earth pressure behind a cantilever retaining wall. The retaining structure supports a 5.0 m high backfill (H = 5.0 m).

To study the effects of wall shear key geometry a parametric matrix consisting of 9 numerical cases was developed (Table 1). Three different shear key's width ratios and three shear key's height were considered:

Table 1. Matrix of Parametric Study.

Case No	Shear key width ratio (β)	Shear key height ratio (α)
1	0.1	0.1
2		0.2
3		0.3
4	0.3	0.1
5		0.2
6		0.3
7	0.5	0.1
8		0.2
9		0.3

The soil backfill has been modeled as cohesive-frictional soil with constant effective cohesion (c) value of 10.0 kPa, an friction angle (ϕ) of 30.0 and °, and a unit weight of 18 kN/m^3. The Hardening Soil (HS) constitutive model [11] has been chosen to include nonlinear stress-dependent behavior, hysteresis effect, and shear hardening of the soil. This material model allows a physically correct description of behavior of the soil's cohesive strength as well as stress dependent stiffness. In particular, reference secant stiffness obtained from drained triaxial tests (E_{50ref}), and reference tangent stiffness obtained under primary loading condition in oedometer test (E_{oedref}) have been assigned as 25.0 MPa. Moreover, reference unloading/reloading stiffness (E_{urref}) is assigned as 75.0 MPa, which avoids strain overestimation during unloading cycles. Also, there is an inclusion of interface strength reduction factor (R_{inter}) of 0.50 to simulate interaction between the retaining structure and the soil.

The cantilever retaining wall along with its base slab and shear key were assumed to be a continuous solid element. In order to simulate the mechanical properties of the concrete material, a Linear Elastic material model was used. This is a common practice for soil-structure interaction numerical analyses because the stiffness of the concrete wall is much greater than that of the backfill and since the main interest of the study is soil yielding processes and not the structural failure of the wall. The concrete material was assumed to be non-porous drainage type material with the unit weight (γ) of 24.0 kN/m^3. The elastic stiffness parameters included the following: Young's modulus (E) of 30 GPa and Poisson's ratio (ν) of 0.20.

The stress-dependence index m for stiffness was selected as 0.60. Also, the "Tension Cut-off" option was enabled with zero tensile strength (0.0 kN/m^2), in order to allow development

of the tensile crack depth (z_c) in view of the physically impossible sustained tensile stress at the upper fill interface.

Staged construction analysis procedure was used for the numerical modeling:

1. **Initial Stage & Excavation:** Activation of the retaining wall and soil-structure interaction interfaces followed by excavation of the soil mass ahead of the wall to create an initial at-rest stress condition.
2. **Translation Mode (Stages 3 to 19):** Application of a horizontal displacement of the wall to induce active limit state of equilibrium. This was achieved through application of an increase in horizontal displacement by 0.001H (0.005 m) in each stage with a maximum of 0.017 (0.085 m).

Vertical Control Section was specified 5 cm behind the retaining wall stem and shear key in order to obtain lateral stress distribution. Active earth pressure condition is assumed to be mobilized when there is no appreciable change in lateral forces with each increment of displacement (approximately 1%).

3 Results and Discussion

3.1 Mobilization of Active Earth Pressure

The relation between the normalized wall displacement (Δx/H) and the total lateral thrust is presented in Fig. 1. In all nine different cases investigated, it can be seen that the transition from the initial state (Δx/H = 0) to the fully active state is demonstrated in Fig. 1. The absolute value of the lateral force experiences a significant decrease at the early stage of the wall displacement. The curves level off at the moment when the change of lateral force becomes negligible, thus reaching the fully mobilized active limit state. As one can see in Fig. 1, this stage is reached at the normalized wall displacement of approximately 0.007 to 0.008, beyond which the curves remain relatively flat.

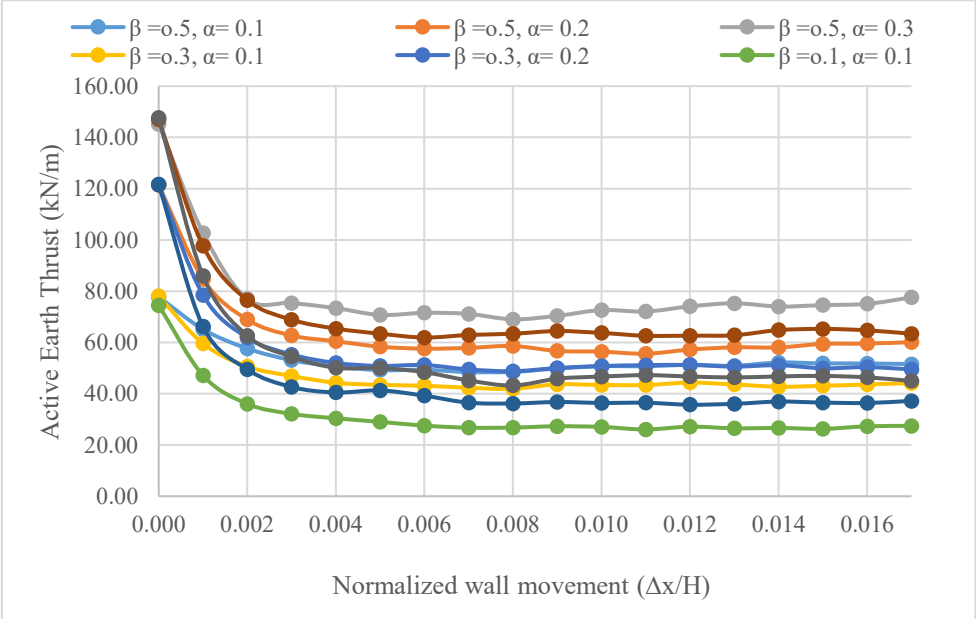

Fig. 1. Variation of active earth thrust with normalized wall movement for different base shear key configurations.

According to the literature data, the active limit state can usually be achieved with a much smaller displacement in conventional walls. Numerical analysis done by Sarfaraz et al. [8] shows that the horizontal earth pressure decreases with the movement of the wall and attains constant values at the active wall movement of about 0.0007 times the wall height. This result

is also consistent with the results of the previous numerical analysis performed by Matsuzawa and Hazarika [12], who showed that active wall movement is equal to ($\Delta x/H$) = 0.0005 to 0.001 for vertical walls.

It should be noted that in the current investigation, the active state is attained at a much larger displacement of $\Delta x/H \approx 0.007$ to 0.008. The considerable delay in active pressure mobilization can be explained by the effect of the presence of the shear key, which is a rigid element of the retaining structure. The shear key becomes a kind of anchor that essentially affects the kinematic behavior of the system, thus replacing the simple and shallow planar failure mechanism with the more complex and deep-seated composite failure mechanism. Therefore, much larger displacement of the wall is required to fully stretch the soil mass and activate the shear strength on the corresponding deep-seated slip surfaces.

3.2 Effect of Shear Key Geometry on Active Earth Thrust

It is apparent from Fig. 1 that the geometry of the shear key has an essential impact on the value of the mobilized lateral earth thrust. From the results of the finite element analysis of the structure, at the fully active state ($\Delta x/H = 0.008$), it can be seen that the relative height ($\alpha = H_{key}/H$) and the relative width ($\beta = b_{key}/H$) modify the active force. An increase in the vertical extent of the shear key leads to an increase in the value of the active force. With the constant width of the key $\beta = 0.5$, the active force increases from 48.52 kN/m at $\alpha = 0.1$, to 58.62 kN/m at $\alpha = 0.2$, and attains 69.02 kN/m at $\alpha = 0.3$. The reason is the increased vertical depth of the sliding soil wedge with the extended shear key, leading to higher geostatic stresses along the slip plane.

Additionally, an increase in the horizontal extent of the shear key β shows an analogous influence on the active force. Comparing the cases with the same relative height of the key $\alpha = 0.3$, the active lateral force increases from 43.20 kN/m for $\beta = 0.1$, to 63.40 kN/m for $\beta = 0.3$, and achieves its maximum value of 69.02 kN/m for $\beta = 0.5$. In general, the minimal active thrust (26.79 kN/m) corresponds to the smallest structural attachment ($\alpha = 0.1$, $\beta = 0.1$). The wider basis of the shear key activates a bigger volume of the cohesive-frictional backfill. Thus, the mechanical contact with this soil wedge moves the slip surface farther from the wall stem.

This is consistent with very recent and sophisticated numerical studies related to the effect of base geometry on soil kinematics. As classical limit equilibrium analysis assumes a simple failure plane, neglecting any structural feature, the above findings support the complexity of such an interaction. For example, Ayman et al. [9] showed that changing the base geometry of a cantilever wall, in particular the heel length at the back, significantly affects the failure process, leading to the choice between the 'short heel' and 'long heel' modes and hence the volume of mobilization of the cohesive backfill. Similarly, the current study clearly indicates that the width and depth of the base shear key have a similar effect as they affect the main slip plane, shifting it outward and increasing the lateral driving thrust. Such local change in the active earth pressure is confirmed by the research of El Yamouni et al. [10], who noted that the boundary conditions and cohesive-frictional interactions result in highly nonlinear earth pressures that classical theories do not properly account for.

3.3 Failure Mechanisms and Plastic Points Analysis

In the analysis of finite element analyses through the use of Hardening Soil (HS) model, it becomes necessary to determine the plastic points in space to understand the yielding and failure characteristics of the backfill. The stresses in PLAXIS 2D models are described using certain plastic point criteria as follows:

Hardening points: are the stresses at which the material first comes to the HS model shear yield surface. Prior to this point, the material response is mainly elastic. However, the HS model has non-linear stress dependent stiffness.

Cap points: Yielding zones under primary volumetric compression.

Failure points: are those zones that have attained the stress state on the Mohr-Coulomb failure envelope and thus active shear slip zones.

Tension cut-off points: Those zones which the stress state is greater than the tensile limit of the cohesive-frictional material resulting to formation of cracks close to the ground surface.

It was essential to evaluate the plastic points distributions both at the mobilized active state (Ax/H=0.008) and after active state (ΔX/H =0.011).

A detailed analysis of the failure angles also shows clear differences from classical geotechnical theory. According to conventional limit equilibrium and Rankine theories, the slip angle (θ) is expected to equal the theoretically predicted value of the active failure angle 45+ϕ/2 (60° for ϕ=30°). Nevertheless, the computed angles are always less than the theoretically predicted values. The explanation of such an inconsistency is that due to the existence of the soil cohesion (c=10 kPa), and the presence of the base shear key, the actual stress path is different from that assumed for the ideal Rankine wedge formation.

Furthermore, the study of the developed failure zones and tension cut-off surfaces indicates that the width (β) and height (α) of the shear key exert considerable effect on the behavior of the system. The increase in the width of the shear key leads to the fact that instead of passing linearly up to the vertical wall stem, the left failure plane (Ψ) runs into an area of tension, failing to continue once it intersects the tension cracks that develop due to the induced tension at the top level. Also, the primary slip surface (θ) is hindered due to the presence of large areas of tension controlled by cohesion of the soil.

Table 2. Measured slip surface angles (Ψ and θ) at active (Δx/H = 0.008) and post-active (Δx/H = 0.011) stages.

		phase 10 (0.008H)		phase 13 (0.011H)	
β	α	Ψ	θ	Ψ	θ
0.5	0.3	65	55	65	50
	o.2	62	55	55	60
	0.1	58	50	50	60
0.3	0.3	70	50	58	55
	o.2	65	55	55	52
	0.1	60	50	55	52
0.1	0.3	65	60	55	50
	o.2	65	50	50	65
	0.1	58	50	57	50

The analysis of failure angles shown in Table 2 gives more insight into the kinematics of the backfill. In accordance with Rankine and Coulomb's theory, the active failure angle is theoretically predicted to be constant and equal to 45° + ϕ/2 (60° for ϕ = 30°). Nevertheless, as can be seen from FEM simulation results, this theoretical prediction is not met due to the significant deviation, which increases with the increasing dimensions of the shear key (α, β).

The Fig. 2 and Fig. 3 present the plastic point distributions acquired from the finite element analysis at the active and after active limit states (Δx / H = 0.008 and Δx / H = 0.011 respectively). An obvious sign of the shear failure surfaces progression can be observed when comparing these two limit states.

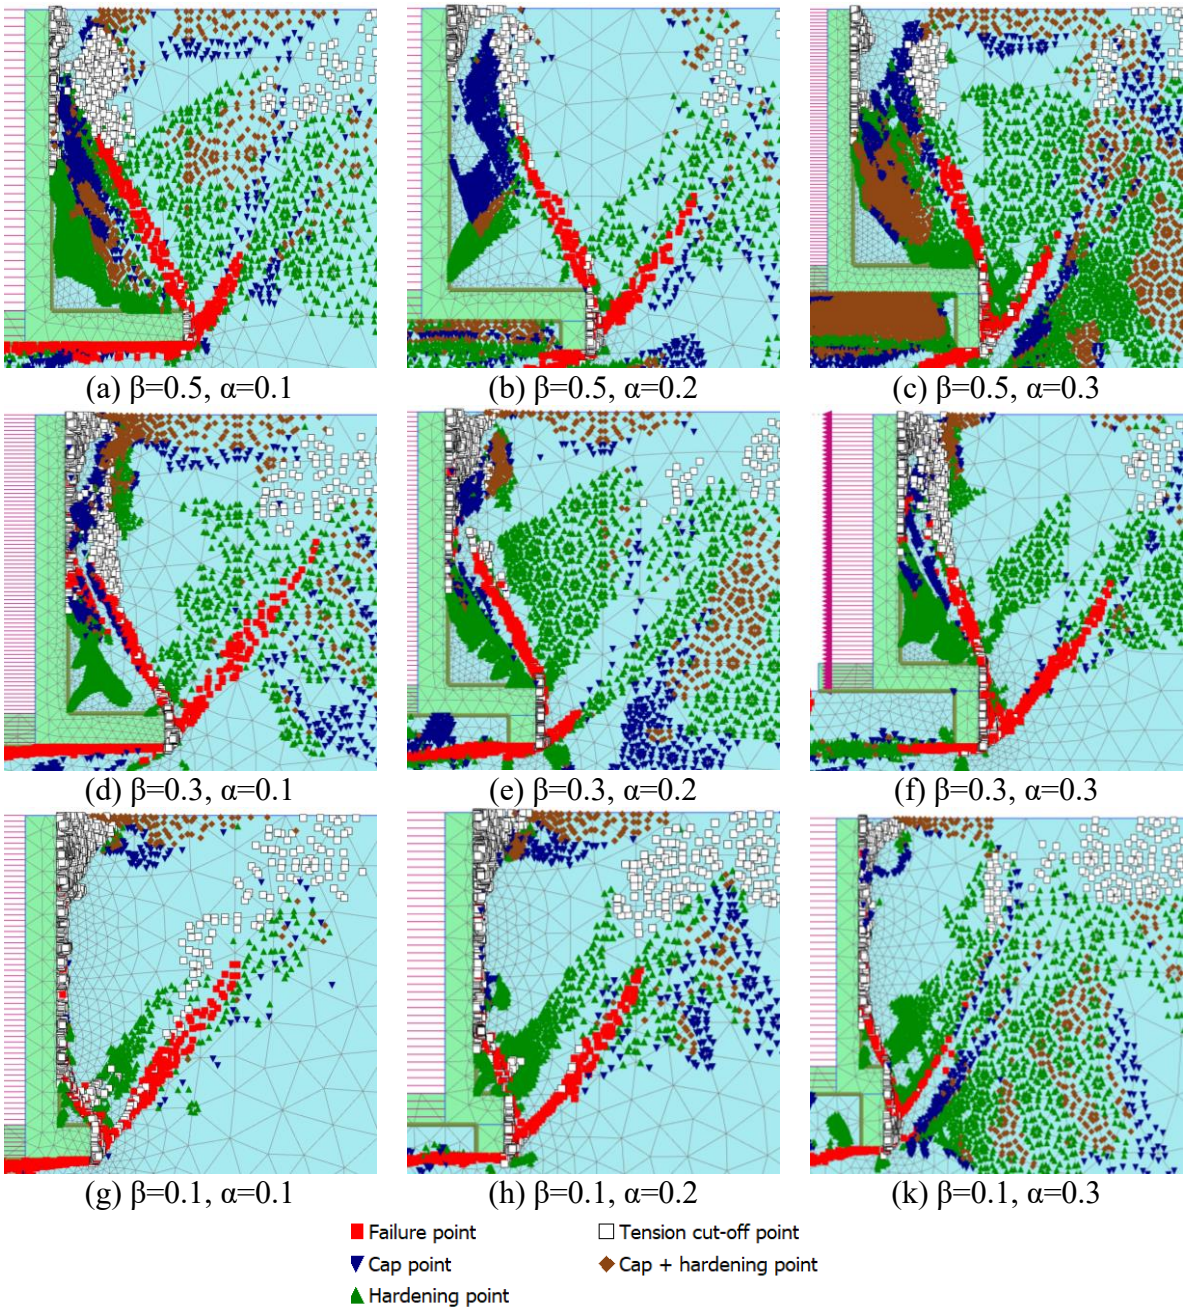

Fig. 2. Plastic point distribution illustrating failure surfaces and tension zones across various α and β configurations at Δx/H = 0.008 wall movement.

In the case of the fully active regime (Phase 10, Δx/H = 0.008), the upper angle of slip (Ψ) generally ranges between 58° to 70°, whereas the lower angle of slip (θ) generally fluctuates between 50° to 55° (sometimes even 60°). As the wall motion proceeds to the post-active regime (Phase 13, Δx/H = 0.011), a certain kind of kinematic change takes place: the upper angle of slip (Ψ) gets reduced (between 50° and 58°), and so does the lower angle of slip (θ).

This shows that the presence of the base shear key does not allow for the development of a single consistent rigid-plastic wedge. The soil mass develops yielding in stages, which means that the presence of cohesion (c = 10kPa) and tensile cut-off zones does not allow the slip surfaces to adhere to analytical formulas.

Upon careful observation of the right-hand failure surface (θ), there appears to be a clear dependence of the slip surface on the width of the shear key (β) and displacement progressions. For instance, in the case where β = 0.5, which represents the widest base key scenario, the right-hand failure surface does not extend up to the wall stem at any ratio of wall height tested (α) in both active and post-active states. In this case, therefore, we can conclude that a wide enough shear key effectively separates the lower failure zone such that the shear is mobilized deep into the backfill. On the other hand, for an intermediate width of β= 0.3, the slip surface does not reach the wall up to Δx/H= 0.008, but gradually reaches and intersects the wall as displacement progresses to the post-active state (Δx/H= 0.011).

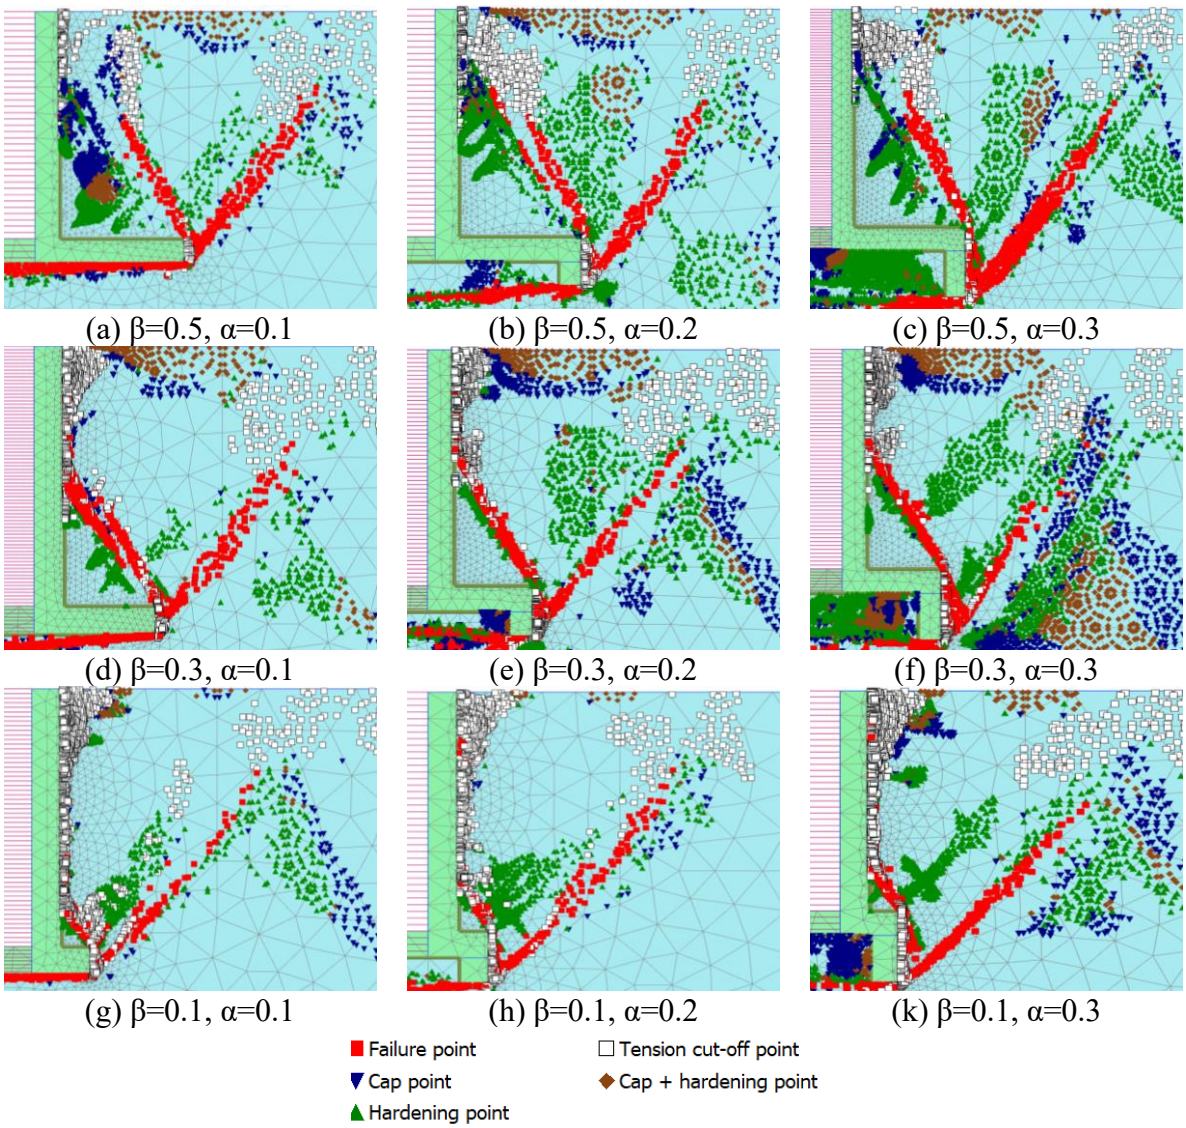

Fig. 3. Plastic point distribution illustrating failure surfaces and tension zones across various α and β configurations at Δx/H = 0.011 wall movement.

4 Conclusion

This study numerically investigated the effect of the shear key on the active lateral earth pressure exerted on cantilever retaining walls supporting cohesive-frictional backfill (c = 10 kPa, ϕ = 30°). Using PLAXIS 2D and the Hardening Soil constitutive model, nine different shear-key geometries have been studied at various displacement stages. The main findings of this analysis are as follows:

• Active Limit State Mobilization: The active limit state is increasingly mobilized by the movement of the wall in the direction of displacement. From the finite element analysis, it can be observed that a lateral displacement of $\Delta x/H$ equal to 0.007 to 0.008 is necessary to mobilize the shear resistance of the cohesive-frictional backfill.

• Effect of Shear Key Geometry: The active lateral force is largely dependent on the two factors: the relative height (α) and relative width (β) of the shear key. An increase in the relative height of the shear key (α) is known to lead to an increase in the active earth thrust. At a constant width ratio ($\beta = 0.5$), when α changes from 0.1 to 0.3, the active force increased from 48.52 kN/m to 69.02 kN/m. An increase in the relative width of the shear key (β) also greatly enhances the lateral thrust. At a constant relative height ratio of $\alpha = 0.1$, when β changes from 0.1 to 0.5, the active force increases from 26.79 kN/m to 48.52 kN/m.

• Failure Mechanisms & Plastic Points: The failure mechanisms and the locations of plastic points, when examined in terms of the plastic points and the failure angles (Ψ and θ), show that the presence of cohesion and the shear key leads to noticeable departures from the classical Rankine and Coulomb theories ($45 + \phi/2$), thereby producing non-linear pressure distributions and areas where tension is cut off which in turn limit the slip surfaces.

Abstract. The transmission and amplification of motion from bedrock to the free soil surface are commonly analyzed using continuum models, such as viscoelastic or hysteretically damped elastic models. However, the discontinuous nature of granular soils makes their response more complex, particularly under large-amplitude vibrations. This study investigates vertical shear-wave propagation in a granular soil deposit using a 2D discrete element model subjected to harmonic base excitation. The analysis focuses on surface motion amplification and its dependence on excitation frequency. The results show that the Dynamic Amplification Factor (*DAF*) increases with frequency, reaches a resonance peak, and then decreases, similarly to an elastic system. However, the resonance frequency is lower than the fundamental frequency obtained from small-amplitude vibrations, with the difference increasing with excitation amplitude. This shift is attributed primarily to strain-dependent shear-modulus degradation in the granular deposit.

Keywords: Sand deposit, Macromechanical behavior, Discrete Element Method, Wave Propagation.

1 Introduction

The propagation of seismic waves from the bedrock to the ground surface is strongly influenced by the mechanical properties of the traversed soil layers. In particular, soil stiffness and damping govern the transmission and amplification of seismic motion. These phenomena are commonly analyzed within the framework of continuum mechanics using constitutive models such as viscoelastic or hysteretic elastic models, which generally provide satisfactory predictions for cohesive soils. However, the discontinuous nature of granular materials makes their dynamic response, especially under large-amplitude vibrations, more complex and difficult to capture using continuum models. In this context, the discrete element method (DEM) offers a valuable framework for investigating the underlying micromechanical mechanisms governing wave propagation and motion amplification in granular soil deposits.

DEM has been widely used to study wave propagation in granular media. Previous studies have examined the effects of contact stiffness, fabric anisotropy, force chains, particle properties, and saturation on wave velocity, attenuation, and dynamic response [1–6]. These investigations have demonstrated that wave propagation is strongly controlled by the contact network and the evolving granular microstructure. Experimental studies have also confirmed the ability of DEM to reproduce wave velocities and dynamic characteristics observed in granular soils [4].

The present study investigates the dynamic behavior of a non-cohesive granular deposit subjected to horizontal harmonic base excitation using a two-dimensional DEM model. Particular attention is devoted to free-surface motion amplification and its dependence on

excitation frequency and amplitude. The macroscopic response of the deposit under large deformations and near-resonance conditions is also analyzed.

1 Discrete element modeling

The discrete element method (DEM), originally proposed by Cundall [7], models granular materials as assemblies of rigid particles interacting through contact laws. The macroscopic response arises from the collective motion of individual particles governed by Newton's laws of motion. Because of their simplicity and the savings in calculation time they involve, circular element shapes are still the most widely used. The motion of each grain is governed by Newton's second law, expressed through the equations of dynamic equilibrium for translational and rotational motion. These equations account for the grain weight, contact forces, and, when applicable, other forces specific to the problem being modeled. Contact forces are decomposed into a normal component and a tangential component. In this work, the normal contact force between two grains is calculated using a viscoelastic model based on their overlap and relative normal velocity, with prescribed normal stiffness k_n and viscous damping constant v_n. The tangential contact force is computed using a viscoelastic model in series with a friction slider, characterized by a tangential stiffness k_s, a viscous damping coefficient v_s and an inter-particle friction coefficient μ_d. Particle velocities and displacements are obtained by integrating the accelerations from the equations of motion. Because contact forces depend on particle positions and velocities, the solution is computed incrementally using successive approximations to ensure consistency between particle positions, velocities, and contact forces at each time step. The time step must be selected such that the evolution of each contact during particle motion is accurately resolved. To account for the damping of natural particle rolling, a rolling resistance torque is introduced by applying the normal contact force with an eccentricity, whose magnitude controls the resistance [8]:. It should be emphasized finally that quantitative agreement with physical experiments requires careful calibration of the model parameters; however, for the present phenomenological study, they are selected primarily to reduce computational cost while preserving physically realistic behavior.

2 Analytical solution of wave propagation in a viscoelastic deposit

Assuming that the granular deposit behaves as a damped elastic continuum, the propagation of a horizontal harmonic displacement (u), along the vertical direction, (z), is governed by the following equation [9]:

$$\frac{1}{c^2}\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial z^2} + \frac{2\xi}{\omega}\frac{\partial^3 u}{\partial t \partial z^2} \tag{1}$$

In which, c is wave propagation velocity, ξ is the hysteretic damping ratio and ω is the circular frequency of the movement. The analytical solution to this equation, for a deposit overlaying a bedrock subjected to a horizontal harmonic oscillation, is given in [17] as follows:

$$\begin{aligned}\frac{A.u(z,t)}{u_0} = &\cosh(ph)\cos(qh)\cosh(pz)\cos(qz)\sin(\omega t)\\ &+\sinh(ph)\sin(qh)\sinh(pz)\sin(qz)\sin(\omega t)\\ &+\cosh(ph)\cos(qh)\sinh(pz)\sin(qz)\cos(\omega t)\\ &-\sinh(ph)\sin(qh)\cosh(pz)\cos(qz)\cos(\omega t)\end{aligned} \tag{2}$$

In which h is the deposit's thickness and z is the vertical coordinate (depth). A, p and q are calculated from equations : $A = cosh^2(ph) - sin^2(qh)$, $(ph)^2 + (qh)^2 = \frac{(\pi^2/4)(\omega^2/\omega_1^2)}{1+4\xi^2}$ and $(ph)(qh) = \xi\frac{(\pi^2/4)(\omega^2/\omega_1^2)}{1+4\xi^2}$.

The fundamental frequency of the deposit being the first resonance frequency for very low damping, it is given by:

$$\omega_1 = \frac{\pi c}{2h} \tag{3}$$

This analytical solution shows that the displacement profile, representing the variation of displacement with depth at a given instant, depends on the excitation frequency. As illustrative examples, Fig. 3 presents the displacement profiles of a deposit subjected to harmonic base excitation with amplitude u_0 for two frequency ratios $\omega/\omega_1 = 0.42$ and $\omega/\omega_1 = 1.12$. In both cases, the hysteretic damping ratio is set to $\xi = 8\%$.

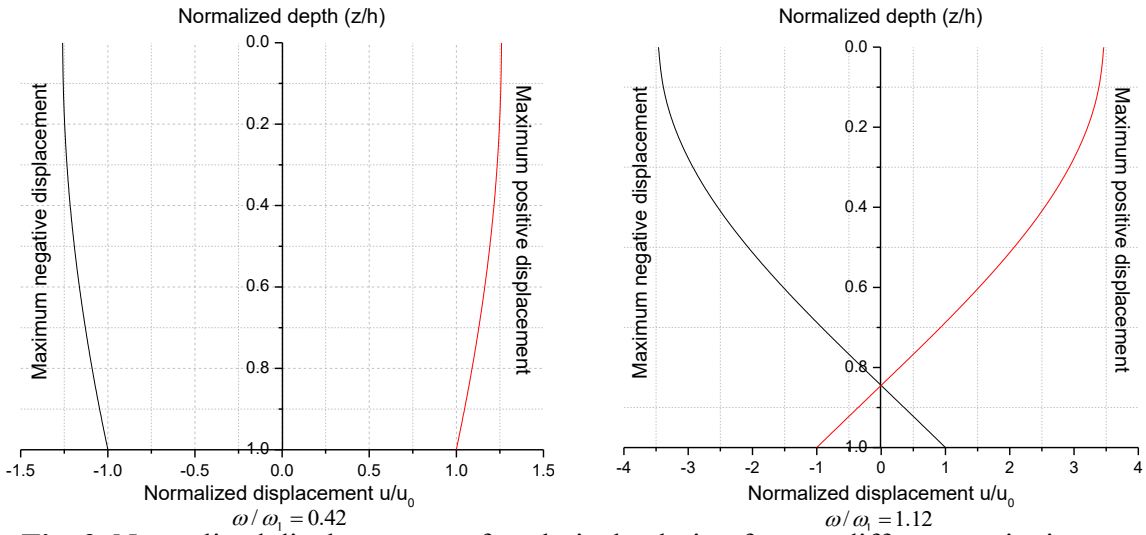

Fig. 2. Normalized displacements of analytical solution for two different excitation frequencies.

Figure 2 shows that when the excitation frequency is lower than the fundamental frequency, the displacement profile resembles the first natural mode shape. As the excitation frequency exceeds the fundamental frequency, the second mode shape emerges, characterized by a nodal point (zero displacement) that moves upward with increasing frequency. Upon reaching the second natural frequency, the third mode shape develops, and the same pattern is repeated for higher modes. In this study, we define the dynamic amplification factor at the top (i.e. the free surface) as $DAF = \frac{u_s}{u_0}$, where u_s and u_0 are the displacement amplitudes at the free surface and at the base respectively. Using the displacement solution (eq. 2), the *DAF* is plotted in figure 3 in terms of the frequency ratio (ω/ω_1) ranging from 0 to 1.12 and for hysteretic damping ratios of 5%, 10% and 15%.

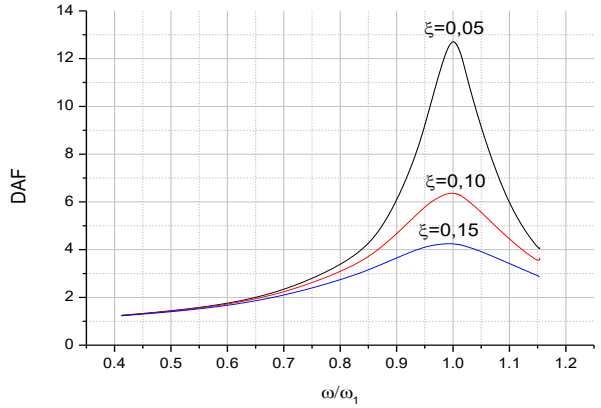

Fig. 3. Dynamic Amplification Factor at the deposit's free surface (*DAF*) in terms of the frequency ratio (ω/ω_1), for hysteretic damping ratios: 5%, 10% and 15%.

This figure shows the typical evolution of the *DAF* with increasing excitation frequency. The *DAF* rises from 1 at low frequencies to a maximum at the first resonance, then decreases. At resonance, its maximum value is inversely proportional to the damping ratio and can be approximated for low damping by $DAF_{max} \approx \frac{2}{\pi\xi}$ [9]. It is worth noting that for common damping ratios, the resonance occurs at frequencies very close to the fundamental frequency.

3 Details of the numerical model to simulate the wave propagation

In the present work, the vertical propagation of a shear wave in a sand deposit is investigated using a 2D discrete element model implemented in C++. A dense deposit is first generated by pluviation under gravity on a horizontal rigid plateau representing the bedrock, with periodic boundaries applied horizontally. After stabilization, the grain positions are stored as reference positions. The deposit is then subjected to horizontal vibration through the bedrock, while its upper surface remains free. To ensure effective motion transmission, the lowest grains are bonded to the bedrock so that they undergo the same imposed displacement. In order to describe the response, the deposit is divided into a number of layers for which the average grain displacements are monitored during the excitation. The deposit width (period) is set to $2m$, resulting in a height of approximately $0.5m$. Figure 3 shows the pluviated sand deposit, its boundary conditions, the bonded grain chain ("excitation chain"), and the subdivision into control layers.

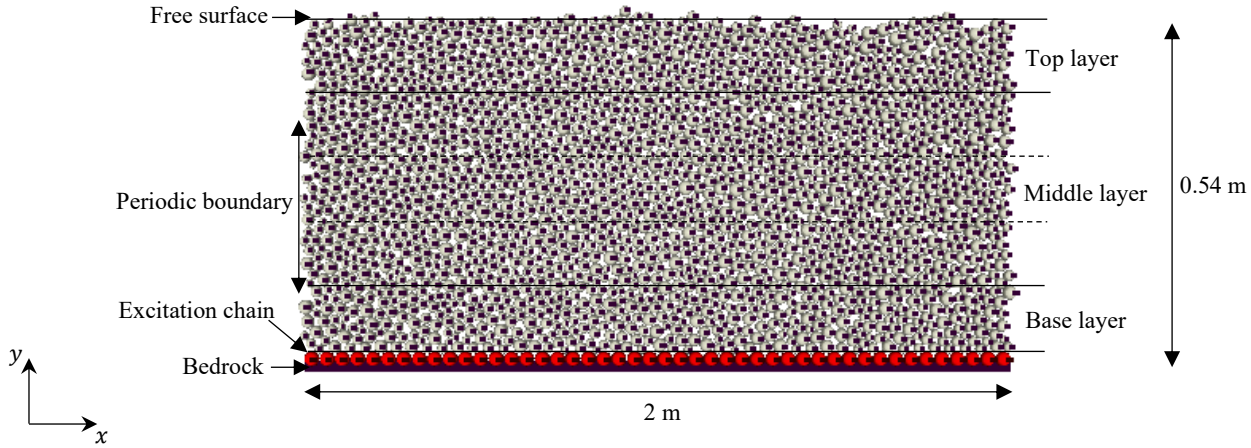

Fig. 4. Illustration of the sand deposit's model, boundary conditions and subdivision into a number of monitoring layers.

The used excitation is harmonic, with prescribed amplitude (u_0) and frequency (ω). To minimize transient effects, the excitation is applied in three stages following [4]: gradual increase to the target amplitude, steady-state oscillation at constant amplitude, and gradual decrease to zero. The durations of these stages are set to $4.5s$, $6s$ and $1.5s$ respectively, allowing transient effects to decay during the steady-state phase. The properties of the grains as well as the micromechanical parameters used in the computation of the intergranular contact forces are presented in Table 1.

Table 1. Model parameters.

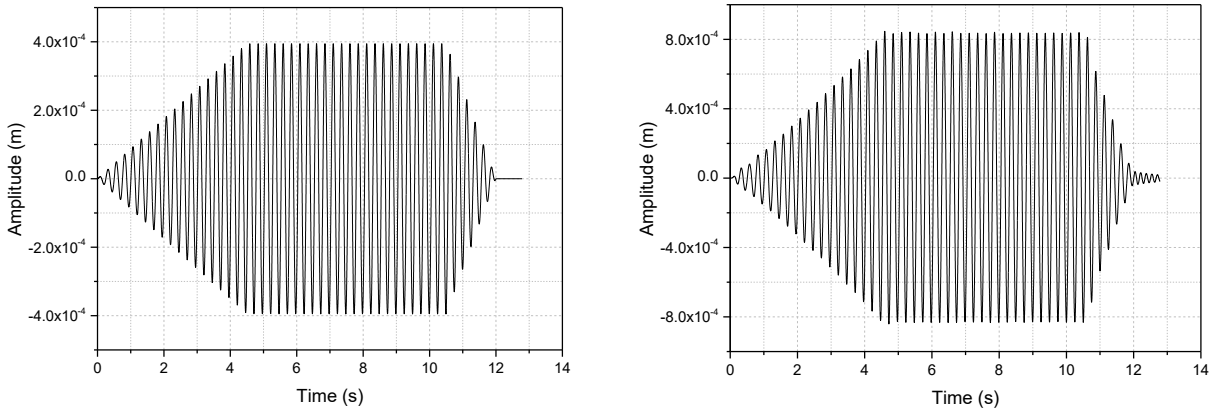
Parameters	Value
Number of Grains	5000
Grains radii r_i	$1.00\text{x}10^{-3}$ *to* $2.00\text{x}10^{-3}m$
Density G_s	$2600\ kg/m^3$
Normal intergranular stiffness k_n	$1.2\ \text{x}10^6 N/m$
Shear intergranular stiffness k_s	$9.6\text{x}10^5 N/m$
Intergranular friction coefficient μ	0.5

The results discussed below are mainly obtained during this phase. The deposit is divided into 10 control layers, and the recorded displacements are the averages over all grains belonging to each layer.

4 Simulations, results and discussions

4.1 Displacement time history and movement amplification from base to the surface

In this simulation, the parameters of the exciting displacement in the steady state stage are set to $u_0 = 4x10^{-4}m$ and $\omega = 25\,rad/s$. Figure 4 shows the displacement time history at the bedrock (Fig. 5a) and at the top layer of the deposit (Fig. 5b).



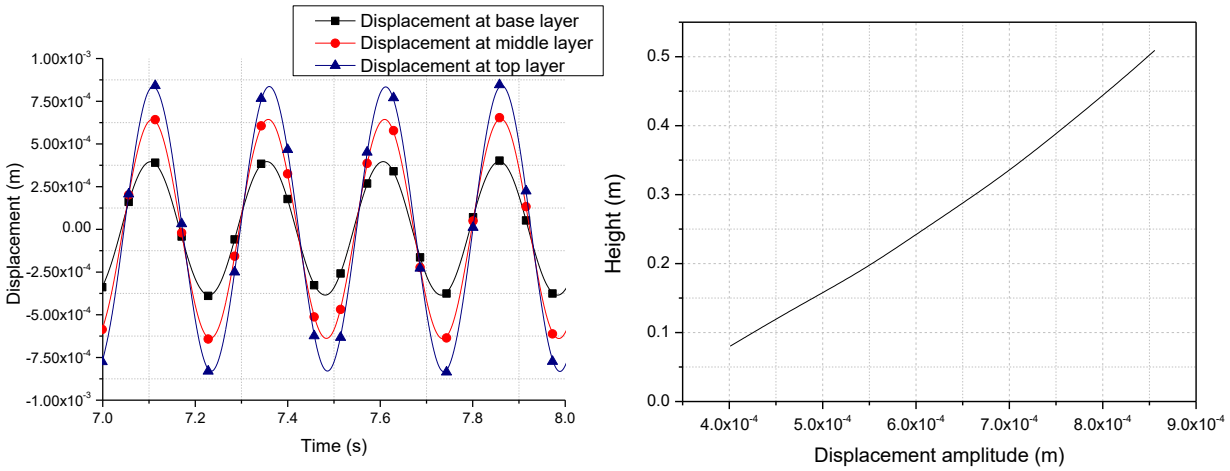


Fig. 5. Displacement time history, left : at the bedrock (excitation), right : at the top layer of the deposit.

The figures illustrate the different motion phases at the bedrock and top layer, representing the deposit surface. In the steady-state phase, the surface amplitude remains nearly constant, indicating that transient effects have decayed. Comparing Figs. 5a and 5b, the imposed bedrock displacement of $0.4mm$ is amplified to approximately $0.85mm$ at the surface. After excitation ends ($t = 12s$), the deposit undergoes free, damped elastic oscillations (Fig. 5b).

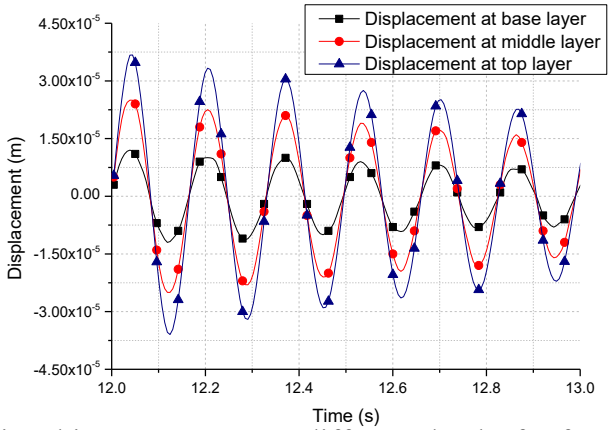
Figures 6a and 6b illustrate the movement amplification within the deposit. Fig. 6a shows a part of the steady-state response $(7s \leq t \leq 8s)$ at the base, middle, and top layers, while Fig. 6b presents the vibration amplitude as a function of layer height above the bedrock. These figures show that displacement amplification increases from the base to the surface. Figure 6b also reveals a first-mode vibration profile, indicating that the excitation frequency is below the first resonance frequency of the deposit.

(a) (b)

Fig. 6. (a) Displacement time history for steady state oscillation at three different depths. (b) Displacement amplitude vs. the layer's height during steady state oscillation.

4.2 Fundamental frequency of the deposit

The fundamental frequency of the deposit is defined as the frequency of free elastic vibration corresponding to the first mode shape. To ensure elastic behavior, the vibration must remain at very low amplitude, since granular soils generally exhibit nonlinear elastoplastic behavior, with the deformation modulus degrading as strain increases. Accordingly, this study focuses on the free vibration occurring after the end of the excitation. The excitation parameters used here are a steady-state amplitude of $u_0 = 4 \times 10^{-4} m$ and an angular frequency of $25 rad/s$. Figure 8 presents a zoom of the time history of displacements corresponding to the free vibration phase (after end of excitation) at different depths of the deposit.



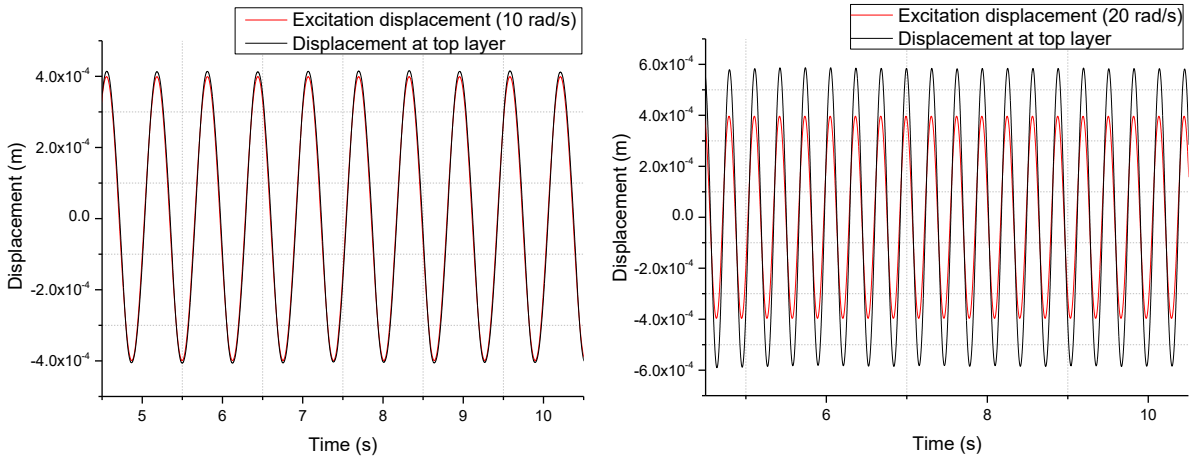


Fig. 8. Zoom of time history response at different depths for free vibration phase.

This figure shows that the displacements are harmonic and without phase offset for the different depths, which corresponds to the oscillation shape of the fundamental mode. The fundamental period can be estimated from the displacement plot, it is about $T = 0.166\, s$. Hence, the fundamental frequency is $\omega_1 = \frac{2\pi}{T} = 37.82\, rad/s$.

4.3 Influence of the excitation frequency on the response of the deposit

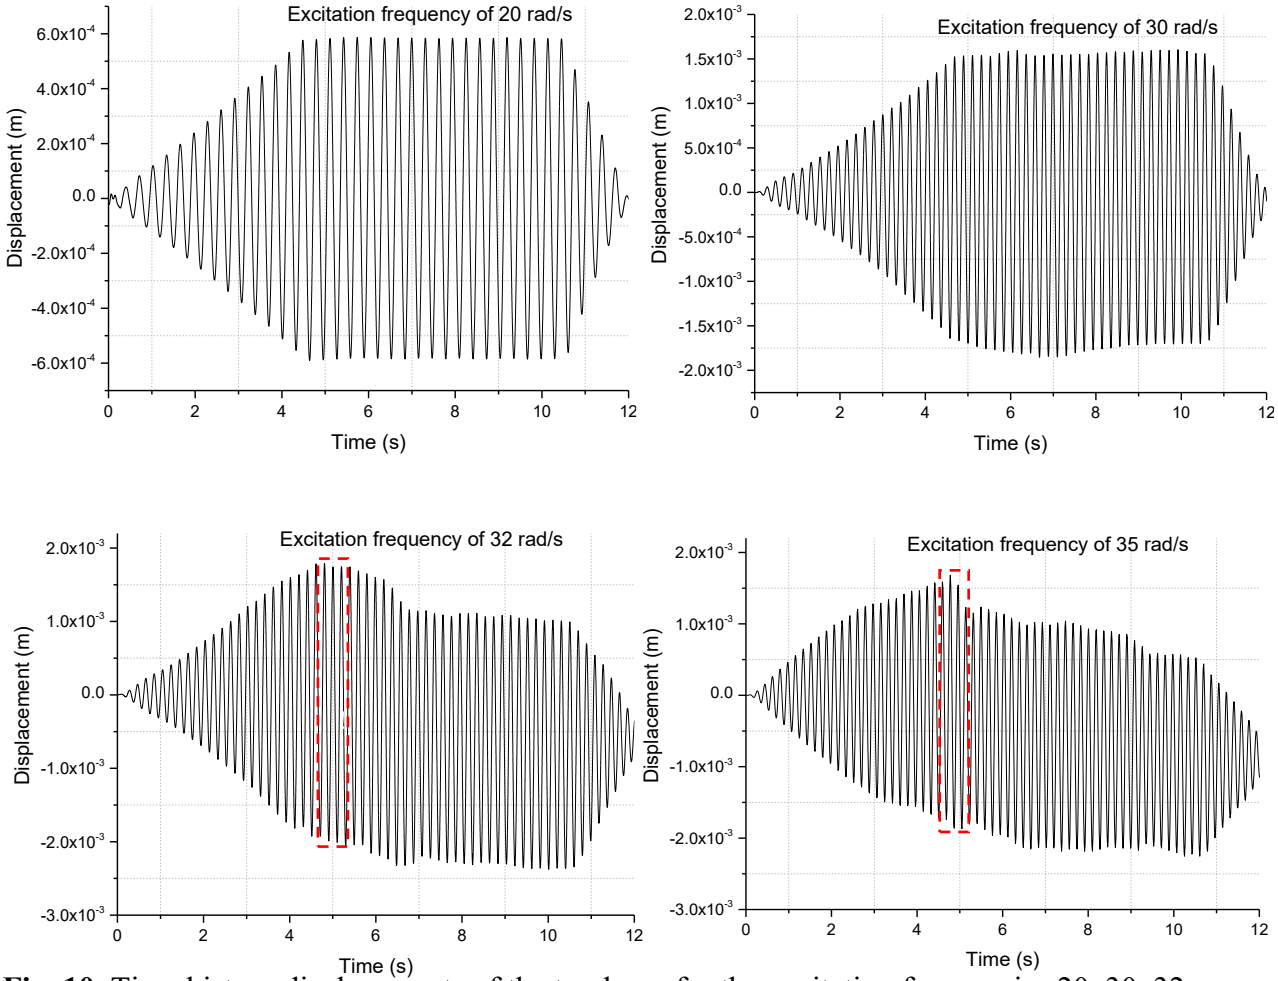
In order to show the excitation frequency effect on the deposit's response, several simulations are performed for frequencies ranging from 10 to 40 *rad/s*, while the excitation amplitude is set to $u_0 = 4x10^{-4} m$. Figure 9 shows the time history of displacements during the steady state excitation stage at the bedrock and at the top layer of the deposit for frequencies of 10 and 20 *rad/s*.

(a) (b)

Fig. 9. Steady state displacements time history at the bedrock and at the top layer of the deposit for excitation frequencies: (a) 10 *rad/s*, (b) 20 *rad/s* ($u_0 = 4x10^{-4} m$).

It can be noted that for the frequency of 10 *rad/s*, there is no movement amplification at the top layer, thus the deposit exhibits a behaviour of a rigid body that follows the bedrock's displacement. However, for the frequency of 20 *rad/s*, the movement is amplified at the top layer, indeed in this case the inertial forces become more significant, which causes the deformation of the deposit.

Figure 10 shows the displacement time history of the top layer throughout the excitation. For clarity, only the responses at 20, 30, 32, and 35 rad/s are presented, as they capture the main evolution of the behavior. Increasing the frequency from 20 to 30 rad/s increases the motion amplification, with the top-layer amplitude rising from 0.6 to approximately 1.6 mm. At 32 and 35 rad/s, the top layer exhibits irreversible grain sliding, attributed to strong amplification and the lack of confinement at the deposit surface. Sliding begins when the vibration amplitude becomes sufficiently large, near the onset of the steady-state stage, after which the layer oscillates around a progressively changing equilibrium position. The slight decrease in amplitude over time may result from deposit densification due to significant grain rearrangement, which reduces its deformability.For frequencies associated with top-layer sliding, the steady-state phase is defined as the short interval immediately following the amplitude ramp-up (after 4.5 s), highlighted by the red windows in Fig. 10. This interval is shortened to capture the response before significant densification occurs. To account for any shift from the initial position, the displacement amplitude is calculated as half the difference between the maximum and minimum displacement peaks over the selected interval.



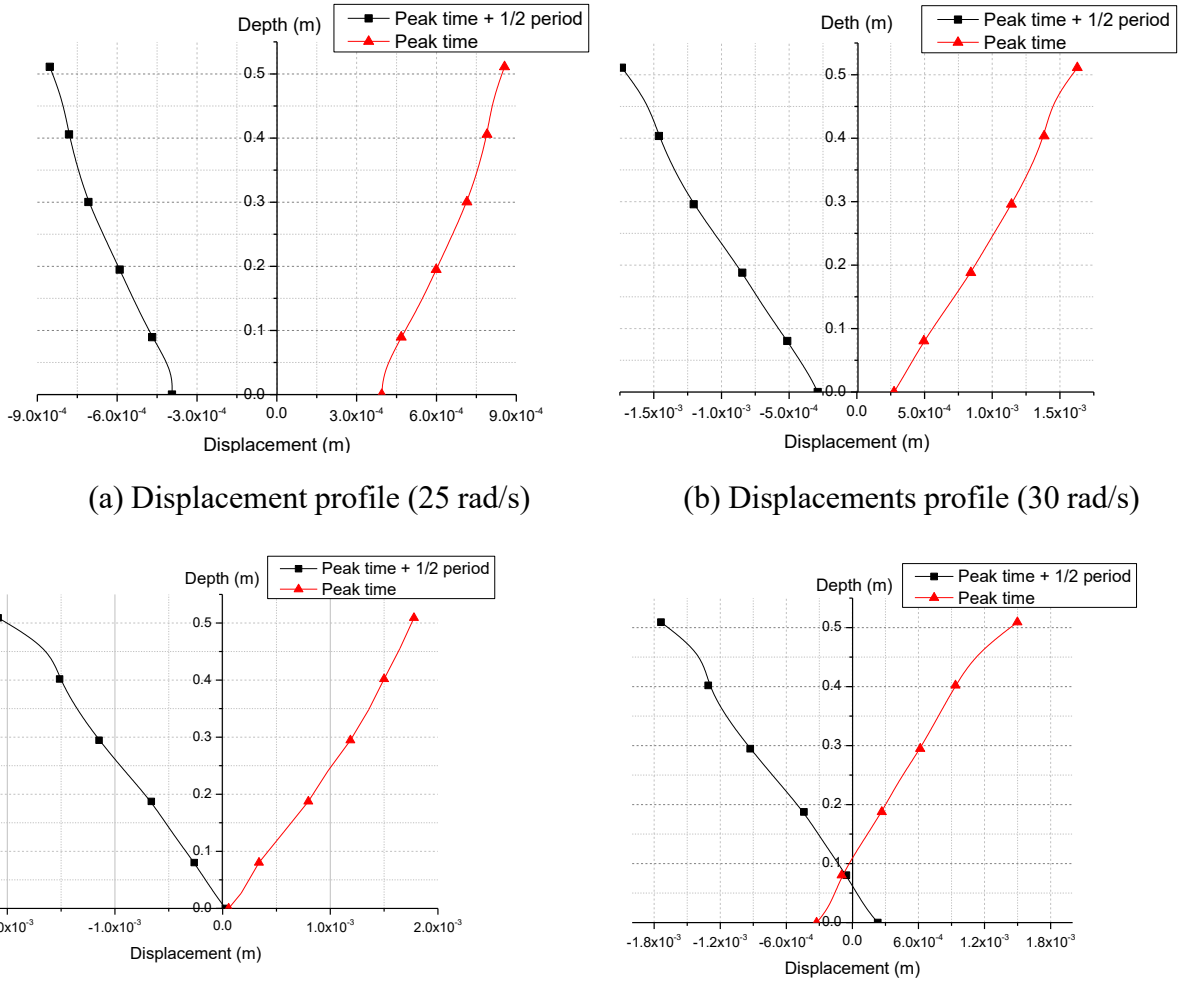


Fig. 10. Time history displacements of the top layer for the excitation frequencies 20, 30, 32 and 35 *rad/s*. Excitation amplitude $u_0 = 4x10^{-4}m$.

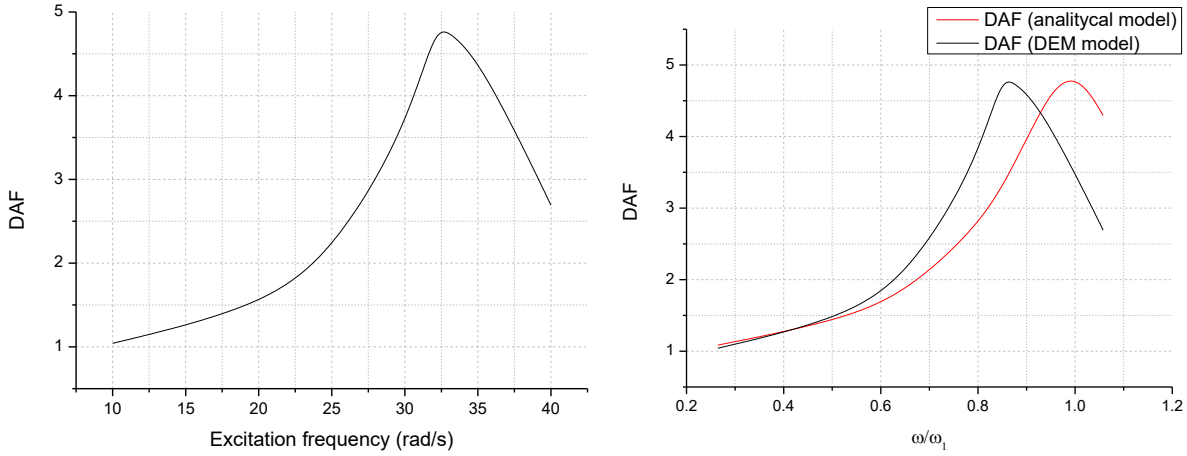
Figure 11 presents the displacement profiles (deposit deformation shapes) at the positive and subsequent negative displacement peaks during steady-state vibration. It can be noted that for frequencies up to 30 *rad/s*, the displacement profiles exhibit the first-mode shape. At 32 *rad/s*, a zero-displacement node appears at the base and rises at 35 *rad/s*, indicating that the first resonance is reached and exceeded. Thus, for the considered excitation amplitude ($u_0 = 4x10^{-4}m$), the first resonance frequency is approximately 32 *rad/s*.

(a) Displacement profile (25 rad/s)

(b) Displacements profile (30 rad/s)



(c) Displacement profile (32 rad/s)

(d) Displacement profile (35 rad/s)

Fig. 11. Displacements profiles for different excitation frequencies. Excitation amplitude $u_0 = 4x10^{-4}m$.

We define in the following the dynamic amplification factor (*DAF*) at the top layer in the steady state vibration phase as: $DAF = \frac{u_s}{u_0}$, where u_s denotes the displacement amplitude at the top layer (surface layer) and u_0 is the displacement amplitude at the bedrock (excitation). In order to show the evolution of the amplification with frequency, the *DAF* is represented in Fig. 12a in terms of the excitation frequency. This figure shows a *DAF* evolution similar to that of an elastic deposit subjected to harmonic base excitation: it increases with frequency up to resonance, then decreases. The resonance frequency being approximately 32 rad/s, is in good agreement with the displacement profiles in Fig. 11. For comparison with the analytical solution, Figure 12b shows the frequency-dependent *DAF* obtained numerically and analytically. The analytical solution uses the numerical deposit parameters, $h = 0.54\ m$ and $\omega_1 = 37.82\ rad/s$, with the damping ratio adjusted to match the numerical resonance peak

($DAF_{max} = 4.75$). From the equation $DAF_{max} \approx \frac{2}{\pi\xi}$, this gives $\xi = 13.4\%$. In this figure, the excitation frequencies are normalized by the model's fundamental frequency. The numerical and analytical *DAF*s show very similar trends, although the numerical resonance frequency is about 13% lower, mainly due to shear-modulus degradation associated with increased shear strains near resonance.

(a) (b)

Fig. 12. Dynamic Amplification Factor vs. excitation frequency for excitation amplitude $u_0 = 4x10^{-4}m$, (a) *DAF* obtained from numerical modelling, (b) *DAF* comparison between numerical modelling and analytical solution.

To assess the influence of strain level on shear-modulus degradation, the analysis is repeated with an excitation amplitude of $4x10^{-6}m$, following the same procedure as for amplitude $4x10^{-4}m$. Therefore, the applied acceleration is reduced by a factor of 100, resulting in lower strains. No sliding of the surface layer is observed, and the motion remains harmonic and regular throughout the deposit. The displacement profiles indicate an increased resonance frequency of approximately 37.5 rad/s. The *DAF* evolution with excitation frequency is presented (Fig. 13), as in Figure 12b.

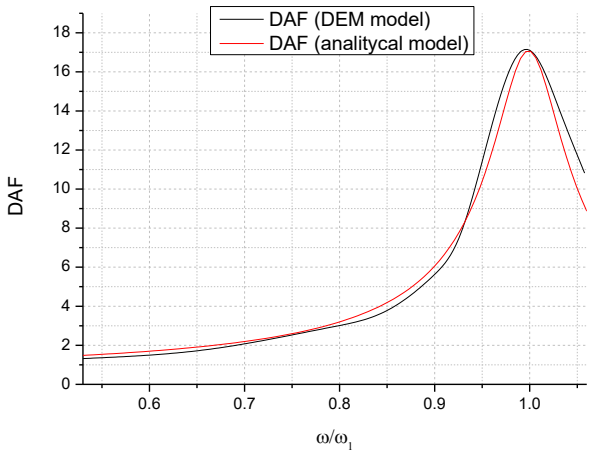


Fig. 13. Dynamic Amplification Factor vs. excitation frequency for excitation amplitude $u_0 = 4x10^{-6}m$, *DAF* obtained from numerical modelling and analytical solution.

This figure shows that the resonance frequency is very close to the fundamental frequency estimated in Section 5.2 ($\omega_1 = 37.82\ rad/s$). Moreover, the maximum dynamic amplification factor increases significantly ($DAF_{max} = 17.08$), corresponding to a damping ratio of approximately 3.73% in the viscoelastic model. These results confirm the well-established

concept in soil dynamics that increasing strain levels lead to shear-modulus degradation and increased damping.

5 Conclusion

This work presented a 2D discrete element analysis of shear-wave propagation in a sand deposit subjected to harmonic base excitation. The model incorporates viscoelastic contact forces, friction, and rolling resistance, with a free surface and periodic lateral boundaries. The simulations qualitatively reproduced key features of deposit vibration, including the displacement profiles and large motions near resonance. Quantitatively, the fundamental frequency was first determined from low-amplitude free vibrations. The frequency-response analysis showed that the Dynamic Amplification Factor (*DAF*) increases from unity at low frequencies, reaches a maximum at resonance, and then decreases. The resonance frequency was found to be close to the fundamental frequency at low excitation amplitudes but decreased as the amplitude increased. This shift is mainly attributed to shear-modulus degradation associated with increasing shear strains.

Abstract. The increasing frequency of severe urban flooding necessitates the development of large-scale flood-regulation infrastructures. This paper presents a case study on the Johoku Chuo Park Regulation Pond project in Tokyo, which involves the simultaneous sinking of twin massive pneumatic caissons, each 33.4 m in width, 80.3 m in length, and 35.3 m in depth. The primary geotechnical challenge of this operation is the extremely narrow 2.0 m clearance between the structures, which induces highly confined and complex soil-structure interactions. To evaluate these proximity-induced behaviors, a real-time in-situ monitoring system was deployed to analyze peripheral skin friction, lateral wall reactions, and caissons sinking records. Field measurements revealed that strict synchronization successfully limited the maximum elevation difference between the caissons to 528 mm, remaining safely below the 1.0 m structural safety threshold. However, in deeper dense strata, localized skin friction and lateral wall reactions near the cutting edge exceeded standard empirical criteria by over 200% due to shear-induced dilatancy and particle interlocking. Furthermore, the results demonstrated the effectiveness of the physical friction cut in reducing these lateral stresses. Additionally, the integration of unmanned excavation and continuous data-driven posture control ensured a safe and stable sinking process. Ultimately, this study is expected to serve as a definitive technical reference for future massive caisson operations in urban environments.

1 Introduction

The pneumatic caisson method (PCM) is a deep foundation technique that uses compressed air in a sealed working chamber to prevent groundwater inflow, enabling dry excavation as the caisson gradually sinks under its own weight. Invented and patented by British engineer Thomas Cochrane in 1830, the method was first deployed by French engineers in 1839 to sink the Granges Shaft at the Chalonnes-sur-Loire coal mines in France [1], [2].

PCM was introduced to Japan in 1899 with diving-type caissons for harbor reclamation at Yokohama Port, followed by its first structural bridge application in 1909 for the Amnokgang (Yalu) River Railway Bridge. Following the 1923 Great Kanto Earthquake, PCM was systematically adopted for Tokyo's urban reconstruction. Starting in 1924 with major Sumida River crossings—such as the Eitai, Kiyosu, Kuramae, and Kototoi bridges —this effort

pioneered subsequent standardization for challenging fluvial foundations across the Kisogawa and Ibigawa rivers in 1926 [3].

Throughout the late 20th and early 21st centuries, Japanese engineers modernized technology to address severe seismicity, complex soil profiles, and strict safety standards, transforming labor-intensive operations into highly automated processes. The efficient mechanization of pneumatic caissons began in 1971 with overhead-traveling caisson excavators during construction of the Hanshin Expressway Minato Bridge. To eliminate the risk of decompression sickness, the industry pioneered unmanned excavation systems. This evolution progressed from pressurized capsules at the Meiko-West Bridge in 1981 to the world's first fully unmanned pneumatic caisson system at the Kuramae Pump Station in 1990 [4].

Over the past three decades, Japan has continuously expanded the scale and depth of caisson capabilities to accommodate complex urban infrastructure [5]. Fig. 1 illustrates notable contemporary achievements in Japanese pneumatic caisson engineering. Prominent examples include the Kamioyamada Emergency Exit Shaft for the Chuo Shinkansen, which represents one of the deepest applications, reaching a sinking depth of approximately 110 m with a base area of around 1,300 m²; the Higashi Ogu Purification Center (Nishi-Nippori Pump Station), which holds the record for the largest pneumatic caisson footprint at 4,837 m², sunk to a depth of 43.9 m; and the Kajigaya Emergency Exit Shaft, successfully constructed to a depth of 79 m under a hyperbaric pressure of 0.73 MPa [6], [7].

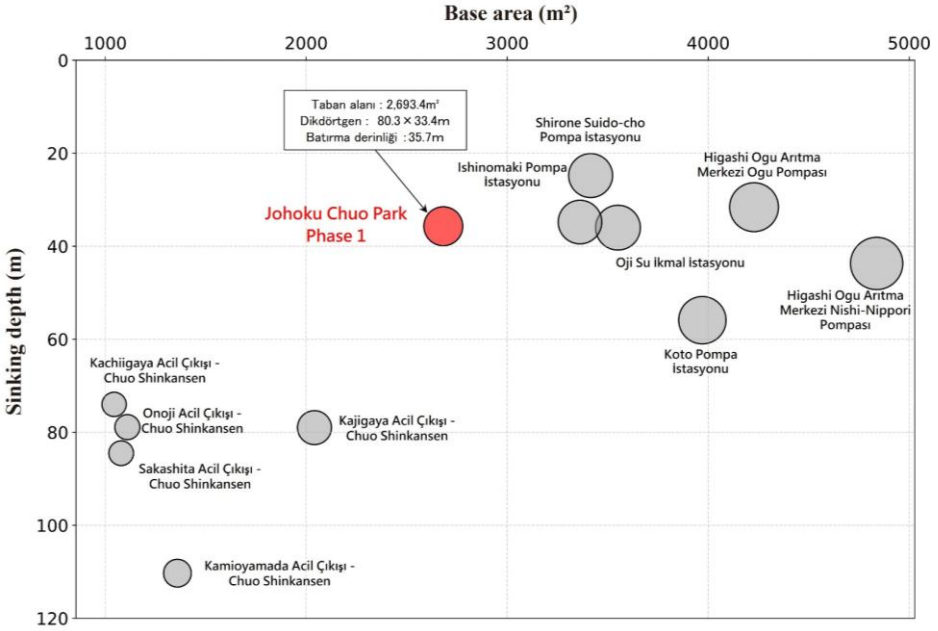

Fig. 1. Base area versus sinking depth of major pneumatic caissons in Japan.

In densely populated regions like Tokyo, severe urban flooding requires large-scale subterranean regulation reservoirs. The PCM has become indispensable for these structures when space constraints prevent conventional open-cut excavations. A prominent example is the Johoku Chuo Park Regulation Pond project. This project involves the simultaneous sinking of twin massive pneumatic caissons. The combined base area of these twin structures is approximately 5,386.8 m², making it the largest pneumatic caisson area in Japan. The primary challenge of this operation is the extremely narrow 2.0 m clearance separating the caissons (Fig. 2). In this context, this paper investigates their sinking behavior using an extensive real-time monitoring network. The study analyzes in situ data on peripheral skin friction, lateral wall reactions, and elevation differences between the caissons. Ultimately, this case study aims to provide a technical reference for future massive caisson sinking operations in confined urban environments.

2 Project Description

The Johoku Chuo Park Regulation Pond is a large-scale subterranean flood mitigation facility along the Shakujii River in Tokyo, designed to withstand intense precipitation events up to 75 mm/h. As shown in Fig. 2, it consists of two adjacent underground structures (Caisson No. 1 and Caisson No. 2) linked by a central connection. Excess river floodwater flows directly into the pond through a dedicated intake structure and is discharged back into the channel once water levels return to normal. The caisson sinking operations commenced from a construction base elevation of A.P. +23.50 m and concluded at a final cutting-edge depth of A.P. −11.8 m. The caisson's top slab will subsequently be covered with a backfill to restore the park surface at a final ground elevation of A.P. +27.0 m.

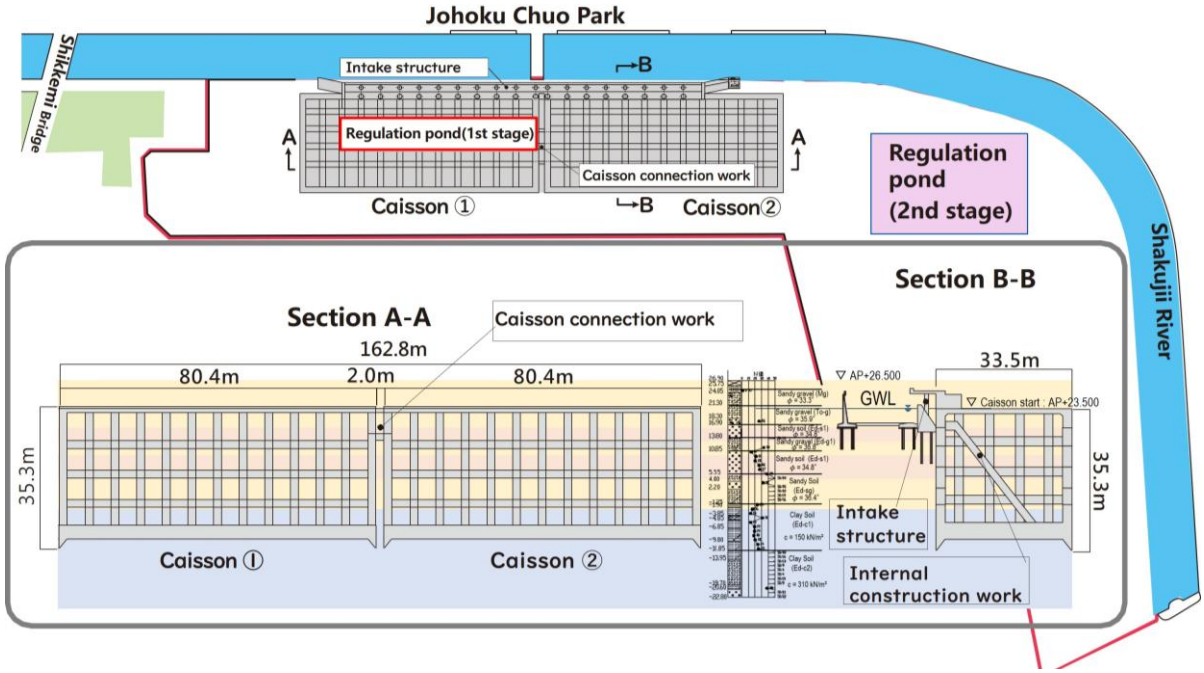

Fig. 2. Plan view and cross-sections of the Johoku Chuo Park Regulation Pond twin caissons.

The primary substructure comprises twin massive pneumatic caissons, each with an excavation base area of 2,693.4 m². Structurally, each rectangular caisson is 33.5 m wide, 80.4 m long, and 35.3 m high. To accommodate massive structural loads, the internal framework is strengthened with a 2.0 m by 2.0 m grid-like arrangement of structural columns and beams. The most critical geotechnical constraint is the extreme proximity of the twin caissons, separated by only 2.0 m. This configuration induces highly confined soil-structure interactions, necessitating strict real-time monitoring and posture control to prevent differential settlement during simultaneous sinking.

2.1 Geotechnical Condition

The project site consists of Late to Early Pleistocene alluvial and diluvial deposits. The natural ground surface elevation is A.P. +26.50 m, and the design groundwater level is A.P. +23.50 m. As shown in Figs. 2 and 6, caisson operations commenced from a construction base elevation of A.P. +23.50 m. The upper profile contains a thin backfill layer (B) and a soft cohesive clay layer (Lc). This soft clay extends down to A.P. +24.05 m and exhibits a low cohesion, c = 11.8 kN/m².

Beneath the surface layer, the stratigraphy transitions into dense granular formations. These include Musashino Gravel (Mg), Tokyo Gravel (To-g), and upper Edogawa Group strata (Ed-

s1, Ed-g1, Ed-sg). These intermediate layers exhibit Standard Penetration Test (SPT) N values ranging from 16 to over 50. Their internal friction angles (ϕ) range between 33.3° and 36.8°.

The bearing layer is the highly consolidated Edogawa silty clay (Ed-c1) with a cohesion of c = 150.0 kN/m². The caisson cutting edges for both caissons were terminated at a depth of A.P. -11.80 m. Directly below this lies the overconsolidated, hard Edogawa Clay (Ed-c2). Starting at A.P. -11.85 m, it has significantly high cohesion of c = 310 kN/m². additionally, an at-rest earth pressure coefficient (K_0) of 0.50 was adopted for all identified strata in structural and lateral stability evaluations.

2.2 Description of the Problem

The primary geotechnical and structural challenge arises when twin caissons sink simultaneously at different depths within a narrow 2.0 m clearance. As illustrated in the geotechnical interaction model in Fig. 3(a), an elevation difference (ΔH) between the leading caisson (No. 1) and trailing caisson (No. 2) causes the ground bearing pressure (Q) beneath the trailing cutting edge to act as a surcharge on the confined soil column. This bearing pressure is defined as $Q = \Sigma(\text{Downward Forces}) - \Sigma(\text{Upward Forces})$. The surcharge transmits an asymmetric horizontal load (P_H) against the leading caisson shaft.

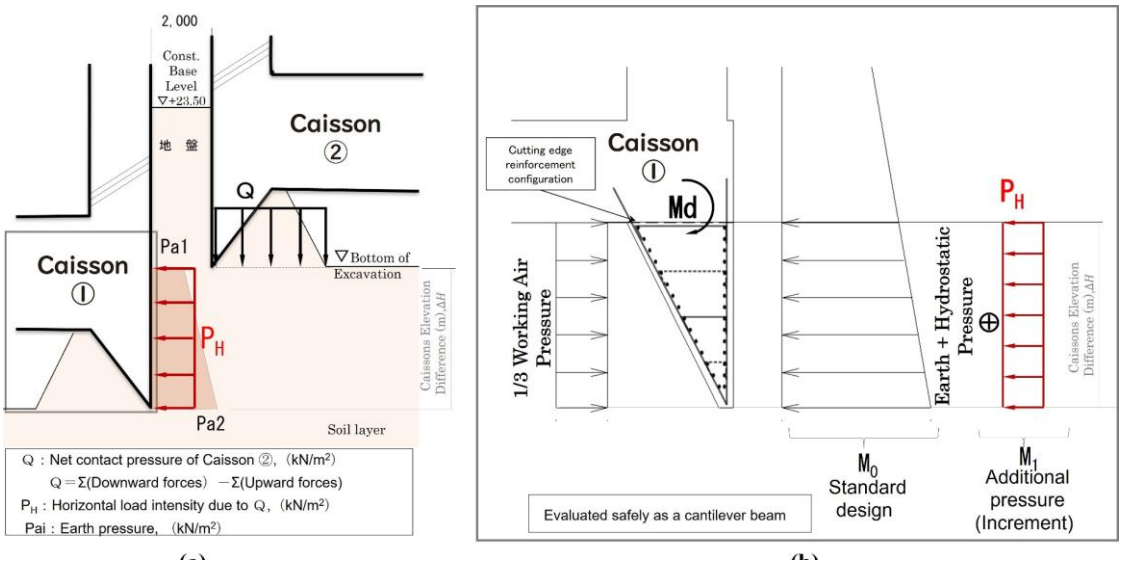

Fig. 3. Proximity-induced stress evaluation: (a) geotechnical interaction model; (b) structural cantilever model.

To evaluate the structural reliability of the reinforced concrete cutting edge under these eccentric forces, a cantilever beam model fixed at the base was used in accordance with the Japan Road Association (JRA) specifications (Fig. 3(b)) [7]. The standards suggest setting the internal air pressure to one-third of its working pressure, acting in the opposite direction to the earth pressure. Under standard conditions, active earth pressure P_a and hydrostatic pressure (P_w) generate a base bending moment (M_0). The additional thrust (P_H) induced by ΔH generates an incremental moment (M_1). To prevent structural cracking or failure, the combined design moment ($\Sigma M = M_0 + M_1$) must maintain tensile stresses in the reinforcement below the short-term allowable limit of 240 N/mm² for SD345 steel.

Analyses were conducted for varying elevation differences (ΔH) between the caissons to establish safe construction tolerances (Fig. 4). The structural limit value was determined as 622.6 kN/m², corresponding to the allowable rebar tensile strength. Calculations demonstrate that maintaining $\Delta H \leq 1.0$ m restricts the maximum horizontal load intensity on the leading caisson to 605 kN/m². Because this value remains safely below the structural limit of 622.6

kN/m², a maximum allowable elevation difference (ΔH) of 1.0 m was established as the primary threshold for construction.

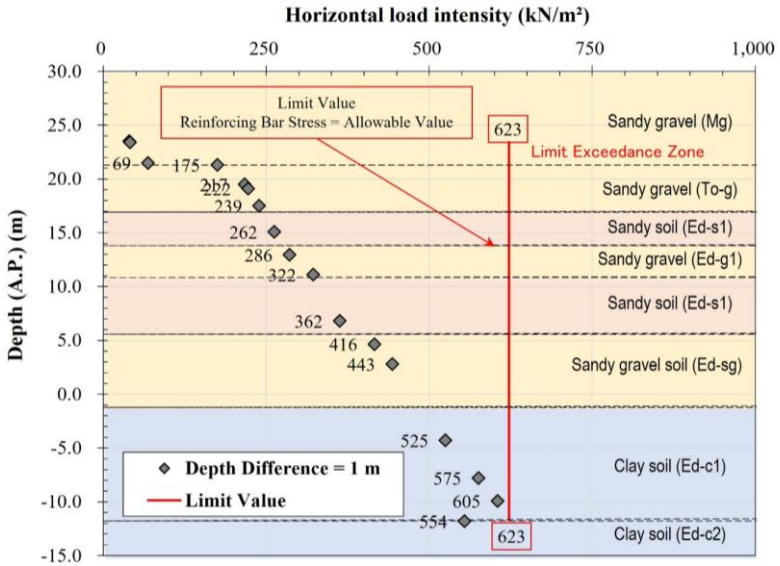

Fig. 4. Horizontal load intensity versus depth for the limit value of 1.0 m elevation difference between caissons.

3 Construction Progress

The sinking of twin caissons commenced on March 18, 2021, with an initial opening phase comprising 644.0 m³ of manual and 5,010.3 m³ of mechanical excavation. Full-capacity mechanized excavation began on June 30, 2021, utilizing 18 unmanned overhead traveling excavators within the pressurized working chamber (Fig. 5), bringing the total excavated volume to 100,731.3 m³ per caisson. Caissons No. 1 and No. 2 reached their final design elevation of A.P. -11.8 m on October 5 and October 6, 2022, respectively. Final working chamber air pressures were recorded at 0.330 MPa for Caisson No. 1 and 0.315 MPa for No. 2.

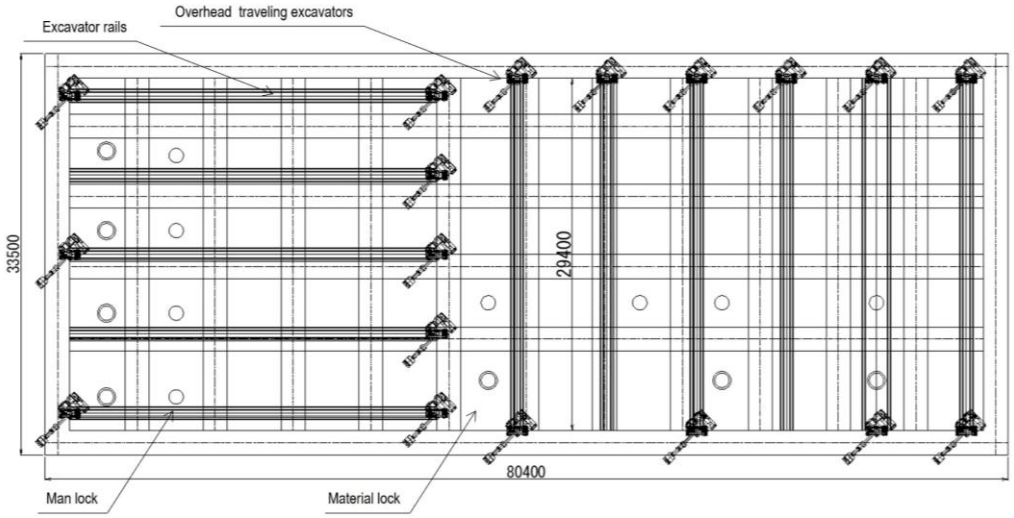

Fig. 5. Layout of unmanned overhead traveling excavators.

To overcome sinking resistance in the dense strata, surcharge water loading was applied from Lot 6 to Lot 9 to increase the downward driving force. Additionally, approximately 402 m³ of bentonite lubricant was injected to reduce peripheral skin friction. Upon completion of the sinking process, 131.5 m³ of contact grouting was injected around the cutting edges to fill peripheral voids and prevent post-construction settlement.

4 Real-Time In-Situ Instrumentation

To evaluate geotechnical forces and ensure structural safety, each caisson was equipped with an array of 58 sensors. As shown in Fig. 6, Lot 1 (1.856 m above the cutting edge) includes 18 vertical reaction gauges, alongside peripheral skin-friction, lateral wall reaction, and pore-water pressure sensors distributed at six horizontal locations. Lot 4 (14.50 m above the cutting edge) has also friction, wall reaction, and pore-water pressure sensors. Lot 7 (26.70 m above the cutting edge) is also instrumented with lateral wall reaction gauges to monitor shallow horizontal pressures. Moreover, laser distance meters and inclinometers continuously tracked the caisson's vertical alignment. This real-time data acquisition enabled immediate operational adjustments, ensuring sinking stability and preventing differential settlement.

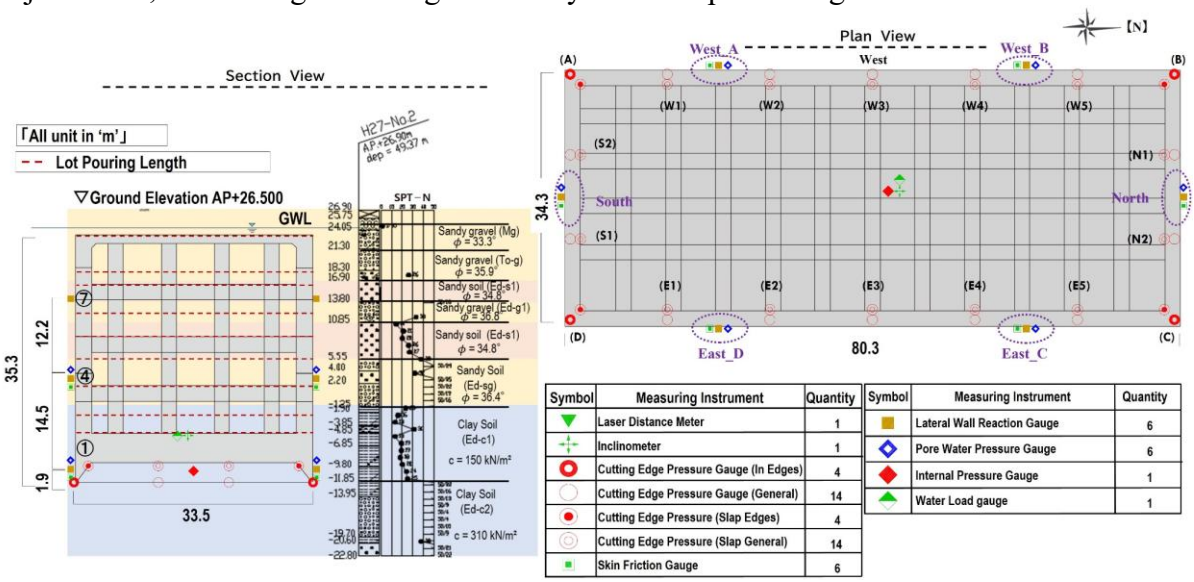

Fig. 6. Instrumentation layout.

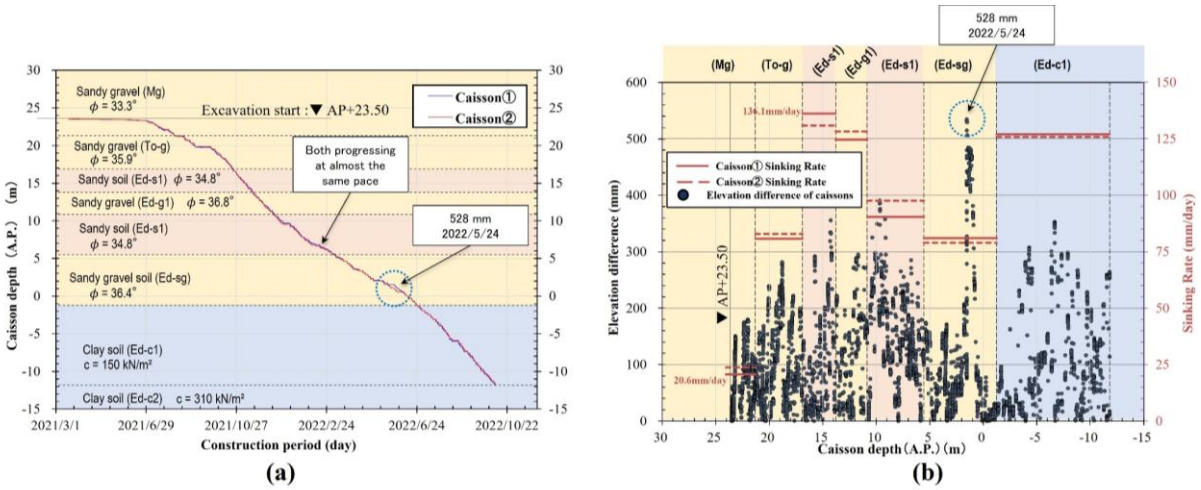
5 Measurement Results and Analysis

This section analyzes in-situ data on caisson sinking records, peripheral skin friction, and lateral wall reactions.

5.1 Caisson Sinking Records

Fig. 7 illustrates the sinking progression of the twin caissons. Fig. 7(a) plots the sinking depth over the 21-month construction period against the soil profile. Complementing this, Fig. 7(b) displays the caisson depth on the horizontal axis, the vertical elevation difference on the left vertical axis, and the depth-dependent sinking rates (mm/day) on the right vertical axis. To ensure data accuracy, the sinking rate for each stratum was calculated by averaging the daily depth changes exclusively on active construction days (non-working days were excluded).

The recorded data confirms strict adherence to the pre-established 1.0 m maximum vertical difference criterion. A maximum difference of 528 mm was recorded between the caissons on May 24, 2022, within the dense Ed-sg stratum, successfully preventing structural overstress at the concrete cutting edges. As shown in Fig. 7(b), the sinking rate fluctuated with geotechnical conditions and operational phases. The maximum sinking rate peaked at 136.1 mm/day in the intermediate Ed-s1 sandy layer, while the slowest sinking occurred in the initial Musashino Gravel (Mg), which may have been due to manual excavation and partial equipment usage. Once all 18 overhead excavators became fully operational, progress accelerated. Geotechnically, correlating sinking rates directly to specific soil strata proved difficult. Although the Ed-s1, Ed-g1, and Ed-sg layers have similar internal friction angles (ϕ), their progress behaviors differ significantly, highlighting the critical need for continuous real-time monitoring.



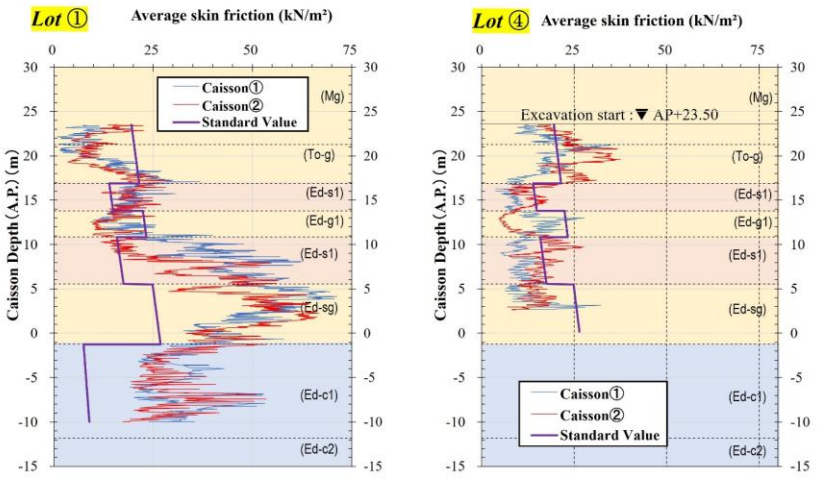


Fig. 7. Caisson sinking records: (a) depth progression over time; (b) caisson elevation difference and sinking rates relative to depth.

5.2 Peripheral Skin Friction Stress

Fig. 8 shows the depth-dependent distribution of average peripheral skin friction at Lots 1 and 4, compared with the Japan Road Association (JRA) standard criteria [7]. In-situ measurements at Lot 1 revealed significant deviations from the suggested standards. While friction in the upper granular layers remained below the standard value, it surged dramatically in the deeper, denser strata, exceeding the JRA empirical criteria by over 200%. This friction spike may be attributed to shear-induced dilatancy of dense sand and gravel particles under high confining pressures. The lateral constraint imposed by the narrow 2.0 m soil column amplifies this volumetric expansion, leading to localized surges in effective normal stresses and particle interlocking.

Average Skin Friction per Layer for Lot 1		
Soil Type	Caisson ①	Caisson ②
Sandy gravel (Mg)	7.14	9.50
Sandy gravel (To-g)	14.40	13.67
Sandy soil (Ed-s1)	19.47	22.63
Sandy gravel (Ed-g1)	19.00	15.95
Sandy soil (Ed-s1)	43.28	31.23
Sandy Soil (Ed-sg)	54.90	51.56
Clay (Ed-c1)	32.33	30.49

Average Skin Friction per Layer for Lot 4		
Soil Type	Caisson ①	Caisson ②
Sandy gravel (Mg)	18.52	22.21
Sandy gravel (To-g)	18.67	27.04
Sandy soil (Ed-s1)	8.86	14.35
Sandy gravel (Ed-g1)	17.56	8.23
Sandy soil (Ed-s1)	10.73	16.15
Sandy Soil (Ed-sg)	10.89	13.27
Clay (Ed-c1)	–	–

Fig. 8. Depth-dependent distribution of average in-situ peripheral skin friction compared with JRA standard values at Lots 1 and Lot 4.

Conversely, skin friction measured at Lot 4 exhibited markedly different behavior. In the upper granular formations, the friction values aligned closely with the standard criteria, likely because the prior sinking of Caisson No. 1 compacted the initially loose soil, increasing the lateral stiffness and normal stresses acting on Caisson No. 2. However, within the deeper layers, friction at Lot 4 was three to four times lower than at Lot 1. This reduction provides clear empirical evidence of the 50 mm friction cut's effectiveness. By creating a physical overcut

void above the cutting edge, the friction cut successfully decoupled the upper concrete shaft from the surrounding soil matrix, reducing mobilized lateral normal stresses.

5.3 Lateral Wall Reactions and Compaction-Induced Stress Amplification

Fig. 9 presents the depth-dependent average lateral reactions at Lots 1, 4, and 7, evaluated against theoretical at-rest ($K_0 = 0.5$, purple line) and active earth pressures (green line). At the upper elevations (Lots 4 and 7), the recorded wall reactions generally remained under these theoretical limits. This data confirms that the physical friction cut successfully maintained lower wall reactions compared to Lot 1. Conversely, Lot 1 measurements near the cutting edge revealed significant stress concentrations. In the deeper Ed-s1 and Ed-sg strata, lateral pressures were approximately 1.5 to 2.0 times higher than standard values. While it might be argued that relatively rapid progress in these strata prevented consistent excavation and increased local deformations, the exact mechanism depends on numerous complex parameters; given these multiple unknowns, a definitive explanation remains elusive and requires further detailed analysis.

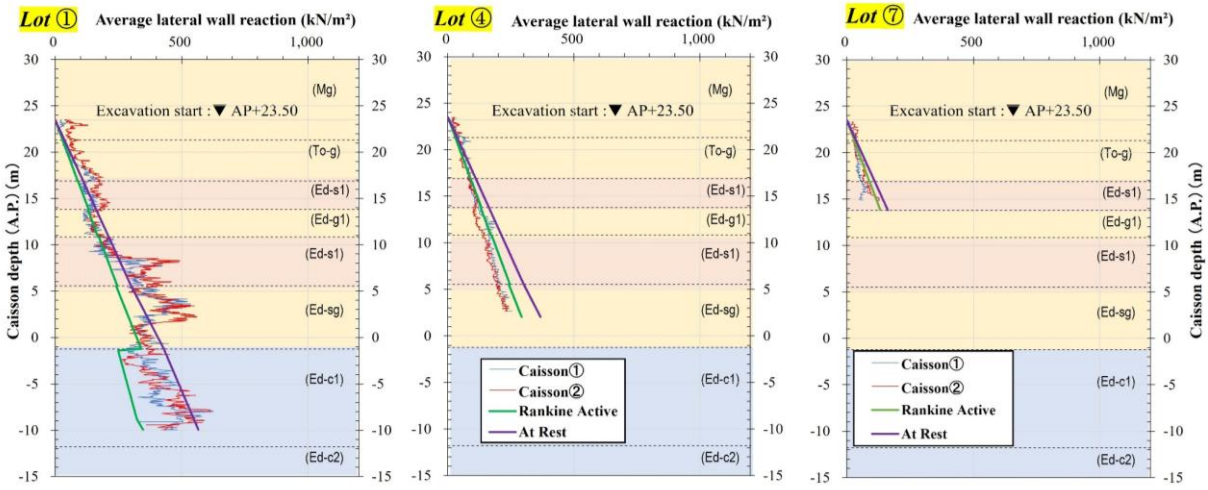

Fig. 9. Depth-dependent distribution of average in-situ lateral wall reactions at Lots 1, 4, and 7, compared with theoretical active and at-rest earth pressures.

Furthermore, comparative analysis revealed a clear "twin-caisson interaction" effect. Across all strata, Caisson No. 2 consistently experienced higher lateral wall reactions than Caisson No. 1. This discrepancy is especially pronounced in the upper granular formations; in the Musashino Gravel (Mg) and Tokyo Gravel (To-g) layers, average reactions for Caisson No. 2 were up to 2.3 times higher. The construction sequence might induce this: Caisson No. 1 was sunk slightly ahead, pre-compacting the loose granular soil confined within the gap. Consequently, Caisson No. 2 penetrated a pre-compacted, significantly stiffer soil matrix, which increased the horizontal normal stresses acting on its shaft.

Fig. 10 shows the spatial distribution of average skin friction and lateral wall reactions for each soil strata. Normalized data reveal an asymmetrical stress distribution, directly governed by twin-caisson interaction. Peak stress concentrations are consistently localized on the adjacent inner boundaries: the North face of Caisson No. 1 and the South face of Caisson No. 2. This stress amplification results from soil confinement and particle interlocking within the clearance gap. Additionally, sinking rates accelerated horizontal soil deformations and shear within this confined zone, inhibiting stress relaxation and further intensifying lateral loads on the adjacent caisson walls.

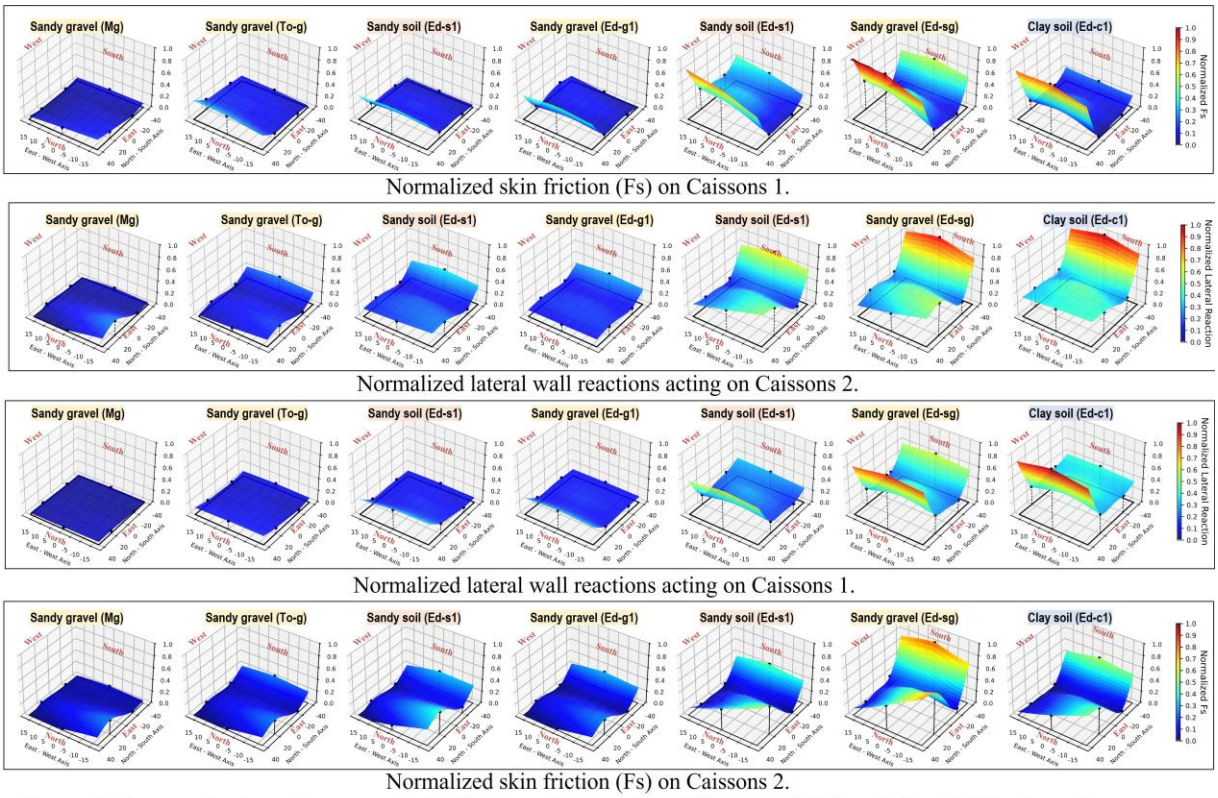

Fig. 10. Normalized skin friction (Fs) and lateral wall reactions act on Caissons 1 and 2 across different soils at Lot 1.

6 Conclusion

The simultaneous sinking of the twin massive pneumatic caissons at Johoku Chuo Park, separated by a narrow 2.0 m clearance, was successfully executed without structural damage. Based on comprehensive in-situ monitoring and geotechnical analyses, the following conclusions are drawn:

- Strict Posture Control: Real-time synchronization effectively limited the maximum depth difference (ΔH) between the twin caissons to 528 mm. This value remained well below the 1.0 m critical design threshold.
- Effectiveness of Friction Reduction: A 50 mm physical friction cut, combined with bentonite lubrication, successfully decoupled the upper concrete shafts from the surrounding soil. This was validated by the in-situ sensors at Lot 4, which recorded skin friction values three to four times lower than those at the cutting edge (Lot 1).
- Proximity-Induced Stress Amplification: In-situ data highlighted stress amplifications within the narrow 2.0 m gap. In deep, dense granular strata, peripheral skin friction and lateral wall reactions at Lot 1 exceeded standard theoretical values by up to 200% due to shear-induced dilatancy and particle interlocking.
- Leading vs. Trailing Caisson Interaction: An interaction effect was recorded based on the sinking sequence. The trailing caisson experienced lateral wall reactions up to 2.3 times higher than the leading caisson in the upper granular layers due to pre-compaction of the soil. Additionally, peak stress concentrations consistently localized on the inner-facing boundaries (the North face of Caisson No. 1 and the South face of Caisson No. 2).

As only standard design formulas proved insufficient to predict complex 3D soil-structure interaction behavior, this study once again highlights the critical importance of integrated real-time in-situ monitoring.

Acknowledgments
The authors wish to express their profound gratitude to the Tokyo Metropolitan Government Bureau of Finance and the engineering execution teams at TODA Corporation and Oriental Shiraishi Corporation for their dedication and technical excellence throughout the Johoku Chuo Park project.

Abstract. Since a large part of Türkiye is located on active seismic zones, safely assessing the behavior of structures under seismic loads is essential. In addition, increasing population and urbanization make construction on weak or problematic soils inevitable, highlighting the need for safe and cost-effective foundation systems. Piled Raft Foundation (PRF) systems are widely used, particularly for high-rise buildings. However, seismic ground motion is transmitted through the piles and raft to the superstructure, exposing the system to kinematic interaction, while inertial forces generated by the superstructure induce additional stresses in the piles. Due to the rigid pile-raft connection, large shear forces and bending moments may develop, particularly at the pile-raft interface. Therefore, the Unconnected Piled Raft Foundation (UPRF), which eliminates the rigid connection and incorporates a cushion layer between the piles and raft, has emerged as an alternative to conventional PRF systems. The cushion layer limits the transfer of shear forces and moments, reduces pile-raft interaction, and contributes to damping earthquake effects. In this study, 1/10-scale laboratory experiments were analyzed using the finite element method (FEM) with PLAXIS 2D. The UPRF system was compared with a traditional PRF system under seismic loading, and its seismic energy damping performance was evaluated in terms of the soil and piles. Depth-dependent horizontal pile displacements, cross-section forces, and horizontal

accelerations in the soil were determined under dynamic loading to evaluate this performance.

Keywords: Structure-pile-soil interaction, Traditional piled raft foundation, Unconnected piled raft foundation, Numerical analysis

1 Introduction

Turkey is highly vulnerable to earthquakes due to its geographic and geological characteristics, and major earthquakes have caused significant loss of life and property. Although earthquake-resistant structural design is essential for mitigating earthquake-induced losses, ground conditions and soil-structure interaction also play a critical role in determining structural performance. Soil-structure interaction describes the mutual interaction between a structure and the surrounding soil under seismic loading. In weak soil conditions, shallow foundations may be inadequate to safely transfer superstructure loads to the ground, making deep foundation systems a common alternative. Among these, piled raft foundation (PRF) systems are widely employed due to their ability to enhance bearing capacity and reduce total and differential settlements. When piles primarily serve as settlement-reducing elements, the main objective of PRF design is to develop an economical foundation system by effectively mobilizing pile capacity while minimizing the number of piles.

While PRF systems offer numerous advantages under static conditions, one of their major disadvantages under dynamic conditions is the severe stress concentration occurring at the rigid connection between the pile heads and the raft foundation [1]. Under seismic action, complex structure-pile-soil interaction takes place. Seismic waves subject the soil, the soil subjects the piles, the piles subject the raft foundation, and the raft foundation subjects the superstructure to kinematic interaction. The resulting inertial behavior of the superstructure due to this interaction subjects the piles to additional distress. Consequently, the base of the raft foundation is subjected to high shear forces and overturning moments, transferring large lateral forces to the superstructure. Furthermore, as specified in the Turkish Building Seismic Code [2], the analysis of PRF systems using decoupled system approaches is complex and time-consuming, whereas integrated system solutions demand high computational capacity. Numerous studies in the literature have investigated the soil-pile-structure response of PRF systems [3,4,5,6]. To overcome these limitations, an alternative foundation system incorporating a cushion layer between the raft foundation and the piles has been investigated to eliminate the rigid connection and limit the transfer of shear forces and bending moments between the two structural elements. Referred to in the literature as Unconnected Piled Raft Foundation (UPRF) or rigid-pile composite foundation, the cushion material in these systems mitigates piled raft interaction by damping seismic loads [7-12]. Because the cushion layer prevents the direct transfer of superstructure loads to the piles, the unconnected piles act primarily as ground improvement elements rather than pure structural load-bearing elements.

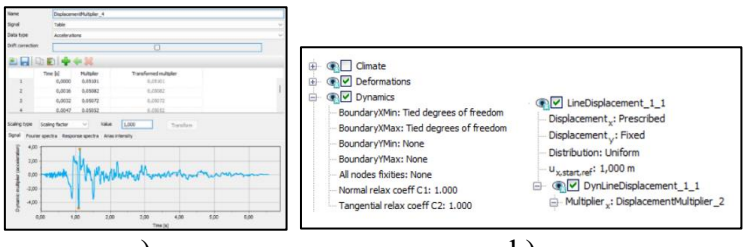
Within the scope of this study, the dynamic response and seismic energy damping efficiency of UPRF systems were numerically investigated as an alternative to traditional piled raft design. Accordingly, 1/10-scale laboratory experiments were analyzed using the finite element method via PLAXIS 2D software. In the study, the dynamic responses of the UPRF system utilizing sand soil with a thickness of 60 mm as a cushion material were comparatively evaluated against the conventional PRF system.

The experimental program to be conducted as part of the Scientific and Technological Research Council of Türkiye (TÜBİTAK) project entitled “Investigation and Development of Design Criteria for the Disconnected Piled Raft Foundation System as an Alternative Approach to Piled Raft Foundation under Earthquake Excitations” (Project No. 224M250) was numerically investigated in this study.

2 Materials and Methods

This section provides a comprehensive overview of the numerical model development process, presenting in detail the modeling steps, the foundation soil and structural material parameters used in the analyses, as well as the definitions and computational settings related to dynamic analyses.

2.1 Modeling of the Soil



To represent the 1/10-scale laboratory experiments, the defined soil profile consists of two distinct layers with a total thickness of 1.50 m. The upper layer, extending from the surface down to a depth of 0.48 m, was modeled as medium-dense sand, whereas the lower layer, situated in the depth range of 0.48-1.50 m, was modeled as dense sand. The material parameters for both layers were determined based on the results obtained from laboratory tests, along with empirical and semi-empirical relationships widely used in the literature. In the constructed models, the HS Small soil model was selected under drained conditions. In the analyses, the elastic modulus was input into the software in scaled form. The selected parameters are provided in Table 1.

Table 1. Selected soil parameters in PLAXIS 2D

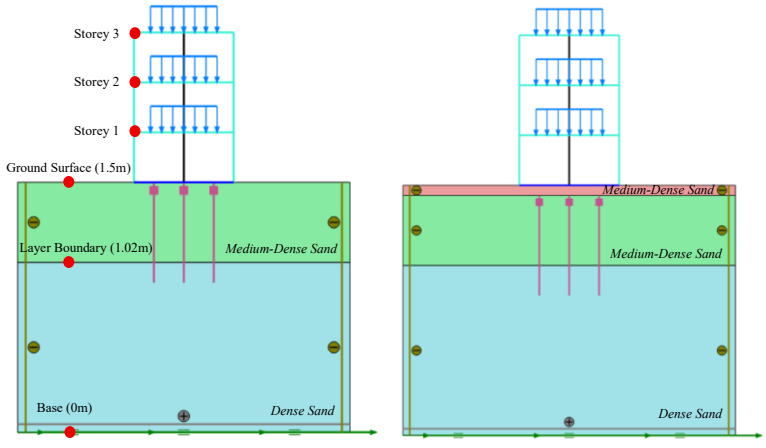
Parameters	Medium-Dense Sand	Dense Sand
Soil Model	HS Small	HS Small
Drainage Type	Drained	Drained
γ (kN/m^3)	14.5	16
e	0.8	0.65
$E_{50}^{ref}=E_{oed}^{ref}$ (kPa)	2500	4750
E_{ur}^{ref} (kPa)	7500	14250
ν	0.3	0.3
power (m)	0.5	0.5
p_{ref}	100	100
G_0^{ref} (kPa)	11000	16600
$\gamma_{0.7}$	0.0006	0.000248
c′	1	1
ϕ'	34	39

2.2 Dynamic Analyses and Numerical Settings

In the PLAXIS 2D dynamic analyses, a scaled acceleration-time record from the 1999 Erzincan earthquake was applied at the base of the soil layer in the horizontal direction (x-axis) using the "Line Displacement" approach. The seismic input is shown in Figure 1a, while the boundary conditions adopted in the numerical model are presented in Figure 1b. Interface elements were defined at the model boundaries to ensure the proper activation of the prescribed boundary conditions during the analyses [13].

a) b)

Fig. 1. PLAXIS 2D numerical model: a) definition of the input motion, b) boundary conditions.



2.3 Modeling of Superstructure and Piles

In the PRF and UPRF models, a two-bay, three-storey superstructure and its supporting piled raft foundation were modeled in PLAXIS 2D. Storey heights and bay widths were 300 mm, with 20x20 mm columns and beams and 600x600x20 mm slabs. The superstructure was supported by a rigid 600x600x60 mm raft foundation. A 3x3 pile group was modeled beneath the raft, with 600 mm long piles spaced 180 mm center-to-center. The raft and piles were represented using "plate" and "embedded beam row" elements, respectively. Steel material properties were adopted for the superstructure and foundation system, with the corresponding parameters given in Table 2. To avoid artificial mass amplification and dynamic response errors caused by the 1 m out-of-plane assumption in PLAXIS 2D plane strain modeling, column unit weight was neglected and the structure mass was assigned to the slabs.

Table 2. Structural element parameters used in numerical modeling.

Plate Element		**Slab**	**Column**	**Raft Foundation**
Unit Weight (w)	[kN/m/m]	1.57	0	4.71
Axial Stiffness (EA)	[kN/m]	$4x10^6$	$133.3x10^3$	$12x10^6$
Bending Stiffness (EI)	[kNm^2/m]	133.3	4.444	3600
Poisson Ration (ν)	-	0.3	0.3	0.3
Thickness (d)	[m]	0.02	0.02	0.06
Embedded Beam Row Element		**Piles**		
Unit Weight (w)	[kN/m^3]	78.5		
$L_{spacing}$	[m]	0.18		
Predefined Cross-section Type	-	Solid Circular Beam		
Diameter	[m]	0.0603		
Young's Modulus (E)	[kN/m^2]	$200x10^6$		
$T_{skin,\ start,\ max}$	[kN/m]	1		
$T_{skin,\ end,\ max}$	[kN/m]	6		
F_{max}	[kN]	8		

In PLAXIS 2D, two cases were modeled: a piled raft foundation system and an unconnected piled raft foundation system. The models created are shown in Figure 3. As part of the dynamic analyses, the horizontal accelerations (a_x) and horizontal displacements (u_x) occurring in the soil during the earthquake duration were evaluated as a function of time. The plotted data were obtained from the measurement points shown in Figure 3.

3 Numerical Analysis

In this section, the numerical analysis results for the PRF and UPRF systems are presented in detail. The 1999 Erzincan earthquake was utilized in the dynamic analyses to reveal the system behavior under realistic earthquake conditions.

3.1 PRF System Analysis

According to the analysis results, the maximum displacement in the PRF system under static loading was observed at the center of the raft foundation. The total vertical displacement at this location was 12.33 mm (Figure 4). This value indicates that the pile-raft interaction enables the load to be carried jointly by the piles and the raft, while differential settlements remain limited.

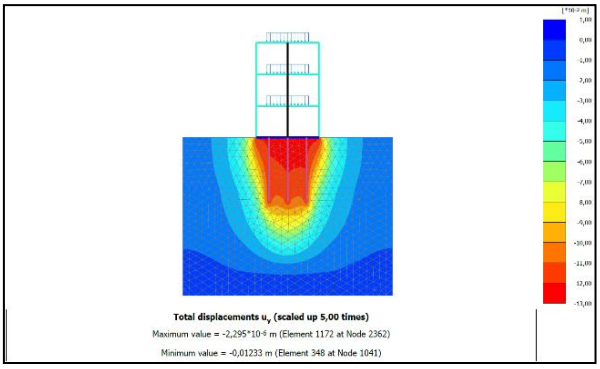

Fig. 4. Vertical displacement (u_y) in the soil in the PRF system under static loading.

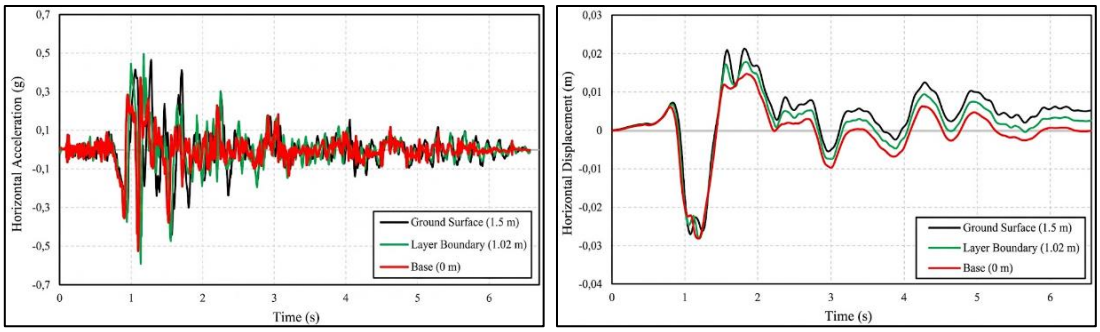
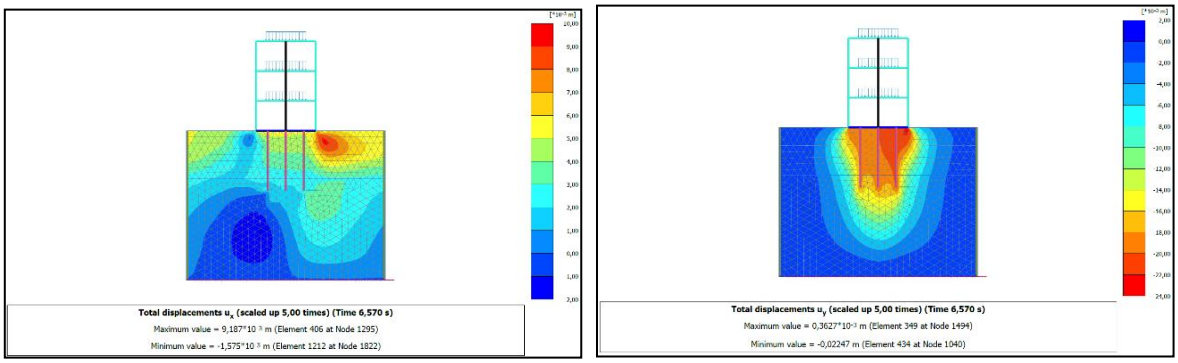


The scaled PRF system model was subjected to a real earthquake input with irregular, multi-component frequency content. Sudden peak values in the acceleration record introduced short-duration, high-amplitude excitations, resulting in irregular displacement time histories with varying amplitudes. Under the Erzincan earthquake excitation, the soil response exhibited a variable time-dependent character (Figure 5).

The maximum horizontal displacement in the soil reached approximately 9.19 mm, while the maximum vertical displacement remained at 22.47 mm (Figure 6). Examination of the soil displacement profiles indicates that horizontal displacements increase toward the ground surface, confirming the presence of the free-surface amplification effect.

The maximum horizontal displacement (u_x) of the piles was 5.34 mm, while the maximum vertical displacement (u_y) was 21.07 mm (Figure 7). The displacement results show that horizontal displacements reach their maximum values near the pile heads and decrease with depth. This indicates that lateral loads from the superstructure primarily induce bending near the pile heads. In contrast, vertical displacements show a more uniform distribution, indicating that the vertical load-carrying capacity of the system is effectively mobilized.



The internal force diagrams show that the maximum shear forces and bending moments occur in the piles located along the outer axes, while the pile along the middle axis is subjected to relatively lower demands due to more symmetric load transfer (Figure 8). Since the lower 12 cm of the piles are embedded in the dense sand layer, a distinct change in slope and increase in the shear force diagram are observed at the layer interface. This indicates that the stiffness contrast between the two layers is reflected in the finite element model. In addition, under the Erzincan earthquake excitation, moment concentration at the pile heads and increasing displacements toward the ground surface are observed.

Overall, the pile heads remained critical zones in the PRF system under the Erzincan earthquake, and the soil-pile-raft interaction was consistently simulated.

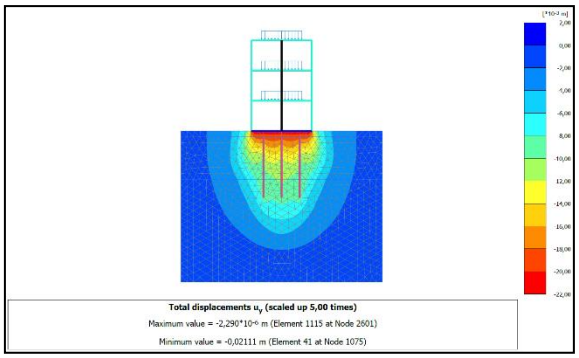
3.2 UPRF System Analysis

In experimental studies reported in the literature, cushion layer thicknesses beneath foundations range from 5 mm to 176 mm, depending on the applied scale factors (e.g., 1/10, 1/25, 1/60) [14-19]. In the numerical analyses of the UPRF system, medium-dense sand was selected as the cushion layer material with a thickness of 60 mm. Considering structural safety, serviceability criteria, and scaled model compatibility, this 60 mm thickness aligns well with literature benchmarks and provides an optimal design parameter.

Under static loading, the maximum vertical displacement (u_y) of 21.11 mm was concentrated in the cushion layer directly beneath the center of the raft foundation (Figure 9).



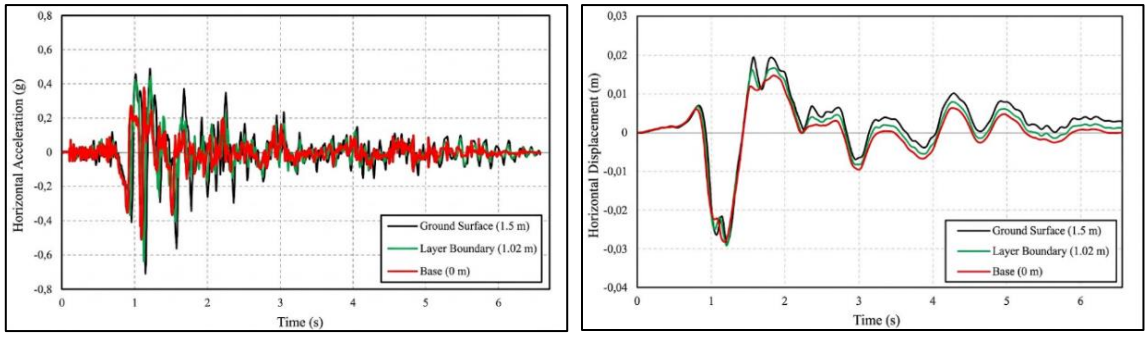


Fig. 9. Vertical displacement (u_y) in the soil in the UPRF system under static loading.

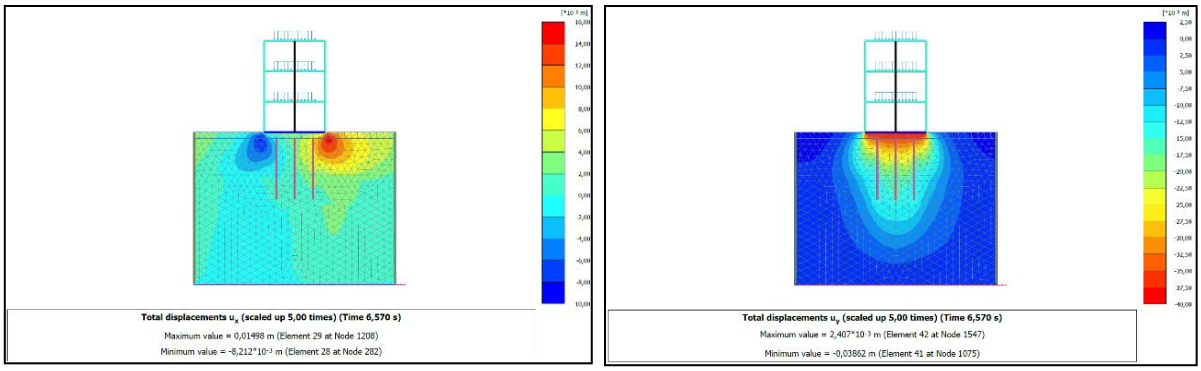
The dynamic analysis results indicate that the system response exhibited an irregular and multi-component character. The sudden peaks observed in the acceleration time histories were accompanied by displacement responses with varying amplitudes in the horizontal displacement time histories (Figure 10). In addition, the frequency content of the input motion was found to be largely preserved throughout the model.



The maximum horizontal displacement in the soil was approximately 14.98 mm, while the maximum vertical displacement was 38.62 mm (Figure 11). Horizontal displacements increased from the base toward the ground surface, indicating that the free-surface amplification effect was also present in the UPRF model.

The maximum horizontal displacement (u_x) of the piles was 8.47 mm, while the maximum vertical displacement (u_y) was 16.37 mm. Horizontal displacements reached their maximum values near the pile heads and decreased with depth (Figure 12). The maximum bending moment and shear force occurred in the piles along the outer axes, while the pile along the middle axis was subjected to relatively lower demands. A distinct change in the shear force diagram was observed at the level where the piles were embedded in the dense sand layer (Figure 13). This indicates that the increase in stiffness at the layer interface was reflected in the model.

3.3 Comparison of PRF and UPRF systems

The horizontal acceleration values obtained at the center of the raft foundation under the Erzincan earthquake are generally similar for the PRF and UPRF systems; however, the maximum acceleration is higher in the UPRF system. In contrast, the horizontal displacements at the raft foundation level are higher in the PRF system than in the UPRF system. The horizontal accelerations and displacements obtained at the ground surface for the two systems are compared in Figure 14.

Fig. 14. Comparison of recorded ground surface responses for the PRF and UPRF systems: (a) horizontal accelerations, (b) horizontal displacements.

Within the scope of this study, the behavior of PRF and UPRF systems under static and dynamic loading conditions was comparatively evaluated, and the obtained data are presented in Tables 3 and 4.

Table 3. Maximum displacements in the soil under static loading for the PRF and UPRF systems.

	Soil	
	$(u_x)_{maks}$ [mm]	$(u_y)_{maks}$ [mm]
PRF	2.72	12.33
UPRF	2.80	21.11

	Soil			**Piles**			
	$(a_x)_{max}$ [g]	$(u_x)_{max}$ [mm]	$(u_y)_{max}$ [mm]	$(u_x)_{max}$ [mm]	$(u_y)_{max}$ [mm]	M_{max} [kNm]	M_{max} [kNm]
PRF	0.019	9.19	22.47	5.34	21.07	0.084	0.022
UPRF	0.012	14.98	38.62	8.47	16.37	0.115	0.015

4 Conclusions

The results demonstrate that the overall behavior of the systems should be assessed through a comprehensive evaluation of multiple performance indicators, including pile internal forces, soil and superstructure displacements, and acceleration demands, rather than relying on a single performance metric. Compared with the PRF system, the UPRF system generally exhibited greater vertical deformations. This behavior may be attributed to the reduced overall stiffness of the foundation system resulting from the presence of the cushion layer, which provides a more flexible load-transfer mechanism between the raft and the underlying soil.

The placement of the cushion layer between the raft and the pile group resulted in a more distributed deformation pattern beneath the raft compared with the PRF system. The deformable nature of the cushion layer limited the direct transfer of superstructure loads to the piles, allowing a portion of the load to be carried by the surrounding soil and resulting in a more flexible system response. As shown in Figures 6 and 11, while displacements in the PRF system remained at similar magnitudes along the pile depth, those in the UPRF system were higher, particularly in the upper portions of the piles, and gradually diminished toward the lower levels. However, the reduction in rigid connectivity due to the cushion layer decreased the overall horizontal stiffness of the system, potentially resulting in higher horizontal displacements at

certain excitation amplitudes. In addition, the cushion layer softened abrupt stiffness transitions and contributed to reducing stress concentrations within the soil-pile-raft system.

Evaluation of pile displacements and internal force distributions indicates that the shear forces and bending moments in the UPRF system are more evenly distributed than those in the PRF system. In particular, the peak bending moments and shear forces in the piles along the outer axes were reduced, resulting in a more homogeneous load distribution. The cushion layer reduces the direct rigid connection between the raft and pile heads, thereby limiting abrupt increases in bending moments at the pile heads. In addition, the variations in shear force observed at the level where the piles are socketed into the dense sand layer exhibit a smoother transition in the UPRF system (Figures 8 and 13).

In conclusion, the 2D finite element analyses showed that the rigid connection between the raft and piles in the PRF system resulted in more direct load transfer, leading to higher bending moments and shear forces, particularly at the pile heads. In contrast, the cushion layer in the UPRF system reduced the overall system stiffness and enabled a more gradual and controlled transfer of vertical loads.

From a dynamic response perspective, the PRF system exhibited a stiffer behavior and effectively limited horizontal displacements, whereas the UPRF system demonstrated a more flexible response. However, the reduced peak values in the internal force distributions of the UPRF system indicate a significant advantage in terms of mitigating pile demands. Overall, while the PRF system exhibited a stiffer response with lower displacements, the UPRF system provided greater deformation capacity while reducing the demands imposed on the piles.

The numerical results obtained in this study will be validated through shaking table model tests to be conducted in the laboratory, and the numerical model will be further developed based on the experimental findings.

It should be noted that evaluating the numerical findings related to the cushion layer under different cushion materials, layer thicknesses, and dynamic inputs is important for establishing the generalizability of the results.

Development of an Artificial Intelligence-Based Water Consumption Forecasting Model for İzmir Province

Ergun Uzlu[1]
[1] 0000-0002-2394-179X, Karadeniz Technical University, Civil Engineering Department, Trabzon, Türkiye, ergunuzlu@ktu.edu.tr

Abstract. Accurate forecasting of future water demand is of critical importance for the sustainable management of water resources. Reliable water consumption projections can help prevent water scarcity and promote the efficient use of available resources. In this study, an artificial intelligence-based forecasting model was developed to predict future water consumption in İzmir, one of the major metropolitan cities of Türkiye. The forecasting framework was established using an Artificial Neural Network (ANN) approach, while the network parameters were optimized through the Teaching–Learning-Based Optimization (TLBO) algorithm. TLBO is a population-based optimization technique known for its strong search and optimization capabilities. The proposed model was developed using population and gross domestic product (GDP) data. Data covering the period from 2004 to 2023 were utilized in the study. The dataset for the years 2004–2019 was used for model training, whereas the data from 2020–2023 were employed for model testing. Model performance was evaluated using average relative error (RE), mean absolute error (MAE), mean square error (MSE), and root mean square error (RMSE) criteria. The results demonstrated that the ANN–TLBO model was capable of predicting water consumption in İzmir with a high degree of accuracy. Therefore, the proposed model can serve as a valuable decision-support tool for planners and policymakers involved in water resources management and long-term water supply planning.

Keywords: Water demand forecasting; ANN; TLBO; İzmir.

1 Introduction

Accurate forecasting of future water demand is one of the fundamental requirements for the planning of drinking water supply systems, distribution networks, and water resources management strategies. İzmir, the third-largest city in Türkiye, is a major metropolitan area characterized by intensive economic, commercial, tourism, and industrial activities. Owing to its well-developed transportation infrastructure, industrial zones, educational institutions, and quality of life, the city has experienced continuous population growth over recent decades. The steady increase in population and accelerated urbanization has led to a substantial rise in domestic water demand. Therefore, accurately predicting future water consumption in İzmir is of critical importance for the planning of new water resources, the improvement of existing infrastructure, and the development of sustainable water management policies.

Among the various approaches employed in water demand forecasting studies based on time-series analysis, Artificial Neural Networks (ANNs) have emerged as one of the most widely used techniques. Numerous studies conducted across different countries and at various spatial scales have demonstrated the superior predictive capability of ANN models for water consumption forecasting. Zhao and Chen [1] developed an ANN model using population and several socioeconomic indicators to predict urban water demand in Beijing, China, and reported satisfactory forecasting performance. Similarly, Tang et al. [2] and Tian and Xue [3] developed ANN-based models for Hubei and Guangdong Provinces in China, respectively,

and concluded that these models could reliably estimate water consumption and be effectively applied in different regions. Studies conducted in Türkiye have yielded similar findings. Altunkaynak and Nigussie [4] utilized ANNs to model water consumption in Istanbul and reported that the approach provided effective results. Uzlu [5] developed a hybrid model integrating ANN and the Rao optimization algorithm to generate water consumption projections for Istanbul. In this model, gross domestic product (GDP) and population data were used as input variables, while water consumption constituted the model output. Likewise, Uzlu and Dede [6] proposed a hybrid ANN–Jaya model based on GDP and population data to forecast annual water demand in Ankara. The hybrid models developed by Uzlu [5] and Uzlu and Dede [6] successfully predicted water demand in Istanbul and Ankara, respectively. Finally, these studies demonstrate that ANNs are powerful tools capable of providing highly accurate water demand forecasts and producing reliable projections, particularly for large metropolitan areas characterized by rapid population growth and dynamic water demand patterns.

The primary objective of the present study is to develop a hybrid model integrating ANNs and the Teaching–Learning-Based Optimization (TLBO) algorithm to forecast water consumption in İzmir, the third-largest city in Türkiye. Population and GDP data were employed as input variables, whereas water consumption values constituted the model output. The dataset used for model development covers the period from 2004 to 2020. One of the main motivations behind this study is the lack of previous research specifically focused on forecasting annual water demand in İzmir. Another important motivation is that the capability of the ANN–TLBO technique for water demand modeling has not been investigated previously. It is anticipated that the water demand projections generated using the proposed models will provide valuable support to decision-makers by facilitating more efficient management and planning of existing water resources.

2 Materials and Methods

2.1 Development of the Water Demand Forecasting Model

In the present study, an ANN approach was employed to model the annual water demand of İzmir. As illustrated in Figure 1, a three-layer feed-forward neural network architecture consisting of an input layer, a hidden layer, and an output layer was adopted. The number of neurons in the hidden layer was selected as 5 and 10 in order to evaluate the effect of network complexity on model performance. Hyperbolic tangent sigmoid and linear transfer functions were utilized as the activation functions for the hidden and output layers, respectively. GDP and population data were used as input variables, whereas annual water consumption data constituted the model output.

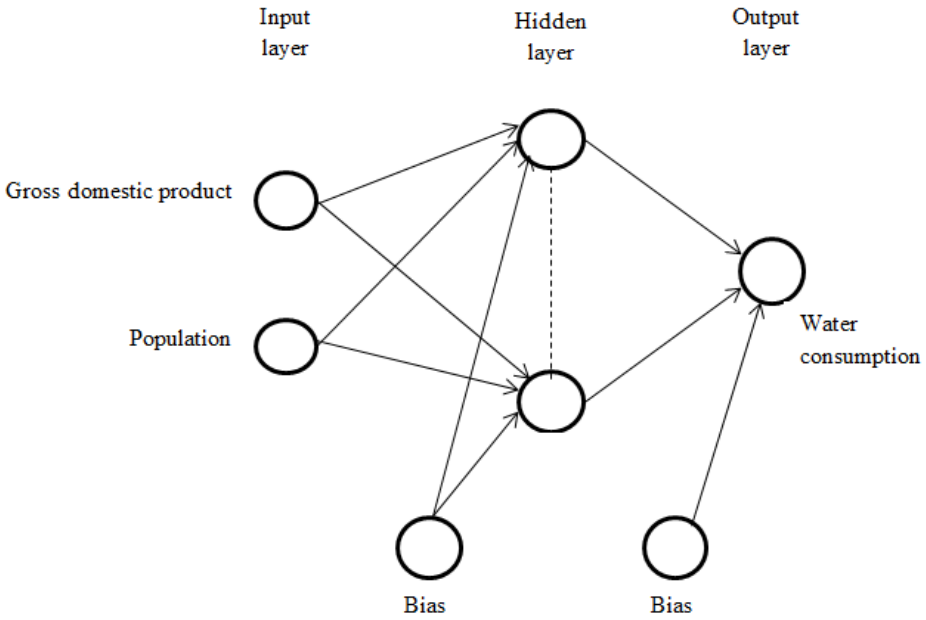

Fig. 1. Proposed ANN model for water demand prediction.

The weights of the ANN models were optimized using the TLBO algorithm. During the training process, the Mean Squared Error (MSE) was adopted as the objective function. The TLBO algorithm iteratively updates the network parameters with the aim of minimizing the MSE value and improving the predictive capability of the model. By integrating TLBO with ANN, the optimization process seeks to identify the optimal set of network weights and biases that yield the highest forecasting accuracy. To evaluate the predictive performance of the trained models, several statistical performance indicators were calculated, including the average relative error (RE), root mean square error (RMSE), and mean absolute error (MAE). These metrics were employed to assess the agreement between the observed and predicted water consumption values and to compare the performance of the developed forecasting models.

$$MSE = \frac{1}{n}\sum_{k=1}^{n}\left(y_k - o_k\right)^2 \tag{1}$$

$$average\ RE = \frac{\sum_{i=1}^{n}\left(\frac{y_k - o_k}{y_k}\right)}{n} \times 100 \tag{2}$$

$$RMSE = \left[\frac{1}{n}\sum_{i=1}^{n}\left(y_k - o_k\right)^2\right]^{1/2} \tag{3}$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|(y_k - o_k)\right| \tag{4}$$

In the above equations, o_k ve y_k represent the predicted and observed values, respectively, while n denotes the total number of data samples. During the development of the ANN models, the number of runs, maximum number of iterations, and target objective function value were set to 10, 500, 8×10^{-8}, respectively. For the TLBO algorithm, the population size was specified as 50. In addition, the search interval for optimizing the ANN weights was defined within the range of [-1,1].

2.2 TLBO Algorithm

TLBO algorithm is a population-based metaheuristic optimization technique developed by Rao and inspired by the teaching–learning process that occurs in a classroom environment [7]. In the algorithm, each individual represents a candidate solution, while the best-performing individual in the population is designated as the teacher. The remaining individuals, referred to as learners, attempt to improve their knowledge and performance through interactions with the teacher and with one another. The TLBO algorithm consists of two main phases: the teacher phase and the learner phase**.** During the teacher phase, the teacher attempts to increase the overall knowledge level of the class by moving learners toward better solutions. In the learner phase, individuals interact with other learners in the population and update their solutions based on the knowledge gained through these interactions. In both phases, newly generated solutions are accepted only if they improve the value of the objective function, thereby enhancing the overall quality of the population. The optimization process is repeated iteratively until a predefined stopping criterion is satisfied, with the objective of identifying the optimal or near-optimal solution to the problem. One of the major advantages of TLBO is its simplicity, as it requires only a limited number of control parameters, primarily the population size and the maximum number of iterations. This characteristic facilitates its implementation and has contributed to its widespread application in a variety of optimization problems in recent years.

2.3 Data

In this study, GDP and population were selected as the independent variables for forecasting the future water demand of İzmir. GDP and population data were obtained from the Turkish Statistical Institute (TURKSTAT) [8, 9], while water consumption data were acquired from the İzmir Metropolitan Municipality [10]. The dataset covers the period from 2004 to 2020. Figure 2 shows the changes in dependent and independent variables between 2004 and 2020. The data collected between 2004 and 2016 were used for model development and training, whereas the data from 2017 to 2020 were reserved for model testing. This division enabled an independent assessment of the predictive performance and generalization capability of the developed ANN–TLBO models.

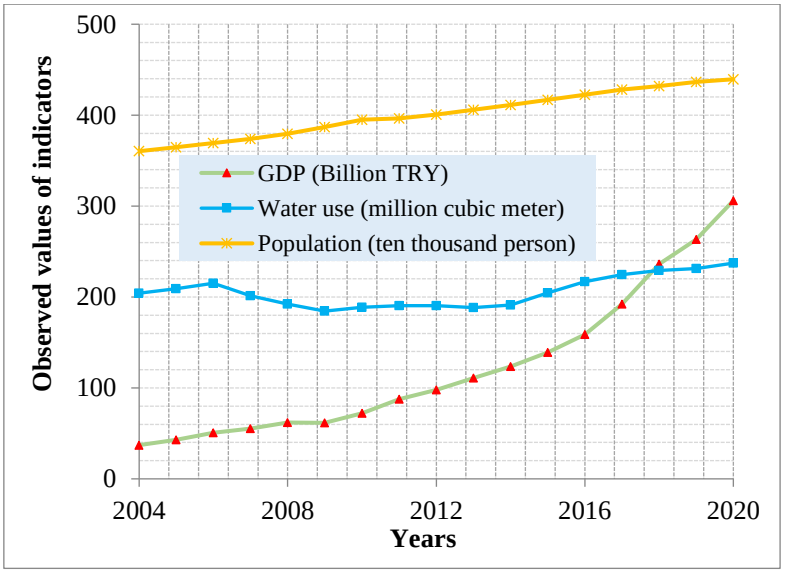

Fig. 2. Variations in dependent and independent variables [8, 9, 10].

2.4 Study Area

İzmir is located in the Aegean Region of western Türkiye and is situated at approximately 38.42° N latitude and 27.14° E longitude. As the third-largest city in the country, İzmir plays a significant role in the national economy due to its strategic port facilities and its well-developed industrial, commercial, tourism, and service sectors. The population of İzmir exceeds 4.5 million, making it one of the major metropolitan areas in Türkiye that continues to experience steady population growth driven by ongoing migration and urban expansion [9]. Consequently, the demand for potable and domestic water has increased substantially over time.

The drinking water demand of İzmir is primarily supplied by several reservoirs, including Tahtalı, Balçova, Gördes, Güzelhisar, Ürkmez, and Alaçatı Kutlu Aktaş dams [10]. Figure 3 illustrates the geographical location of İzmir and the locations of the principal reservoirs used for the city's drinking water supply. These water resources play a critical role in meeting the domestic and municipal water requirements of the population residing in different parts of the metropolitan area. Considering the combined impacts of population growth, urbanization, and climate change, the sustainable management of existing water resources has become increasingly important.

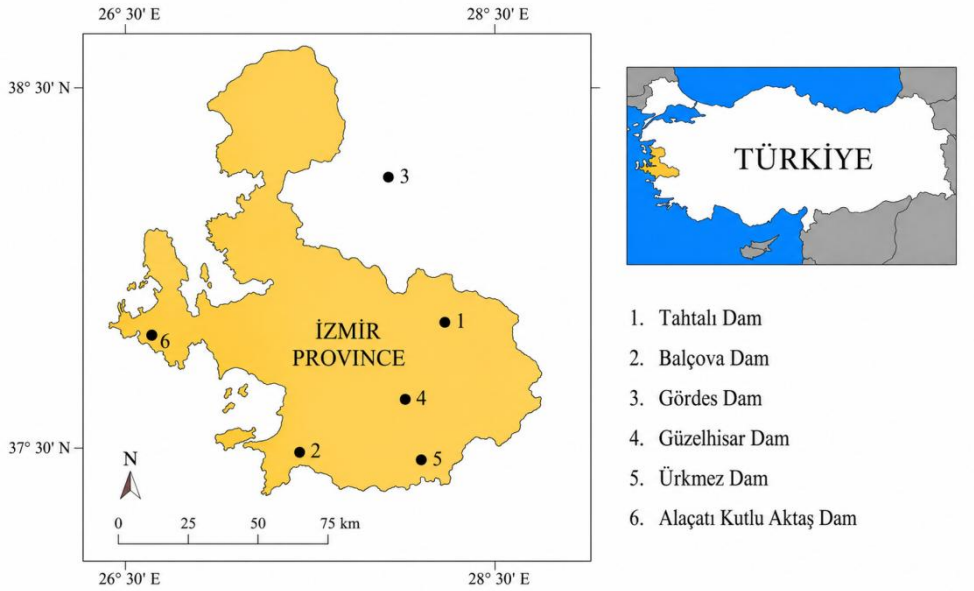

Fig. 3. Location of the İzmir and her water resources.

3 Results and Discussion

In this study, a three-layer ANN architecture, as shown in Figure 1, was selected. The two neurons in the input layer represent GDP and population data. The neuron in the output layer represents water consumption. The TLBO algorithm was preferred for the optimization of the ANN weights. The number of neurons in the hidden layer was selected as 5 and 10, considering the experience gained from previous studies [5, 6]. The training and testing error values obtained for the developed models are presented in Table 1. In addition, comparisons of the values predicted by the developed models with the observed data for the training and testing datasets are presented in Figures 4 and 5, respectively.

Table 1. Error values for the proposed ANN-TLBO models.

ANN architecture	Training set	Testing set		
	MSE (m^6)	RMSE (m^3)	MAE (m^3)	Average RE(%)
2-5-1	55.129	8.463	6.962	3.028
2-10-1	28.503	3.012	2.689	1.167

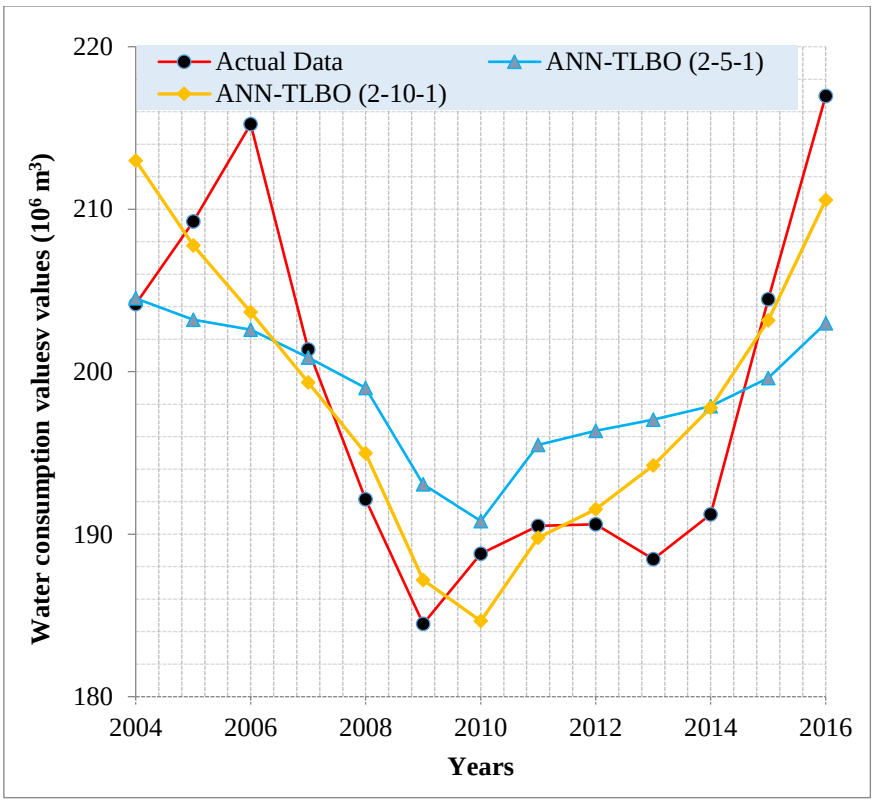

Fig. 4. Performances of the ANN-TLBO (2-5-1) and ANN-TLBO (2-10-1) for the training set.

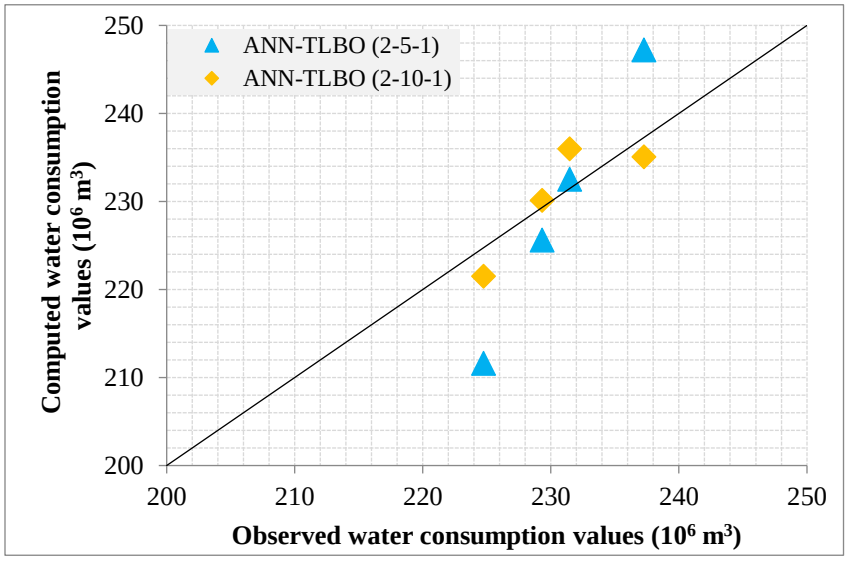

Fig. 5. Performances of the ANN-TLBO (2-5-1) and ANN-TLBO (2-10-1) for the test data.

Examination of Figures 4 and 5 reveals that the ANN–TLBO (2–10–1) model produced predictions that were closer to the observed data than those generated by the ANN–TLBO (2–5–1) model. Similarly, according to the error values presented in Table 1, the best-performing model was the ANN–TLBO (2–10–1) model with 10 neurons in the hidden layer. For the ANN–TLBO (2–10–1) model, the MSE value for the training dataset was 28.503 m^6, while the RMSE, MAE, and mean RE values for the testing dataset were calculated as 3.012 m^3, 2.689 m^3, and 1.167%, respectively. Uzlu [5] reported RMSE, MAE, and mean RE values of 17.649 m^6, 14.197 m^3, and 1.715%, respectively, for the testing dataset of the ANN–Rao model developed to forecast water consumption in Istanbul. In addition, Uzlu and Dede [6] calculated RMSE, MAE, and mean RE values of 8.787 m^6, 7.036 m^3, and 1.475%, respectively, for the testing dataset of the ANN–Jaya model developed to forecast water consumption in Ankara. The error values obtained in the present study are lower than those reported by Uzlu [5] and Uzlu and Dede [6]. Therefore, the performance of the model proposed in this study can be considered satisfactory, and the associated prediction errors are within acceptable limits.

4 Conclusion

Reliable forecasting of water consumption for İzmir is of great importance for the planning of drinking water supply systems, the effective allocation of infrastructure investments, and the sustainable management of water resources. In this study, the water consumption of İzmir was successfully modeled using the ANN–TLBO (2–10–1) model developed based on GDP and population data. As a result of the performance evaluation, the mean RE value for the testing dataset was found to be 1.167%. This result indicates that the proposed model has a high level of forecasting accuracy. The findings demonstrate that the combined use of ANNs and the TLBO algorithm constitutes an effective approach for water demand forecasting. Therefore, the developed model can be considered a reliable tool for predicting the future water demand of İzmir. Furthermore, it is anticipated that water demand projections generated using the proposed model will provide valuable support for decision-makers in the planning and management of water resources, thereby contributing to more efficient and sustainable water resource utilization.

Abstract.
Increasing water scarcity and climate-induced droughts pose significant challenges for water allocation systems, particularly in countries like Türkiye where irrigated agriculture accounts for a large share of water use. Ensuring adaptive and resource-aligned water allocation is therefore a critical policy challenge. This study evaluates agricultural water allocation practices in Türkiye through a stakeholder-based assessment. The survey was developed based on the European Union policy document *The Implementation of Water Allocation in the EU* [1], drawing on its key challenges and good practices. Survey questions were structured around four dimensions covering legal and policy frameworks, resource-aligned allocation, intersectoral coordination and reallocation, and compliance. The survey was conducted with 50 participants representing independent experts, managerial actors, and technical staff. Respondents were also classified according to governance level as central or local actors. Responses were analysed using a threshold-based dominance approach, classifying each question as "Yes-dominant", "No-dominant", or "Don't Know (DK)-dominant" within each stakeholder group. The results indicate that the fundamental legal and institutional components of the allocation system are largely in place, particularly regarding permitting procedures, resource monitoring, and formal compliance mechanisms. However, important implementation challenges persist, especially in intersectoral coordination, adaptive water allocation, and the operational use of decision-support systems. Overall, the findings suggest that while Türkiye's water allocation system is structurally defined, its capacity to adapt allocation decisions under drought conditions remains limited. Observed inconsistencies across governance levels further suggest that this adaptive capacity is unevenly distributed across the system, potentially constraining implementation effectiveness.
Keywords: Water Allocation; Agriculture; Drought; Stakeholder Assessment.

1 Introduction

Türkiye faces increasing challenges related to water scarcity and drought. Agriculture accounts for approximately 77% of total water use in the country and plays a critical role in food production and rural development [2]. At the same time, agriculture is highly vulnerable to drought, as water shortages can cause yield fluctuations, reduce agricultural output, and affect farmers' livelihoods, particularly in semi-arid regions of the country [3]. Climate change is expected to put additional pressure on already limited water resources by increasing the frequency and severity of drought events. Various regions of Türkiye have been identified as particularly vulnerable to drought, while the Mediterranean basin is considered a climate change hotspot with predicted decreases in rainfall and increases in extreme temperatures [4,5].

Under these conditions, sustainable water allocation has become an essential component of water governance. Water allocation policies play a crucial role in determining how limited water resources are distributed among competing users and sectors. Effective allocation systems are expected not only to ensure efficient resource use but also to support environmental sustainability, economic development, and resilience to climate variability [6]. However, increasing water scarcity and drought conditions place growing pressure on existing allocation arrangements, creating challenges related to implementation, coordination, monitoring, and adaptability.

In recent years, the European Union has devoted increasing attention to water allocation as a policy instrument for addressing water scarcity and drought. A key contribution in this area is the report Implementation of Water Allocation in the EU (hereafter referred to as the EU Water Allocation Report), prepared under the Common Implementation Strategy (CIS) on Water Scarcity and Droughts [1]. The report identifies key implementation challenges and good practice principles related to legal frameworks, allocation practices, cross-sectoral coordination, and compliance mechanisms, providing a structured basis for evaluating water allocation systems.

Türkiye has established a broad legal and institutional framework for water allocation, supported by permitting systems, basin planning instruments, monitoring mechanisms, and sectoral coordination processes. Agricultural water allocation is inherently a governance process requiring coordination among multiple institutions operating at different administrative levels. The implementation of agricultural water allocation involves multiple actors with different mandates and responsibilities, including planning, regulation, implementation, monitoring, and water use. Ensuring effective coordination among these actors is essential for translating legal and policy frameworks into consistent allocation practices, particularly under increasing water scarcity and drought conditions.

Against this background, this study uses a stakeholder-based survey to assess agricultural water allocation governance in Türkiye, drawing on the policy assessment logic of the EU Water Allocation Report. Based on the perspectives of actors involved in different stages of the allocation process, the analysis examines perceived strengths, implementation challenges, and areas of institutional uncertainty across four dimensions of water allocation governance. In doing so, the study aims to provide a structured assessment of how existing allocation arrangements are perceived across governance levels and stakeholder groups, and to identify priority areas for improving agricultural water allocation under increasing water scarcity and drought conditions.

2 Methodology

2.1 Conceptual Framework

Drawing on the challenge areas and good-practice principles identified in the EU Water Allocation Report, this study developed a survey instrument tailored to the institutional context of Türkiye, with a specific focus on agricultural water allocation. This focus reflects both the dominant share of agriculture in national water use and the fact that allocation pressures under drought are most acutely experienced in irrigated agriculture. Accordingly, the analytical framework was applied with a sector-specific focus on agricultural water allocation.

In line with this framework, the survey was structured around four analytical dimensions:

1. A supportive legal and policy framework for agricultural water allocation
2. Alignment of water allocation decisions with available water resources including consideration of surface–groundwater interactions and basin-scale water balance;
3. Intersectoral harmonisation and sustainable management of water allocations, with a focus on coordination mechanisms and reallocation practices;

4. Compliance with allocation decisions, including monitoring, enforcement, and sanction mechanisms.

The overall analytical framework adopted in this study is illustrated in Fig. 1.

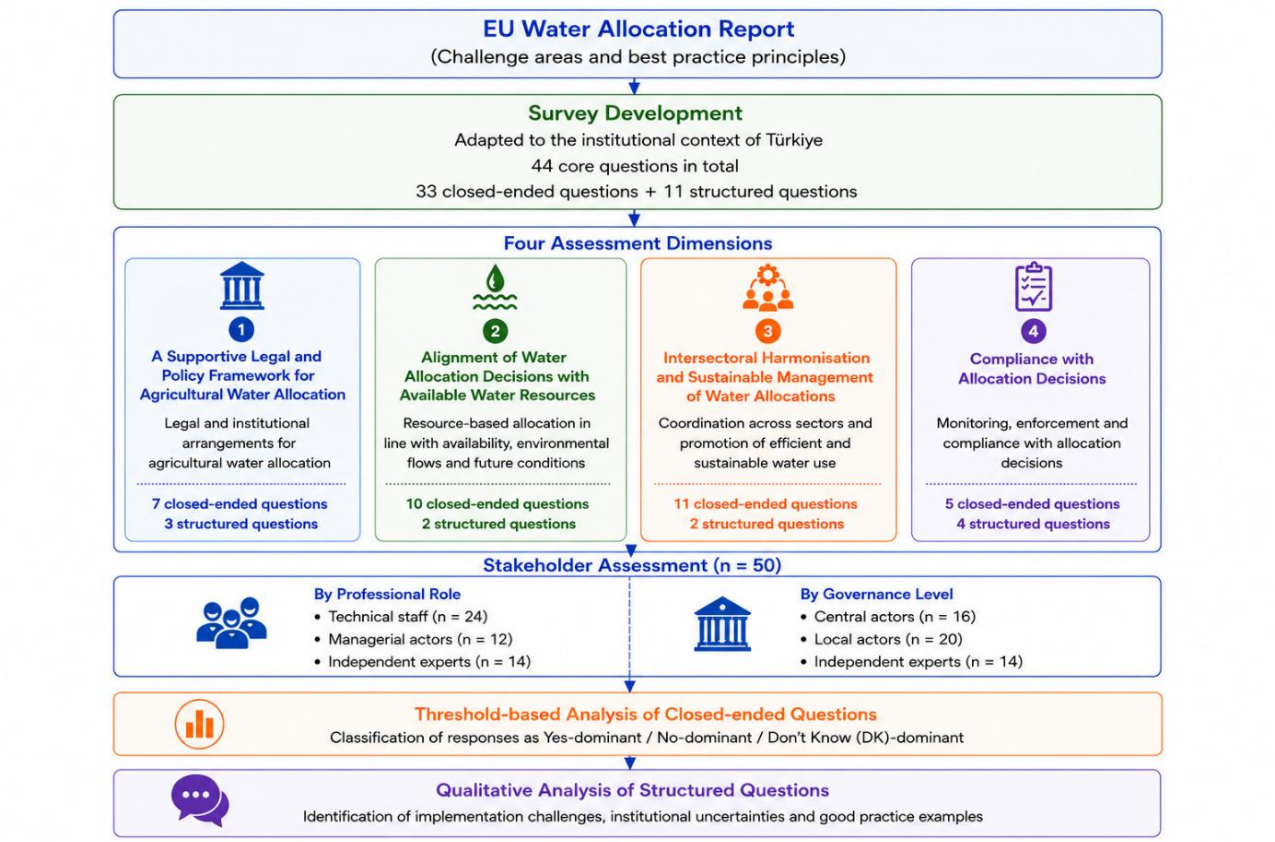

Fig. 1. Conceptual and methodological framework of the study

2.2 Survey Design and Structure

The survey was implemented using Google Forms and administered in Turkish to ensure accessibility and clarity for respondents. The survey questions are provided in Appendix A. The survey consisted of 44 core questions, including 33 closed-ended questions and 11 structured and qualitative questions, allowing respondents to elaborate on specific challenges and examples of good practice. Ethical approval for the survey was obtained from the Middle East Technical University Human Research Ethics Committee (Protocol No. 0522-ODTÜİAEK-2025) prior to data collection.

Survey responses were analysed using a threshold-based interpretive framework. A response category was considered dominant when it accounted for more than 50% of responses within the relevant stakeholder group. Accordingly, each question was classified as Yes-dominant, No-dominant, or Don't Know (DK)-dominant based on the prevailing response pattern.

The survey questions were deliberately formulated as positively framed statements reflecting good practices in water allocation governance. Within this framework, Yes-dominant responses were interpreted as indicating the presence or effective functioning of a governance mechanism or practice. No-dominant responses were interpreted as evidence of implementation gaps, institutional weaknesses, or barriers to effective water allocation management. Rather than being treated as missing data, DK-dominant responses were analysed as indicators of institutional uncertainty, fragmented knowledge, limited information flows, or weak visibility of governance processes across administrative levels.

In addition to the closed-ended questions, optional structured qualitative questions were included to capture contextual information, practical experiences, and stakeholder perspectives that could not be fully reflected through predefined response categories. These qualitative responses were used to support the interpretation of quantitative findings, provide illustrative examples of implementation challenges and good practices, and identify recurring themes related to coordination, enforcement, adaptive management, and stakeholder engagement.

2.3 Stakeholder Groups

As illustrated in Fig. 1, the survey targeted stakeholders involved in different stages of agricultural water allocation planning, implementation, regulation, and monitoring in Türkiye. A total of 50 respondents participated in the survey and were classified according to both professional role and governance level.

Respondents were grouped into three professional categories: technical staff, managerial actors, and independent experts. The independent expert category included academics and other respondents with relevant expertise in water resources management and policy but without direct involvement in institutional decision-making or implementation. Respondents were also classified as central actors, local actors, or other stakeholders. Comparisons across governance levels focused primarily on central and local actors to examine differences in perceptions across administrative scales and institutional responsibilities.

3 Results

Fig. 2 provides an overview of the dominant response patterns identified across all closed-ended survey questions. The following sections discuss these patterns by assessment dimension, supported by qualitative evidence obtained from the open-ended responses.

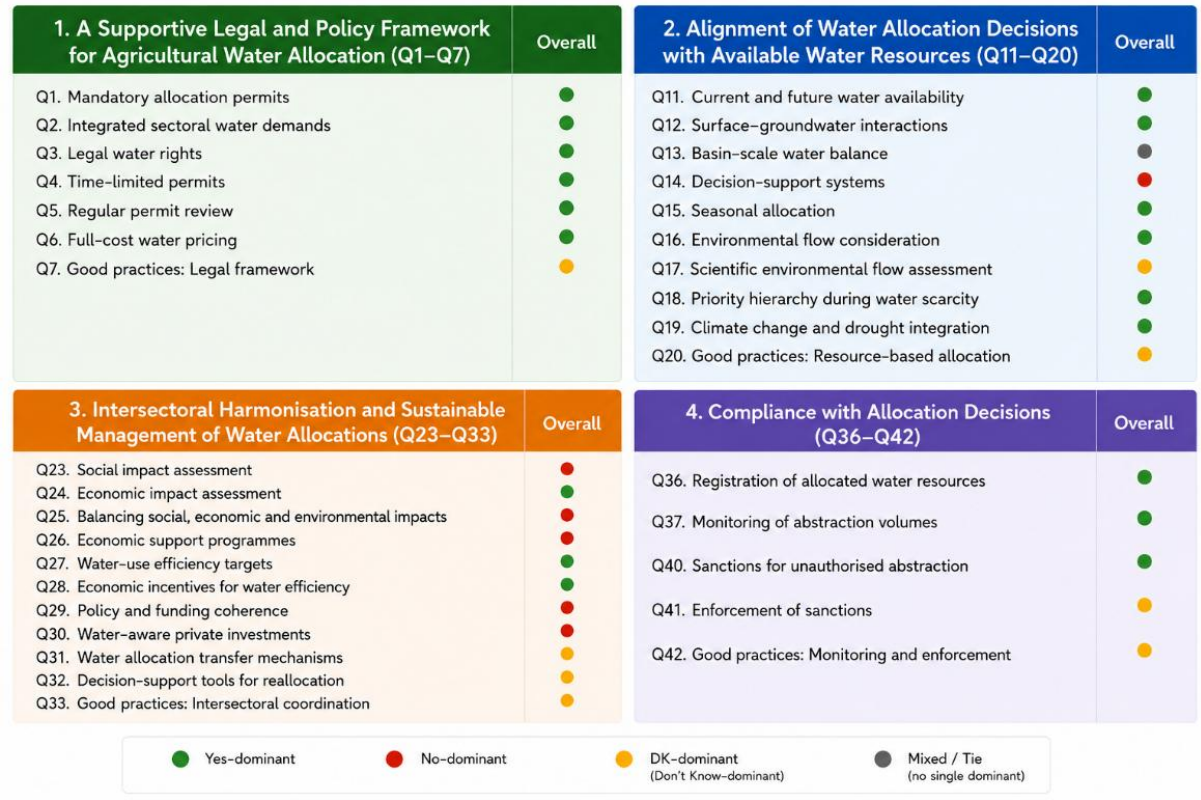

Fig. 2. Summary of Responses to the 33 Closed-Ended Questions Across the Four Assessment Dimensions. Responses to the 11 structured questions are not shown and are discussed separately in the qualitative analysis

3.1 A Supportive Legal and Policy Framework

Positive response patterns were observed for questions concerning the existence of allocation permits, the consideration of sectoral water demands, the legal definition of water ownership and use rights, the existence of time-bound allocation permits, the regular review of allocation permits, and water pricing policies. However, qualitative responses (from the structured open-ended questions) indicate that these arrangements are often implemented through context-specific practices rather than uniformly applied procedures. Permit requirements were described as applying mainly to specific user groups, permit reviews as largely event-driven, and pricing as not fully reflecting supply, environmental, and depreciation costs.

The prevailing DK response was observed for questions regarding examples of good practice within the existing legal and policy framework, suggesting limited visibility and recognition of successful practices across institutions. These findings suggest that compiling and making good practice examples publicly accessible could strengthen knowledge sharing, enhance transparency, and support more consistent implementation across governance levels.

3.2 Alignment of Water Allocation Decisions with Available Water Resources

Positive response patterns were observed for questions concerning the consideration of current and future water availability, surface water–groundwater interactions, seasonal allocation practices, environmental flow requirements, predefined priority mechanisms during water scarcity, and the integration of climate change and drought considerations into allocation decisions. These findings suggest that the key principles of adaptive water allocation are generally recognised within existing allocation practices. This pattern is also broadly consistent with the wider planning context in Türkiye, where basin-scale drought management plans and sectoral water allocation plans constitute important planning instruments for addressing water scarcity and drought-related pressures [7].

The only prevailing No response was associated with the use of decision-support systems. Although qualitative responses acknowledged the availability of modelling approaches and technical assessment tools, respondents frequently indicated that these are not yet routinely integrated into operational allocation decisions. Recent policy developments nevertheless suggest that this may be an area of ongoing institutional improvement. Directorate General of Water Management (GDWM) has initiated work on a Drought Forecasting and Early Warning System, indicating an emerging effort to strengthen the analytical and anticipatory basis of drought and water management in Türkiye [8]. Participants also highlighted challenges related to data availability, monitoring capacity, groundwater management, and institutional coordination, which were perceived to limit the practical application of adaptive water allocation approaches.

The question regarding basin-scale water balance analyses exhibited no dominant response pattern, indicating divergent perceptions among respondents regarding their implementation. This should not be interpreted as the absence of basin-scale analytical work, as hydrological and hydrogeological assessments are included in the General Directorate of State Hydraulic Works' (DSI) river basin master plans [9]. However, it remains unclear to what extent these analyses are systematically incorporated into allocation decisions and day-to-day practice.

In addition, DK-dominant responses were observed for questions concerning the scientific determination of environmental flow requirements and the identification of good practices related to matching allocations with available water resources. These findings suggest that although adaptive water allocation principles are widely recognised, their practical implementation and visibility remain uneven across institutions.

3.3 Intersectoral Harmonisation and Sustainable Management

Positive response patterns were observed for questions concerning the consideration of economic impacts in allocation decisions, the existence of efficiency-oriented rules within the allocation system, and the use of economic instruments to promote efficient water use. These findings suggest that economic considerations and water-use efficiency objectives are formally incorporated into the allocation framework. In practice, such considerations may be reflected through irrigation pricing arrangements, support for irrigation modernization and water-saving technologies, and broader policy efforts aimed at improving water-use efficiency in agriculture. However, the extent to which these instruments systematically shape allocation decisions in practice remains less clear from the survey findings.

However, prevailing No responses were observed regarding the consideration of social impacts, the availability of sufficient knowledge and awareness to balance social, economic, and environmental objectives during reallocation processes, the existence of allocation-specific support mechanisms, the alignment of allocation policies with other sectoral policies, and the compatibility of new private sector investments with available water resources. Taken together, these findings suggest that while economic considerations appear to be more visibly embedded in allocation practice, the social and environmental dimensions of allocation remain comparatively weak, which may also limit alignment with environmental and social safeguard expectations in future water-related investment processes. Qualitative responses frequently highlighted fragmented institutional responsibilities, weak inter-institutional coordination, operational constraints, and inconsistencies between policy objectives and implementation practices.

The DK-dominant questions were associated with mechanisms for transferring water allocation rights, the use of decision-support tools during reallocation processes, and examples of good practice in cross-sectoral coordination. These findings indicate limited awareness and visibility of reallocation mechanisms and coordination practices.

3.4 Compliance with Allocation Decisions

Positive response patterns were observed for questions concerning the registration of allocated water sources, the monitoring of allocation holders' abstraction volumes, and the existence of sanctions for unauthorized use or exceedance of allocated volumes. These findings suggest that the basic monitoring and enforcement framework is formally established. Qualitative responses further indicated that monitoring responsibilities are shared among multiple institutions, with DSI and its regional directorates perceived as the primary authorities responsible for monitoring activities. Several respondents nevertheless pointed to weak coordination among institutions, while others emphasised shortcomings in measurement infrastructure, data verification, and field inspection. These comments suggest that the involvement of multiple actors may complicate implementation and weaken the consistency of monitoring and enforcement practices across basins.

DK-dominant responses were observed regarding the effective enforcement of sanctions and the identification of good practices in monitoring and enforcement. Qualitative responses highlighted challenges related to institutional fragmentation, insufficient monitoring infrastructure, limited field inspection capacity, weak data verification mechanisms, and regional disparities in implementation. Respondents also noted that social and political pressures may influence the consistent application of sanctions, particularly in cases involving unauthorized abstractions and illegal wells.

3.5 Differences Across Stakeholder Groups

Although the overall assessment identified the dominant response patterns presented in Fig. 2, additional differences emerged across stakeholder groups. Managerial actors generally

provided more positive assessments of existing governance arrangements, particularly regarding legal and institutional provisions, whereas independent experts more frequently identified implementation gaps and institutional weaknesses. Technical staff exhibited more heterogeneous response patterns, with relatively positive assessments of allocation practices but greater variation across governance-related issues.

Comparisons across governance levels further indicated that central actors tended to report more positive assessments regarding formal governance arrangements and existing allocation practices, while local actors more frequently expressed uncertainty on implementation-oriented issues, particularly those related to environmental flow assessment, basin-scale water balance, decision-support systems, monitoring practices, and good practice examples. In several of these questions, uncertainty among local actors was accompanied by mixed or negative response patterns, suggesting differences not only in awareness but also in the perceived maturity of implementation across administrative levels. These differences suggest that perceptions of agricultural water allocation governance vary according to institutional role and administrative level.

4 Discussion and Conclusions

The findings indicate that Türkiye has established the principal legal and institutional foundations for agricultural water allocation. While positive response patterns dominated the legal framework, allocation practices, and compliance dimensions, weaker patterns emerged for intersectoral coordination, reallocation processes, and the operational implementation of adaptive allocation measures. Overall, the results suggest that the principal challenges are not associated with the existence of governance arrangements, but rather with their implementation, coordination, and operational application.

An important finding of this study is the relatively high number of DK-dominant responses, particularly regarding reallocation mechanisms, cross-sectoral coordination, environmental flow assessment, and examples of good practice. Depending on the issue considered, these patterns may indicate either limited institutional visibility and uneven awareness across organisations, or the absence and limited operationalisation of certain governance mechanisms. This was particularly evident for reallocation-related questions, where uncertainty was often accompanied by negative response patterns across stakeholder groups. These findings suggest that both the development of governance mechanisms and the communication of existing practices require further attention.

Although this study is based on stakeholder perceptions rather than direct measurements of allocation performance, it provides a systematic governance-oriented assessment of agricultural water allocation in Türkiye. The proposed assessment framework may support future policy development by identifying priority areas for strengthening implementation, coordination, and adaptive governance, while also providing a practical basis for periodically evaluating agricultural water allocation governance.

Based on these findings, several priority areas may be highlighted for strengthening agricultural water allocation governance in Türkiye:

- Document and disseminate good practices on allocation, drought response, monitoring, and environmental flow implementation.
- Strengthen cross-institutional learning and capacity building on basin-scale water balance, environmental flows, and adaptive allocation approaches.
- Operationalise reallocation and coordination mechanisms during periods of water scarcity and intersectoral competition.
- Reinforce the environmental and social dimensions of allocation, which remain less visible than economic and administrative considerations, including in contexts where

water-related investments are expected to align with environmental and social safeguard requirements.

Future research could complement stakeholder-based assessments with basin-scale case studies, hydrological modelling, and performance-based indicators to provide a more comprehensive evaluation of agricultural water allocation systems.

Acknowledgments

The authors would like to thank all survey participants for their valuable contributions and insights. Their experience and perspectives provided an important basis for the analysis presented in this study.

Appendices

Appendix A. Survey Questions

The survey consisted of dimension-specific closed-ended and structured questions organized under four assessment dimensions.

Assessment Dimension	Questions
A Supportive Legal and Policy Framework	• Is an allocation permit mandatory for all water users? • At which spatial scale are the studies conducted when allocation decisions are made? (Administrative boundaries (province/district/village) / Water source scale (river reach/lake/well group) / Basin scale / I don't know) • Are the water demands of different sectors considered in an integrated manner during the allocation process? • Are ownership of water resources and authority over access and use clearly defined in legal terms? • Are allocation permits issued for a limited duration? • Are allocation permits reviewed on a regular basis? • Do pricing policies applied in water allocation reflect the full cost of supply?
Alignment of Water Allocation Decisions with Available Water Resources	• Are allocations determined by taking into account the current availability of water resources and projected future changes? • Are surface water–groundwater interactions considered when allocating water resources? • Are water allocation decisions based on basin-scale water balance analyses? • Are decision-support systems used when determining water allocations? • Are allocations defined with seasonal variations in allocated volumes? • Are environmental flow requirements taken into account during water allocation? • Are environmental flow requirements determined using scientific methods? • Is there a predefined plan or hierarchy that identifies priority sectors in the event of water scarcity? • Are climate change and drought considerations incorporated into allocation decisions?
Intersectoral Harmonisation and Sustainable Management	• Are the social impacts on local communities taken into account in water allocation decisions? • Are economic impacts included in the assessment of water allocation decisions? • Do you think there is sufficient knowledge and awareness to balance social, economic, and environmental impacts when reallocating water resources among different uses? • Are support programmes implemented to mitigate potential negative economic impacts arising from allocation processes? • Does the allocation system include defined targets or rules aimed at promoting more efficient water use? • Does the allocation system include economic instruments to incentivise efficient water use?

	• Are allocation priorities and policies aligned with other public sectoral policies and funding mechanisms? • Are new private sector investments planned in alignment with water resource availability? • Are there mechanisms that allow the transfer of water allocation rights to another user? • Are decision-support tools used during the reallocation process?
Compliance with Allocation Decisions	• Are all water resources subject to allocation permits fully registered? • Are the abstraction volumes of allocation holders regularly monitored by the allocating authority? • Which institution is responsible for monitoring the abstraction volumes of allocation holders? • Which technologies and methods are used to monitor the abstraction volumes of allocation holders? • Are sanctions in place in cases of unauthorised use or abstraction exceeding allocated volumes? • Are these sanctions effectively enforced in practice?

The following three questions were asked for each of the four assessment dimensions:

- What are the main implementation challenges encountered in this dimension? *(Legal basis / Institutional arrangements / Operational challenges / Regional disparities / Other problems (please explain) / I don't know / No problems are encountered)*
- At which stage do these challenges most frequently occur? *(Planning / Decision-making / Implementation / Monitoring and evaluation / Other / Don't know)*
- Are there any examples of good practice related to this dimension?

The findings reflect stakeholder perceptions and reported practices rather than direct measurements of hydrological performance or allocation outcomes. In addition, the study adopts an expert-based diagnostic approach and does not aim to provide statistically representative results. The results should therefore be interpreted as complementary to quantitative and field-based analysis.

Note: Following the conference, this Publication Note will be added to each paper; therefore, authors are kindly requested not to remove the note below and to complete the author(s) and paper title information.

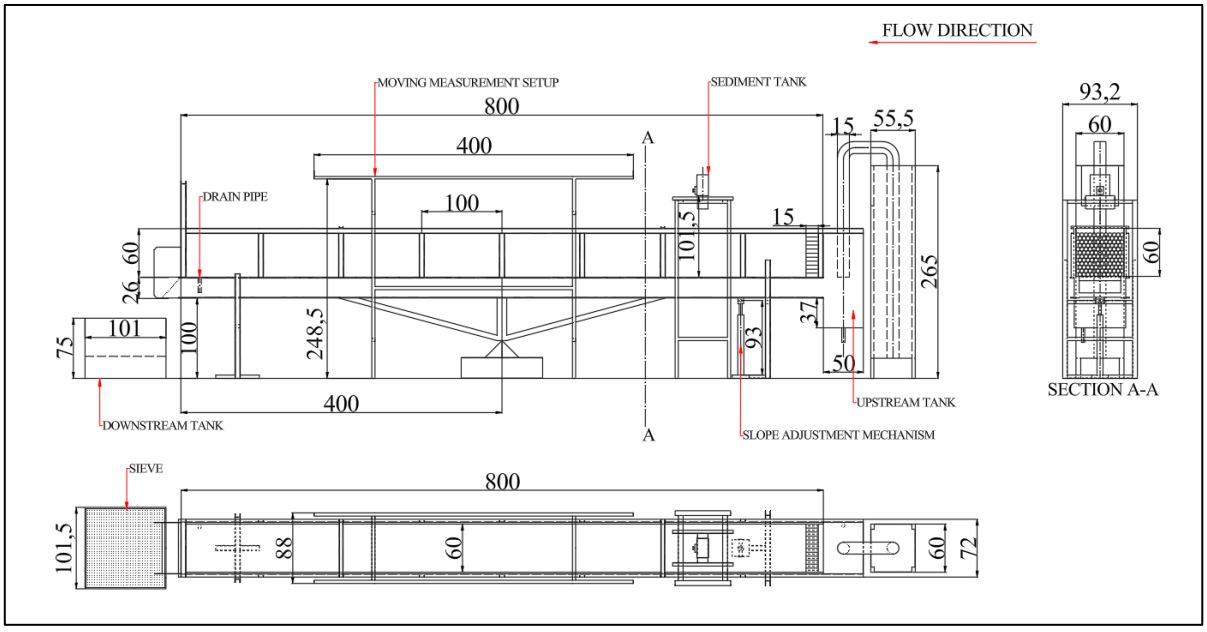
Abstract. Open channel experiments are widely used to investigate many hydraulic problems. In open channel experiments, prototype models are generally created using the Froude scale, and parameters such as water depth, velocity, discharge, and surface profiles can be measured or observed in these models. The established models also allow the investigation of the effects of different parameters. Among these parameters, channel slope has a direct and significant impact on the solution of the problem. However, in many studies in the literature, the effect of slope could not be investigated due to the constant slope of the channel. In this study, the general hydraulic properties of flow (such as Froude numbers and critical depth) and the water surface profile were investigated in an open channel with variable slopes of % 0.5, % 1.0 and % 2.0. In all three experiments, the same discharge was maintained. Thus, the effect of the slope parameter on the flow was examined. In this experimental setup, discharge was measured with an electromagnetic flowmeter, and depths were measured with ultrasonic depth gauges. Experimental results showed that the slope of the channel is one of the primary parameters determining the geometric and hydraulic characterization of the water surface profile. The obtained data demonstrate that variations in slope lead to highly sensitive variations in profile depth and flow regime.

Keywords: Open channel experiments; slope of the channel; open channel flow characteristics

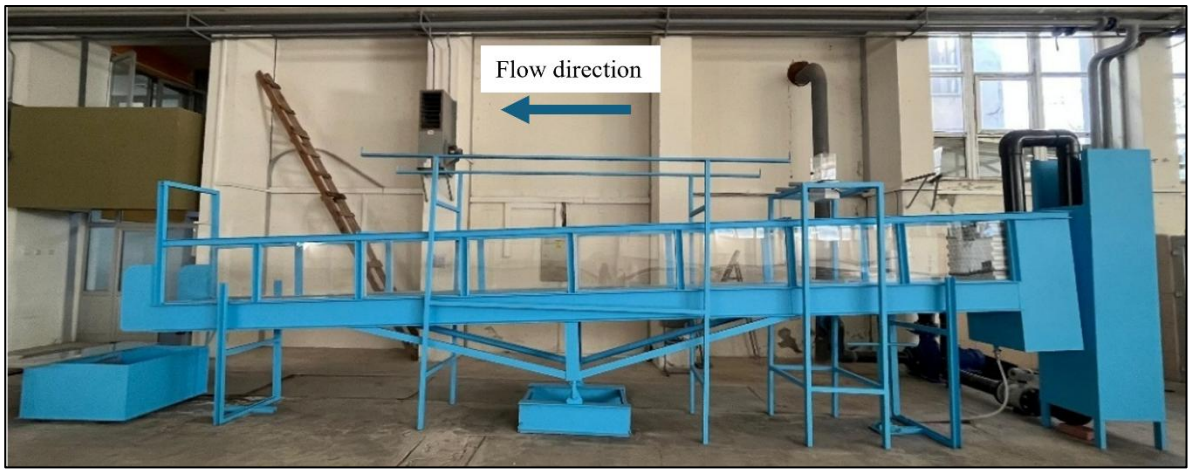
1 Introduction

Many problems in hydraulic engineering relate to open-channel flows. Open-channel systems are used in the experimental solutions to these problems. In these open-channel experiments, the Froude scale is used to model the design project discharge, the dimensions of the structure, the catchment area and the slope. Scaling is a powerful tool in the design of physical models and can be used to ensure that the results of the analysis are like those of a prototype [1]. The Froude number is widely used to characterize dynamic similarity in hydraulics [2-4]. Examples of such problems include issues concerning dam design, discharge coefficients for different types of weirs, the determination of water surface profiles, and sediment transport. As examples of such studies, Kırkgöz and Ardıçlıoğlu [5] investigated velocity profiles, whilst Basak and Alauddin [6] examined pressure losses and velocity profiles occurring during subcritical flow via step-wise widening in rigid-bottomed channels. Emiroğlu, Ağaccioğlu and Kaya [7] conducted research on a sharp-crested rectangular side weir in a straight channel, whilst Emiroğlu and Kaya [8] investigated trapezoidal labyrinth side weirs, and Bilhan et al. [9] on circular labyrinth weirs, and Azimi and Shabanlou [10] on the effect of the Froude number on the flow field in the supercritical flow regime along a weir in a U-shaped channel. Furthermore,



Asnaashari et al. [11] investigated subcritical flow along a transition from rectangular to trapezoidal channels, whilst Al-Hashimi et al. [12], Jiang et al. [13], Muhsun et al. [14], Imanian et al. [15] and Nourani et al. [16] carried out experimental studies on broad-crested weirs to investigate the effects of various hydraulic parameters on flow characteristics and discharge coefficients. In addition, Simsek et al. [17] carried out experimental studies on the characteristics of hydraulic jump at high Froude numbers. Schalko et al. [18] can be cited as an example of studies related to inclined bar screens, while Anılan et al. [19] and Emiroğlu et al. [20] can be cited as examples of studies involving open channel experiments in open check dams.

In most of these studies the channel slope is assumed to be constant due to laboratory constraints. Consequently, in many problems, the effect of the slope parameter which is one of the key factors in many problems is neglected. In this study, however, the effect of the slope parameter on the water surface profile is discussed using a channel setup where the slope varies between 0 and 10%.



2 Material and Methods

2.1 Physical Methods

The experiments were carried out at the Hydraulics Laboratory of Karadeniz Technical University in Türkiye. The open channel, which has a rectangular cross-section, is 8.00 m long, 0.60 m high, 0.60 m wide and has an adjustable bed slope. Water is supplied to the open channel system from the laboratory's water circulation system, which consists of two water tanks, via a pump with a power of 11 kW and a maximum flow capacity of 90 L/s. The open flume system also incorporates a movable measurement rig. Four depth measurement sensors have been installed in this system to measure water depths (y). Thanks to these depth sensors, the y-value was continuously measured and recorded at four different points throughout the experiment. The positions of the sensors can be adjusted to the desired points using the rig mounted on the flume. An electromagnetic flowmeter (EMDE.CM.0150) was used to measure and adjust the flow rate supplied to the system. The flowmeter operates within a measurement range of 19.08–636.10 m³/h with an accuracy of ±0.5%. The open channel system is shown in Fig. 1.

(a)

(b)

Fig. 1. a) Profile design of the test channel (AutoCAD drawing), b) Manufacturing view.

2.2 Data and Equations Used

The experiments were carried out with a constant discharge of 36.5 m³/h in an open-channel system, for slope (j) values of 0.5 %, 1.0 % and 2.0 %. The critical depth (y_c), one of the key parameters used to determine the flow regime and type, was calculated using the Froude number. For the calculation of uniform water depths at different slopes—another key parameter, Equation (1) was used, obtained by substituting the channel-specific values into Manning's equation. The flow type was determined using the measured water depths and the calculated parameters.

$$0.01014 = \left[\frac{(2y+0.6)}{\left(\frac{2y}{100^{1.5}}+\frac{0.6}{71^{1.5}}\right)}\right]^{2/3} \times \left(\frac{0.6y}{0.6+2y}\right)^{2/3} \times j^{1/2} \times (0.6y) \quad (1)$$

3 Results

In the open channel, under steady-flow conditions and for three different slopes, depths were measured at intervals of 0.5 meters along the channel. In all experiments, fluctuations were observed in the first meter due to inlet turbulence, whilst in the final meter, changes in the water level were observed due to the 5 mm threshold located at the channel outlet. For these reasons, depth measurements were not taken at the end of the channel. The uniform water depths calculated for channel slopes of 0.5 %, 1 % and 2 % were 3.370 cm, 2.724 cm and 2.200 cm respectively, whilst the critical water depth was calculated as 3.076 cm. Table 1 presents the water depths formed in the channel at different slopes values, whilst Fig. 2 shows a graphical representation of these water depths.

Table 1. Water depths in different slopes.

Location (m)	Water depths (cm)		
	0.5%	1.0%	2.0%
0.5	1.915	1.274	0.961
1.0	2.355	1.617	1.120
1.5	2.375	1.699	1.259
2.0	2.629	1.660	1.330
2.5	2.881	1.630	1.050
3.0	2.900	1.607	1.286
3.5	2.912	1.612	1.288
4.0	3.018	1.670	1.138
4.5	3.307	1.742	1.225
5.0	3.377	1.730	1.246
5.5	3.412	1.710	0.862
6.0	3.444	1.870	1.254
6.5	3.472	1.895	1.276
7.0	3.544	1.610	1.325
7.5	3.737	1.320	0.456

As can be seen from Fig. 2, as the channel's slope increases, water levels decrease; however, when each slope is examined individually, depths increase progressively along the length of the channel. A decrease is observed in some of the depth measurements; these decreases may be due to measurement errors. When the slope is 0.5%, a comparison of the calculated depths shows that the uniform water depth exceeds the critical depth; therefore, the flow is in the subcritical regime. However, an examination of the depths obtained from the experiment reveals that the water depth at the point where the flow begins is below the critical depth; consequently, the flow in the channel begins as type M3. The flow continued as an M3-type flow up to a range of 4 – 4.5 m, and within this range, it exhibited a hydraulic jump. By undergoing a hydraulic jump, the flow passed through the uniform water level in the 4.5 – 5 m range and, as the water depth increased, reached above the uniform water level, forming an M1-type flow along the remainder of the channel. When the channel slope is 1%, the uniform water depth is below the critical depth, so the flow is in supercritical regime. As the water depths formed along the channel are less than the uniform water depth, the flow is of type S3 along the channel. As the flow is of type S3, water depths along the channel should increase. However, as can be seen, there are slight decreases at certain points. These decreases may be measurement-related, and it has been observed that the measurements obtained fall within a relative error limit of 2.3%. When the channel slope further increased to 2%, the water depths decreased even further. As the uniform water depth once again fell below the critical depth, flow developed under supercritical conditions. Upon examination of the water depths, it was observed that, similarly to the case where the slope was 1%, the flow along the channel consisted solely of type S3. As the flow is of the S3 type when the slope is 2%, the water depth should have increased; the reductions in water depth observed are due to measurement errors. When the flow in the channel was examined for different slopes, it was observed that whilst a subcritical flow regime formed in the channel when the slope was 0.5 %, the system transitioned to a supercritical flow regime as the slope increased. When the rates of increase in water depth in the channel were examined within the range of 1.5 - 6.5 m to ensure they were not affected by changes at the channel's inlet and outlet it was calculated that the water depth increased by 46.19 % at a slope of 0.5 %, by 11.54 % at a slope of 1 %, and by 1.35 % at a slope of 2 %.

Upon examination of the calculated values, it was observed that as the slope increased, the rate of increase in water depth decreased.

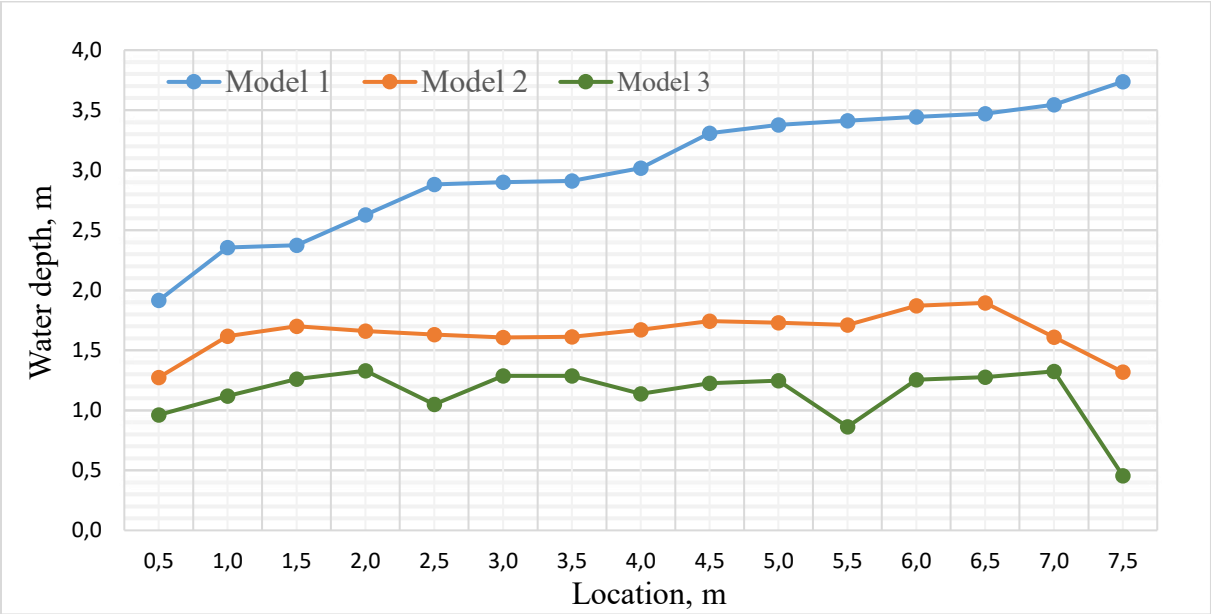


Fig. 2. Water depth values per 50 cm and graphical representation of the water profile.

4 Conclusion

In many problems encountered in open-channel flow, the slope parameter is one of the key parameters that significantly influences the solution. In this study, the effect of the slope parameter was investigated in a rectangular channel 8 metres long with a cross-section of 60 × 60 centimeters. Experiments were carried out under three different conditions: a constant flow rate of 36.5 m^3/h, with channel slopes of 0.5%, 1% and 2%. The effect of a change in channel slope on the flow was observed by examining the flow type and changes in water depth. The results obtained from the experiments are as follows:

- As the channel slope increases, the water depths in the flow decrease, and the rate of this decrease gradually diminishes as the slope increases.
- As the channel slope increases, the rate of increase in water depths along the channel decreases.
- When the channel slope is 0.5%, a river regime is established in the channel, whilst a supercritical regime is established when the slope is set to 1%. It can therefore be concluded that the critical slope value for the channel lies within the range of 0.5–1%.
- When the channel slope is 0.5%, a subcritical regime forms, creating an M3 type in the initial sections of the channel. With the progressively increasing depth, a hydraulic jump occurred in the 4–5 meter range, forming an M1 type.
- Due to the flow types formed in the channel, water depth consistently increases along the length of the channel.

Abstract. Spillway structures in high-head dams are subject to severe cavitation risks due to high-velocity flow regimes and localized low-pressure gradients. Aeration via specialized devices remains the primary strategy to mitigate potential damage. However, predicting air-water interaction at prototype scales presents challenges due to physical modeling limitations in capturing complex flow dynamics. This research proposes a numerical framework to investigate cavitation development and the aeration performance using the Finite Volume Method (FVM) within the ANSYS Fluent software. The numerical model is validated against the experimental benchmarks of Aydin et al. [1], addressing scale effects encountered in laboratory models. The study focuses on a comparative assessment of the predictive accuracy of various turbulence models, specifically evaluating the Standard k-ε, RNG k-ε and SST k-ω approaches within a multiphase Volume of Fluid (VOF) environment. By analyzing critical hydraulic parameters such as pressure distributions, velocity profiles and air concentration levels along the spillway chute, the research aims to identify vulnerable zones susceptible to cavitation inception. The numerical results demonstrate a strong correlation with experimental data, with the RNG k-ε model providing the highest predictive precision for the cavitation index, yielding an Average Absolute Error (AAE) of 0.3165 and an Average Absolute Percentage Error (AAPE) of 21.67%. Furthermore, the interaction between turbulent boundary layer development and aeration efficiency is examined to characterize the protective cushion effect on the spillway surface. The investigation extends to evaluating the stability of the air-water mixture and its role in energy dissipation, providing a multi-dimensional perspective on flow behavior.

Keywords: Spillway Aerator; Cavitation Index; Computational Fluid Dynamics; Finite Volume Method.

1 Introduction

In high-head dams, water flows at very high speeds over the spillways. This high velocity causes the pressure on the concrete surface to drop significantly. If the pressure drops below the vapor pressure of water, vapor bubbles begin to form. When these bubbles travel downstream and burst, they create a strong impact that damages the concrete. This phenomenon is called cavitation. To prevent this damage, the most effective method is to introduce air into the water flow. Special structures called aerators are used to do this. The aerator lifts the water jet off the ground, creating a cavity underneath it. This allows air to mix with the water. The air mixture acts like a cushion and protects the spillway surface from the impact of bursting bubbles. Designing these aerators correctly is very important for dam safety. However, physical tests can sometimes be inaccurate because small-scale models do not behave exactly like real dams. Therefore, CFD simulations are widely used to analyze these flows. In this study, we investigate if a numerical model can reasonably estimate the risk of cavitation. This estimation is performed using various turbulence models to assess their impact on the predicted results.

In order to address these numerical challenges and establish a reliable predictive baseline, numerous investigations have been documented in the literature. Aydin et al. [1] investigated the two-phase flow dynamics and air entrainment rates of a high-head dam spillway aerator using prototype-scaled numerical models to evaluate cavitation mitigation performance. Fadaei-Kermani et al. [2] implemented a numerical approach to detect potential zones of cavitation damage along dam spillways by evaluating critical hydrodynamic parameters. Fadaei Kermani et al. [3] proposed an alternative predictive framework utilizing the fuzzy k-nearest neighbor algorithm to evaluate both the location and intensity levels of cavitation damage along dam spillways. Samadi-Boroujeni et al. [4] conducted a combined physical and numerical study using the VOF framework and RNG k- ε turbulence model within ANSYS Fluent to investigate the specific effects of bed roughness height on the cavitation index along chute spillways. Yusuf and Micovic [5] presented a prototype-scale case study combined with a calibrated numerical model to analyze concrete erosion patterns and evaluate structural mitigation options for spillway steps experiencing cavitation damage. Shayanseresht and Manafpour [6] utilized ANSYS Fluent and the VOF method to perform a comparative assessment of five distinct turbulence models, demonstrating that the RNG k- ε approach provides superior accuracy in predicting flow depth, jet velocity, and cavity characteristics over chute spillway aerators. Almawla et al. [7] implemented ANSYS Fluent and the VOF method combined with the Realizable k- ε turbulence model to simulate free-surface flow patterns over a dam spillway, validating the numerical results against a small-scale physical hydraulic model to predict potential zones of cavitation damage under varying discharges. Wang et al. [8] investigated the subpressure and backwater behavior of chute aerators under varying atmospheric pressures, highlighting how reductions in ambient pressure significantly affect air intake velocity and cavity dimensions. Mozaffari et al. [9] combined a 3D CFD numerical framework with an artificial intelligence model called Gene Expression Programming (GEP) to predict flow discharge over an ogee spillway, noting that the RNG turbulence model achieved the highest compatibility with experimental data among the evaluated formulations. Foroudi and Barati [10] performed a physical experimental study using a 1:50 scale model to analyze the variations in the cavitation index across an ogee spillway by considering different sidewall convergence angles and unit flow rates. Varçın et al. [11] developed a three-dimensional ANSYS Fluent model using the two-phase VOF method and k-ε turbulence formulation to analyze spillway hydraulics, while simultaneously introducing an OpenCV-Python image processing code to track flow velocity and depth. Salmasi and Abraham [12] conducted a comparative numerical analysis using the RNG k- ε turbulence model and multiphase mixture method to evaluate the hydraulic properties and cavitation index values of stepped and smooth spillway configurations. Gadge and Patil [13] conducted numerical studies on a high-head orifice spillway to assess cavitation mitigation performance, demonstrating how aerators protect the chute surface by modifying parameters such as pressure, velocity, air concentration, and jet length under critical gate openings. Safiloo et al. [14] performed a numerical evaluation of various chute spillway aerator configurations using the RNG k-ε turbulence model and multiphase mixture method, indicating that combining bottom and side-wall ramps increases the cavitation index by approximately 55% compared to using a bottom ramp alone. Bagherzadeh et al. [15] utilized 3D two-phase flow simulations within FLOW-3D integrated with a support vector machine (SVM) model to predict the specific locations and intensity levels of cavitation damage along an ogee spillway based on key hydrodynamic parameters. Aydin and Kaplan [16] utilized computational fluid dynamics (CFD) to evaluate the performance of the Ilısu Dam spillway aerators, comparing the initial 1982 design with the revised 2010 geometry to analyze cavitation protection efficiency across different flow conditions. Kökpınar and Göğüş [17] presented an extensive experimental analysis to investigate air-entrainment mechanisms and pressure fluctuations over spillway aerators, evaluating the effects of flow

conditions and different ramp designs under varying bed slopes. Jothiprakash et al. [18] developed a three-dimensional two-phase numerical model using FLUENT to investigate the flow field, pressure distribution, and air entrainment characteristics of an aerator on a deep-seated orifice spillway, validating the results with a 1:25 scale physical model. Arami-Fadafan et al. [19] performed a regression analysis based on experimental data to evaluate bottom air concentration transport downstream of aerators, deriving an empirical equation linked to water jet length to predict aeration rates along the chute. Kumcu and Uçar [20] performed a comparative study using results obtained from a 1:70-scaled physical model and computational fluid dynamics (CFD) simulations to investigate the hydraulic characteristics, velocity patterns, and pressure distributions of a dam spillway.

2 Aim of the Study

This study aims to investigate the cavitation behaviour of a spillway aerator using Computational Fluid Dynamics (CFD). Unlike the reference study by Aydın et al. [1], which utilized Flow-3D with a detailed multiphase model, the present work employs ANSYS Fluent with a two-phase air–water formulation. The main objective is to examine the influence of mesh resolution and turbulence model selection on the calculated cavitation index at various locations along the spillway. For this purpose, a mesh independence study is first performed, followed by a systematic comparison of three commonly used turbulence models: Standard k–ε, RNG k–ε and SST k–ω. The numerical results are subsequently compared with experimental data of Aydin et al., [1] in order to assess the capability of the Fluent two-phase model to predict cavitation risk in spillway aerators.

3 Theory

In this study, the Reynolds-Averaged Navier-Stokes (RANS) equations are solved using the Finite Volume Method (FVM). Since the flow over the spillway involves air-water interaction, the Volume of Fluid (VOF) method is employed to track the free surface.

3.1 Governing Equations (VOF Method)

The VOF model treats the two phases (air and water) as a single continuum. The properties appearing in the transport equations are weighted averages based on the volume fraction (α) Density and Viscosity: The density (ρ) and viscosity (μ) in each computational cell are calculated as:

$$\rho = \alpha_w \rho_w + (1 - \alpha_w)\rho_a \tag{1}$$

$$\mu = \alpha_w \mu_w + (1 - \alpha_w)\mu_a \tag{2}$$

Where:

- α_w: Volume fraction of water$(0 \leq \alpha \leq 1)$
- ρ_w, ρ_a: Density of water and air(kg/m^3)
- μ_w, μ_a: Dynamic viscosity of water and air$(kg/m \cdot s)$

Continuity and Momentum Equation: To ensure mass conservation for the mixture:

$$\frac{\partial}{\partial t}(\rho u) + \nabla \cdot (\rho u u) = -\nabla p + \nabla \cdot [\mu(\nabla u + \nabla u^T)] + \rho g \tag{3}$$

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0 \tag{4}$$

Where:

- u: Velocity vector(m/s)
- p: Staticp ressure(Pa)
- g: Gravitational acceleration(m/s^2)

Volume Fraction Transport Equation: To track the interface between air and water, the transport equation for the volume fraction is solved:

$$\frac{\partial \alpha_w}{\partial t} + \nabla \cdot (\alpha_w u) = 0 \tag{5}$$

Cavitation Index (σ): The potential for cavitation risk is evaluated using the cavitation index, defined as:

$$\sigma = \frac{p - p_v}{\frac{1}{2}\rho V^2} \tag{6}$$

Where:

- p_v: Vapor pressure of water(Pa)
- V: Flow velocity(m/s)

3.2 Turbulence Models

To close the RANS equations, three different turbulence models were applied to predict the Reynolds stresses.

3.2.1 Standard k−ε Model. This model solves two transport equations for turbulent kinetic energy (k) and dissipation rate (ε).

$$\frac{\partial(\rho k)}{\partial t} + \nabla \cdot (\rho k u) = \nabla \cdot \left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\nabla k\right] + G_k - \rho\varepsilon \tag{7}$$

$$\frac{\partial(\rho \varepsilon)}{\partial t} + \nabla \cdot (\rho \varepsilon u) = \nabla \cdot \left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\nabla \varepsilon\right] + C_{1\varepsilon}\frac{\varepsilon}{k}G_k - C_{2\varepsilon}\rho\frac{\varepsilon^2}{k} \tag{8}$$

3.2.2 RNG k−ε Model. The RNG model includes an additional term Rε in the ε equation to improve accuracy for rapidly strained flows and swirling flows.

$$\frac{\partial(\rho \varepsilon)}{\partial t} + \nabla \cdot (\rho \varepsilon u) = \nabla \cdot \left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\nabla \varepsilon\right] + C_{1\varepsilon}\frac{\varepsilon}{k}G_k - C_{2\varepsilon}\rho\frac{\varepsilon^2}{k} - R_\varepsilon \tag{9}$$

Where:

- Rε: Additional term responsible for the superior performance of RNG in high-curvature flows (like spillway aerators).

3.2.3 SST k–ω Model. The Shear Stress Transport (SST) model combines the k–ω formulation in the near-wall region and the k−ε formulation in the free stream.

Turbulent Kinetic Energy (k):

$$\frac{\partial(\rho k)}{\partial t} + \nabla \cdot (\rho k u) = \nabla \cdot [(\mu + \sigma_k \mu_t)\nabla k] + G_k - \beta^* \rho k \omega \tag{10}$$

Specific Dissipation Rate (ω):

$$\frac{\partial(\rho \omega)}{\partial t} + \nabla \cdot (\rho \omega u) = \nabla \cdot [(\mu + \sigma_\omega \mu_t)\nabla \omega] + \alpha\frac{\omega}{k}G_k - \beta\rho\omega^2 + D_\omega \tag{11}$$

Where:

- ω: Specific dissipation rate(s

- D_ω: Cross-diffusion term (blending function) that triggers the switch between models.

4 Numerical Model

A three-dimensional (3D) two-phase CFD model was developed in ANSYS Fluent to simulate the flow over the spillway. The numerical model aims to investigate how mesh density and turbulence model selection affect the cavitation index along the spillway chute for the discharge Q = 5223 m^3/s.

4.1 Computational Domain and Boundary Conditions

- **Inlet:** An open channel inlet boundary condition was applied at the upstream boundary. The design discharge specified as Q = 5223 m^3/s, along with the corresponding upstream reservoir water level of 417.15m obtained from the discharge-water level. The water volume fraction was set to 1.0
- **Outlet:** A pressure outlet boundary condition was applied at the downstream boundary. The tailwater level of 331.00m, corresponding to the design discharge was prescribed as the outlet boundary conditions.
- **Free Surface:** The top boundary was kept open to the atmosphere, allowing air exchange in the two-phase model.
- **Walls (No-Slip):** The chute floor, aerator ramp and side surfaces were treated as stationary no-slip walls. Wall roughness was neglected.

4.2 Mesh Generation

The flow domain was discretised using a fine grid. A total of 15 mesh levels were created by gradually reducing the cell and face size. The number of cells ranged from approximately 4.1×10^5 to 5.8×10^6 for the best selection (Fig. 1.) For each mesh level, simulations were first carried out with the RNG k–ε turbulence model. The cavitation index σ were recorded and compared between successive meshes. As the mesh was refined, the changes in σ became progressively smaller. For cell counts above approximately 4.4×10^6, the differences in σ were negligible. Therefore, the fine mesh with about 4447179 cells (fine grid) was adopted as the reference mesh for the turbulence model comparison.

4.3 Turbulence Modeling

Following the mesh independence study, the simulations were performed on the selected mesh using ANSYS Fluent. To determine the most accurate approach for this flow type, three different turbulence models were tested: Standard k–ε, RNG k–ε and SST k–ω. The results obtained from these models were then compared to see which one best predicts the cavitation index.

5 Results and Discussion

Numerical analyses were conducted on the spillway geometry to evaluate grid sensitivity and assess the accuracy of different turbulence models. The grid independence study, spanning mesh sizes from approximately 4.1 x 10^5 to 5.8 x 10^6 cells, revealed that the cavitation index exhibited significant fluctuations in fine grids but achieved convergence beyond 4.4 million cells for the Fluent solver. Consequently, these refined mesh configurations were adopted for the final simulations. Upon comparing the predictive performance of the three turbulence models, it was observed that the solvers exhibited different optimal behaviors; the RNG k–ε model yielded the most accurate results for Fluent with Average Percentage Errors (APE) of 21.67%. Table 1 presents a detailed comparison of the predicted cavitation index values from the three turbulence models against the experimental data at various points. Table 2 compares the predictions of the optimal RNG k-ε model with the numerical results obtained by Aydin et

al. [1] using Flow-3D. The comprehensive statistical performance metrics, including I_ , AAE, AAPE and RMSE for the evaluated models are summarized in Table 3. Furthermore, Table 4 provides a direct statistical comparison between the developed CFD model (RNG k–ε) and the reference numerical study by Aydin et al. [1].

6 Conclusion

- In this study, three widely used turbulence models (RNG k–ε, SST k–ω and Standard k–ε) were evaluated to predict the cavitation index along the spillway.
- The RNG k–ε model provided the highest predictive accuracy among the evaluated configurations (based on RNG k–ε= 21.67%, SST k–ω= 23.03% and Standard k-ε=24.05% AAPE values, respectively).
- Since the RNG k–ε model yielded the most accurate results, it was adopted in the developed Computational Fluid Dynamics (CFD) model.
- The developed CFD model showed a closer agreement with experimental data compared to the reference Flow-3D study by Aydin et al. [1] (based on Flow-3D= 41.32% AAPE value).

Is Türkiye Drying? Regional and Seasonal Drought Trends from High-Resolution SPEI

Ahmet Faruk İpek[1] and Ercan Kahya[2]

Abstract. Long-term drought variability across Türkiye has become increasingly important under intensifying climate pressures in the Eastern Mediterranean. In this study, the spatial and seasonal distribution of drought trends across Türkiye was analyzed using a high-resolution Standardized Precipitation Evapotranspiration Index (SPEI) dataset covering the 1981–2022 period, with trends assessed using the Modified Mann–Kendall (M-MK) test. The results reveal a spatially heterogeneous pattern with clear seasonal variability rather than a widespread, homogeneous drying trend. Significant drying remained limited throughout the year, ranging from about 2.3% in November to 4.6% in December. In contrast, significant wetting consistently covered larger areas, ranging from about 5.3% in December to 11.9% in March. The most persistent drying signal was detected throughout the year in Southeastern Anatolia (GAP region) and the Upper Euphrates Basin of Eastern Anatolia, whereas the western and central Black Sea hinterland, Thrace, and northern Central Anatolia consistently exhibited wetting trends. These findings demonstrate that drought trends in Türkiye are characterized by pronounced regional and seasonal contrasts rather than a uniform nationwide drying pattern. The persistent drying observed in the GAP region has important implications for agricultural water management and irrigation planning.

Keywords: Drought; Trend; Standardized Precipitation Evapotranspiration Index (SPEI); Modified Mann–Kendall (M-MK) trend test; Türkiye

1 Introduction

The Mediterranean Basin is recognized as one of the regions most vulnerable to the impacts of climate change, with substantial reductions in winter precipitation projected [1]. Therefore, reliable identification of drought trends is essential for water resources management and agricultural planning in Türkiye, which is influenced by Mediterranean, continental, and semi-arid climate regimes. The Standardized Precipitation Evapotranspiration Index (SPEI), one of the most widely used indices for drought assessment, accounts for both precipitation and potential evapotranspiration, thereby incorporating the influence of temperature on drought conditions. In addition, its ability to be calculated at multiple temporal scales provides a significant advantage for drought analysis and monitoring [2]. Previous studies in Türkiye have reported increasing drought trends, particularly in the central and southeastern regions of the country [3].

In this study, drought trends across Türkiye were analyzed at a monthly scale using the Modified Mann–Kendall (MMK) test and a gridded SPEI dataset with an approximate spatial resolution of 5 km covering the period 1981–2022. This approach enables the assessment of drought trends at both monthly and high spatial resolution. The main objectives of the study were to (i) quantify the spatial distribution of statistically significant drying and wetting trends

across Türkiye, (ii) determine the monthly variability of these trends, and (iii) identify regions exhibiting persistent drought signals throughout the annual cycle.

2 Materials and Methods

2.1 Study Area and Data

Türkiye is located in the eastern Mediterranean and is characterized by the coexistence of Mediterranean, continental, and semi-arid climate regimes. Covering an area of approximately 780,000 km² with a mean elevation of 1,130 m, the country exhibits pronounced topographic and climatic diversity [4]. These characteristics make Türkiye particularly sensitive to drought variability.

This study used the CHIRPS–GLEAM subset of the high-resolution global Standardized Precipitation Evapotranspiration Index (SPEI) dataset developed under the Hydro-JULES project [5]. The dataset provides monthly SPEI values for the 1981–2022 period at an approximate spatial resolution of 5 km. To characterize long-term moisture deficits and hydrological drought conditions, the 12-month Standardized Precipitation Evapotranspiration Index (SPEI-12) was used in the analysis. Small data gaps over water bodies were interpolated for visualization purposes only; all analyses were based on the original data.

2.2 Standardized Precipitation Evapotranspiration Index (SPEI)

The Standardized Precipitation Evapotranspiration Index (SPEI), one of the most widely used indices for drought assessment, is based on the standardization of the climatic water balance calculated as the difference between precipitation and potential evapotranspiration (PET) [2]. By accounting for atmospheric evaporative demand in addition to precipitation, SPEI differs from precipitation-based drought indices and provides a more suitable framework for drought assessment under a warming climate [6]. Owing to its multi-temporal nature, SPEI can be calculated over different accumulation periods.

In this study, the 12-month accumulation timescale (SPEI-12) was used to characterize long-term drought conditions. Negative SPEI values indicate dry conditions, whereas positive values indicate wet conditions. A detailed description of the SPEI calculation procedure is available in the literature [2].

2.3 Modified Mann–Kendall (M-MK) Trend Test

Trend analysis was performed using the Modified Mann–Kendall (MMK) test proposed by Hamed and Rao [7], which corrects the variance of the Mann–Kendall test statistic to reduce the over-detection of significant trends in the presence of serial correlation. The analysis was conducted independently for each grid cell by separating the SPEI-12 time series into individual calendar months and applying a separate MMK test to each month. This approach minimizes the influence of the seasonal cycle and enables the long-term trend for each calendar month to be evaluated independently. Trend direction and statistical significance were determined using the standardized test statistic (z), with grid cells having an absolute z-value greater than 1.96 considered significant at the 95% confidence level. Positive z-values indicate wetting trends, whereas negative z-values indicate drying trends.

3 Results

The areal summary of the pixel-based Modified Mann–Kendall (MMK) analysis performed for each calendar month during the 1981–2022 period is presented in Table 1, while the spatial distribution of statistically significant trends is shown in Figure 1. Areal percentages were calculated relative to the total area with valid data for each month. Overall, the results reveal a spatially and seasonally heterogeneous pattern rather than a uniform drying trend across Türkiye. Areas exhibiting statistically significant drying ($z < -1.96$) remained limited

throughout the year, ranging from 2.3% of the study area in November to 4.6% in December. In contrast, statistically significant wetting ($z > +1.96$) consistently covered larger areas, varying from 5.3% in December to 11.9% in March. Accordingly, the area exhibiting significant wetting exceeded that affected by significant drying in every month of the year.

The seasonal distribution of the trends exhibited clear variability. Wetting reached its greatest spatial extent during late winter and early spring, accounting for 11.3% of the study area in February and 11.9% in March, before declining to 5.5–6.3% during summer and autumn. Drying reached its maximum spatial extent in December (4.6%), followed by April (3.9%). December also recorded the smallest extent of significant wetting (5.3%), making it the month in which the spatial extents of drying and wetting were most similar.

From a spatial perspective, the most notable finding was the persistence of drying in specific regions. Statistically significant drying was detected throughout the year in Southeastern Anatolia (the GAP region) and the Upper Euphrates section of Eastern Anatolia. A secondary drying cluster repeatedly occurred in the northeastern interior, while in December the drying pattern expanded across a larger portion of Eastern Anatolia. In contrast, wetting trends were concentrated primarily in the hinterland of the western and central Black Sea region, as well as in Thrace, northern Central Anatolia, and the vicinity of Artvin in northeastern Türkiye. No statistically significant trends were detected across most of the Aegean and Mediterranean coastal zones or over large parts of Central Anatolia throughout the study period.

These spatial patterns are consistent with previous studies identifying Southeastern Anatolia as a major drought hotspot [3, 8] and northern Türkiye as a region exhibiting relatively wetter conditions [3].

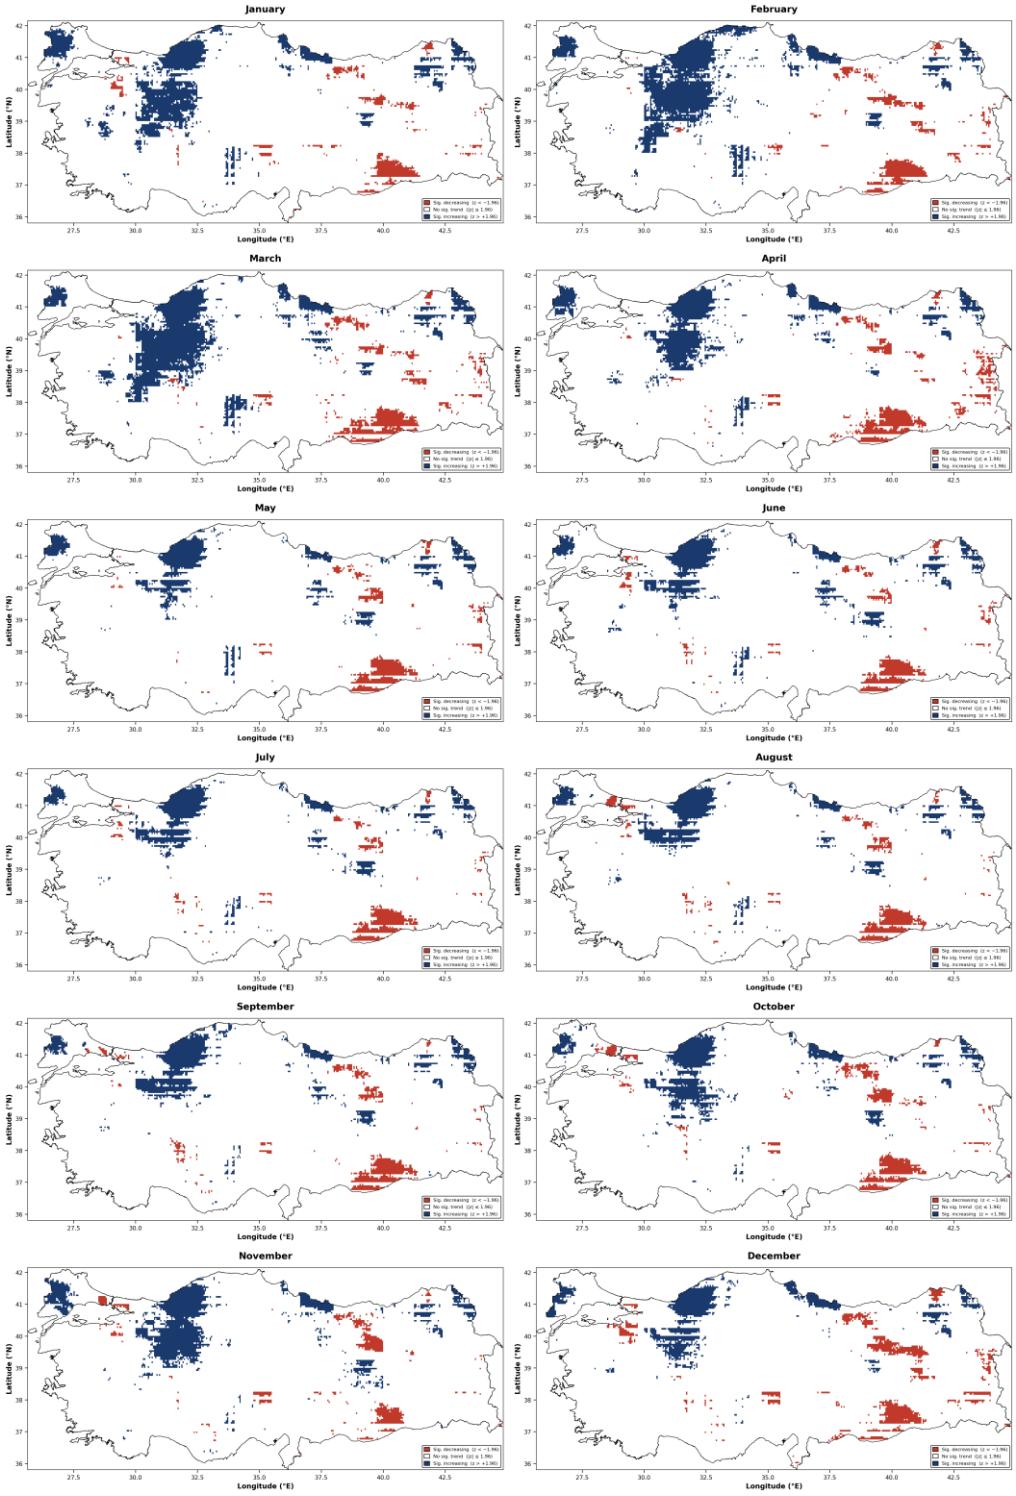

Figure 1. Monthly M-MK trend maps of SPEI-12 (January–December). Red: significant drying; blue: significant wetting; white: non-significant.

Table 1. Areal extent of significant drying and wetting trends from the monthly M-MK analysis

Month	Sig. drying (%)	Sig. wetting (%)
January	2.73	9.33
February	3.14	11.25
March	3.77	11.90
April	3.95	7.65
May	2.76	5.56
June	2.72	6.10
July	2.52	5.62
August	2.66	5.79
September	2.79	6.18
October	3.32	6.33
November	2.33	8.13
December	4.60	5.29

4 Conclusion

This study investigated monthly drought trends across Türkiye for the 1981–2022 period using the Modified Mann–Kendall (M-MK) test applied to a high-resolution gridded SPEI-12 dataset. The use of a high-resolution gridded dataset enabled a detailed assessment of regional drought patterns. The results showed that statistically significant drying remained limited throughout the year, affecting approximately 2.3–4.6% of the study area, whereas significant wetting consistently covered larger areas, ranging from 5.3% to 11.9% of the study area. Persistent drying was detected throughout the year in the GAP region of Southeastern Anatolia and the Upper Euphrates Basin, while recurrent wetting was observed in the western and central Black Sea hinterland, Thrace, and northern Central Anatolia. Overall, the findings indicate that drought trends in Türkiye are characterized by pronounced regional and seasonal variability rather than a uniform nationwide drying pattern. These findings highlight the importance of regional-scale drought assessment for water resources management and agricultural planning, particularly in drought-prone regions. Future studies incorporating multiple SPEI accumulation timescales together with large-scale climate teleconnection indices may provide further insight into the mechanisms driving these regional drought patterns.

Investigation of Uncertainties in 2D Dam Break Simulations by Monte Carlo Simulations

Muhammed Furkan Kart[1] and Ali Ercan[2,*]

Abstract. Manning's roughness coefficient is a key input in two-dimensional (2D) dam-break flood modelling, yet it cannot be measured directly and is estimated from terrain classification. Deterministic models assign a single fixed value, which does not reflect this estimation uncertainty and can produce overconfident predictions. A Monte Carlo framework is applied to dam-break modelling with GeoClaw, a 2D nonlinear shallow-water solver with adaptive mesh refinement. The 1959 Malpasset dam failure, documented by post-event police high-water marks, is used as the test case. Two roughness configurations (a spatially uniform random coefficient and a region-wise variable field over thirteen sub-regions) and two priors (uniform and log-normal) are combined into four cases, each with fifty Latin-Hypercube realizations. Maximum water-surface elevation, depth and arrival time are extracted at the surveyed points and valley gauges, and a probabilistic inundation map is built from each ensemble. Results show that the inundation footprint is geometry-limited and nearly insensitive to roughness, whereas local depths, peak elevations and especially the wave arrival time are sensitive, the arrival spread growing from seconds near the dam to minutes downstream, broadly consistent with documented field records. The region-wise variable field gives a small improvement in coverage (24–29%) and median error, and the uniform prior outperforms the log-normal one. The framework thus quantifies how roughness uncertainty propagates into the predicted flood and identifies the modelling choices that most affect the depth and timing estimates.

Keywords: Malpasset dam break; Monte Carlo simulation; Manning roughness uncertainty.

1 Introduction

Dam-break floods are among the most destructive hydraulic hazards, and their reliable simulation is essential for hazard assessment, risk mitigation, and emergency planning. Two-dimensional (2D) solvers of the nonlinear shallow-water equations (NSWE) are now routine tools for reproducing a dam-break wave over complex terrain [1, 2, 3]. The predictive quality of such models depends not only on the numerical scheme and the terrain but also on the bottom friction, which is commonly expressed by Manning's roughness coefficient n.

Unlike geometric parameters, Manning's n cannot be measured directly and instead is estimated from land-cover characteristics, and engineering tables which introduce unavoidable uncertainty. Deterministic practice assigns a single roughness n and produces a single flood prediction, hiding parameter uncertainty and conveying a false sense of confidence in the predicted water levels, flood extent, and arrival time. A probabilistic treatment, in which n is

described by a distribution rather than a point value, enables this uncertainty to be explicitly propagated through the numerical model.

Monte Carlo (MC) simulation provides a general framework for such uncertainty propagation by repeatedly sampling the roughness field from a prescribed prior distribution, executing the numerical model for each realization, and statistically analyzing the resulting ensemble. Although roughness-induced uncertainty has been widely investigated for riverine flood modelling using generalized likelihood uncertainty estimation (GLUE) and MC approaches [4-6], similar studies for 2D dam-break simulations remain limited. Existing investigations are generally validated against simulated or mapped inundation extents rather than independent field observations [7]. Moreover, two further modelling choices have been rarely examined together: (i) representing Manning's roughness as either a single domain-wide random variable or a spatially variable field, and (ii) which prior distribution is assigned to the coefficient [7]. This study addresses both issues using a well-established benchmark while directly validating the uncertainty predictions against independent field observations.

The 1959 Malpasset dam failure serves as the benchmark case because it provides a unique set of independent observations, including maximum water levels surveyed at seventeen field locations and recorded failure times of three electrical transformers, which constrain flood-wave arrival times [8-10]. A GeoClaw-based Monte Carlo framework is developed in which Manning's roughness is sampled using Latin Hypercube Sampling under two spatial representations and two prior distributions, resulting in four experimental cases with fifty realizations each. The objectives of this study are to: (i) quantify the propagation of Manning's roughness uncertainty into predicted inundation extent, water depth, and water-surface elevation; (ii) evaluate the influence of roughness representation and prior distribution on prediction uncertainty; (iii) assess the capability of the simulated uncertainty bounds to capture the independent field observations; and (iv) characterize how the uncertainty in the wave arrival time develops along the valley.

2 Study Area and Observational Data

The Malpasset arch dam, located on the Reyran River about 12 km upstream of Fréjus in south-eastern France, failed on the night of 2 December 1959 and released roughly 42 million m^3 of water into the narrow Reyran valley [11, 12]. The flood wave travelled down the valley and reached the Fréjus plain and the Mediterranean Sea in about twenty minutes, causing more than four hundred fatalities [13]. The event has become a standard benchmark for 2D dam-break solvers because of the combination of complex topography, a strongly bending valley, and a documented set of observations [9, 14].

The computational domain used here spans approximately 17.3 km in the along-valley direction and 9.3 km across, covering the reservoir, the Reyran valley, the Fréjus plain, and the coastal outlet. Figure 1 shows the domain topography together with the dam axis, the seventeen police high-water marks (P1–P17) that provide the field validation data, the nine physical-model gauges (G6–G14), and the three electrical transformers (A–C). While the high-water marks and gauges record the peak water level, the three transformers record the wave timing: short-circuited in turn by the arriving flood, their logged power-failure times give observed wave-arrival times of about 100, 1240 and 1420 s [8, 11]. The observed maximum water-surface elevations decrease monotonically along the valley, from about 88 m near the dam (P2) to about 14 m in the downstream reach (P17), reflecting the progressive attenuation and spreading of the wave.

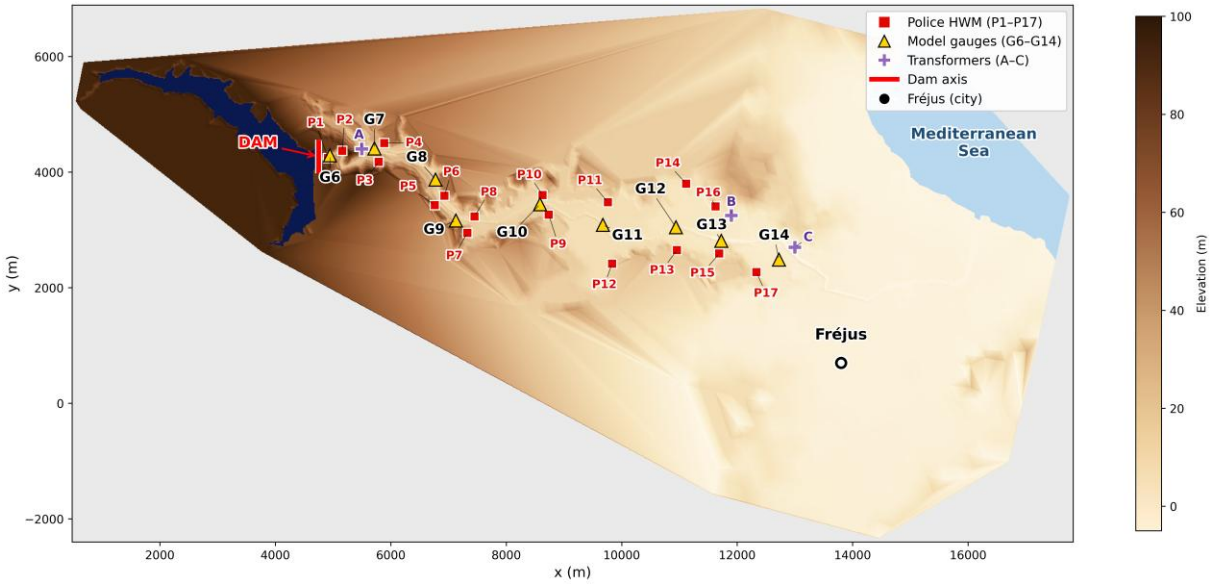

Fig. 1. Malpasset study area: topography, dam axis, police high-water marks (P1–P17), physical-model gauges (G6–G14) and transformers (A–C).

The valley gauges originate from an undistorted 1:400 laboratory model of the flooded reach, built by the Laboratoire National d'Hydraulique (LNH) of Électricité de France (EDF) in 1964, on which peak water levels were recorded at fourteen gauges (S1–S14) [9, 10]. The five reservoir gauges (S1–S5) were unavailable, leaving the nine downstream stations S6–S14 (labelled G6–G14 here), later distributed to the CADAM participants with the digitized topography [8, 11].

Only the seventeen police high-water marks are used as the validation reference in this study. Numerical gauges at the G6–G14 locations are still recorded and are used to examine the simulated flow dynamics (Section 4.5), but they are excluded from all validation metrics, because the 1:400 scaled model was built with a single, spatially uniform roughness by construction [8, 10]; comparing spatially variable roughness configurations against a uniform-roughness laboratory benchmark would be methodologically inconsistent. The field high-water marks, by contrast, are independent observations of the real event.

3 Methodology

The flood is simulated with GeoClaw, an open-source solver of the 2D nonlinear shallow-water equations built on the Clawpack finite-volume framework with block-structured adaptive mesh refinement (AMR) [1, 2, 15]. GeoClaw uses a well-balanced, wave-propagation Riemann solver with robust wetting-and-drying treatment, which makes it suitable for dam-break flows over irregular, initially dry terrain [9]. A high-resolution flux limiter is applied to control numerical oscillations [1]. Three levels of adaptive refinement are used, concentrating resolution on the moving wave front and reaching a finest cell size of about 12.6 m in the valley. Bottom friction is imposed through the Manning formulation, and the roughness field is the uncertain input sampled in the Monte Carlo experiment.

The reservoir is initialized hydrostatically and released instantaneously at t = 0, and each realization is integrated for 4000 s, long enough for the maximum water levels to be established at all validation points. Peak water-surface elevation and depth are recorded on a fixed 20 m grid with the solver's maximum-monitoring (fgmax) capability, and water-depth time series are stored at the surveyed points and the valley gauges (G6–G14) to characterize the flow dynamics and arrival time.

Uncertainty in Manning's n is propagated by Monte Carlo simulation, combining two spatial representations of the roughness field and two priors into the four cases of Table 1. The constant-n cases share one random coefficient over the domain; the variable-n cases partition the flooded envelope into sub-regions with an independent coefficient each. Two priors are tested: a uniform distribution (the standard non-informative choice) and a log-normal distribution (physically motivated for strictly positive parameters and increasingly used in flood modelling).

Table 1. Monte Carlo experimental design.

Case	Roughness field	Prior distribution	Sampled dimensions	Number of samples
1A	Constant	Uniform	1	50
1B	Constant	Log-normal	1	50
2A	Variable	Uniform	13	50
2B	Variable	Log-normal	13	50

In all cases the samples are generated by Latin Hypercube Sampling, which stratifies each marginal and covers the parameter space more efficiently than independent random sampling [16]. The roughness bounds and the number of realizations were guided by a preliminary sensitivity analysis against published values for the site. The uniform prior spans n in [0.020, 0.060], a physically defensible range for the mixed vegetated, rocky and built terrain of the valley; the log-normal prior is centred on the widely used nominal value n = 0.033 [8, 9, 10] with a coefficient of variation of 0.20. The adequacy of fifty realizations was verified for every case by tracking the 5th, 50th and 95th percentiles of the P-RMSE distribution against the cumulative sample size; in each case the median and the 5th–95th range stabilize well before N = 50, in both the one- and thirteen-dimensional configurations.

For the variable-n cases the domain is divided by a 5 × 4 grid clipped to the flooded envelope, yielding thirteen active sub-regions in which the coefficient is sampled independently; the remaining, always-dry or permanently wet cells retain a fixed baseline value. This regular grid is a deliberately simple, geometry-based proxy for spatial heterogeneity rather than a land-cover-derived roughness field; it keeps the sampled dimension modest (thirteen) while letting the roughness differ between reaches, which is sufficient for the present purpose of contrasting a variable field with a single domain-wide value.

Model performance is quantified against the seventeen police high-water marks, whose observed maxima were digitized from the published comparison figures of [9, 10]. For each realization the simulated maximum water-surface elevation is interpolated to every observation point using an inverse-distance weighting of the four nearest fgmax cells, and the point root-mean-square error (P-RMSE) between simulated and observed elevations is computed. The ensemble of P-RMSE values characterizes the accuracy distribution of each case. In addition, the observation coverage is defined as the number of the seventeen field points whose observed elevation falls within the min-max envelope of the ensemble at that point; it measures how well the simulated uncertainty bounds bracket reality. The wave timing is checked separately against the three documented transformer failure times (Section 2). Finally, a probabilistic inundation map is built by counting, for each grid cell, the fraction of realizations in which the depth exceeds a given threshold.

4 Results

The accuracy across the four cases, the water-surface and inundation results, the probabilistic maps, and the flow dynamics and arrival times are presented in turn.

4.1 Accuracy Across Cases

Table 2 summarizes the P-RMSE distribution of the four cases. The median P-RMSE ranges from 3.73 m (Case 2A) to 3.96–3.97 m (Cases 1B and 2B), and the best individual realization reaches 3.23 m, obtained in the constant-n case 1A at the upper end of the roughness range (n ≈ 0.060). This best value is reached without any site-specific calibration, purely as the most favourable draw of the friction prior. Across the constant-n ensemble the P-RMSE is strongly and negatively correlated with the sampled roughness (correlation about −0.97): higher friction reduces the peak elevations and improves the fit at the field points, indicating that in the present configuration the fit improves towards roughness values above the nominal 0.033 (Fig. 2). Because the correlation is monotonic, the best fit is pushed to the upper bound of the prior; since n = 0.060 already represents the upper end of the physically plausible range for this mixed vegetated, rocky and built terrain, the roughness is effectively exhausted at its ceiling, and the residual error cannot be removed by admissible friction alone.

Table 2. P-RMSE distribution and observation coverage for the four cases.

Case	P-RMSE min (m)	P-RMSE median (m)	P-RMSE max (m)	Coverage
1A	3.23	3.78	4.19	4/17 (24%)
1B	3.48	3.97	4.19	4/17 (24%)
2A	3.26	3.73	4.15	5/17 (29%)
2B	3.45	3.96	4.20	5/17 (29%)

Two systematic effects are visible. First, the variable-n cases give a small but consistent improvement over their constant-n counterparts: the median P-RMSE decreases from 3.78 m to 3.73 m and the coverage rises from four to five of the seventeen points. Second, for both spatial representations the uniform prior outperforms the log-normal one by about 0.2 m in median error, because the log-normal samples concentrate near the nominal 0.033 value, which is sub-optimal for this configuration. These error levels are of the same order as earlier deterministic studies of the benchmark: the finite-element (TELEMAC-2D), finite-volume and multi-code CADAM results [8, 9, 10, 11, 17, 18] report their agreement graphically rather than as a single value, and re-evaluating their digitized curves with the present seventeen-point P-RMSE gives about 3.0 m. A strict cross-code ranking is deliberately avoided, however: differences in scheme, mesh, topography and boundary treatment mean that two codes need not reach the same field error even under identical roughness. The analysis is therefore framed as an internal comparison of the four cases, with the solver, mesh and topography held fixed and only the roughness representation and prior varied.

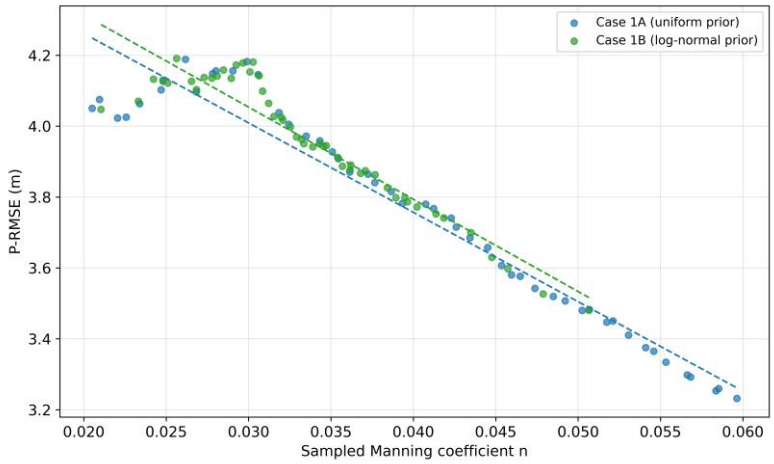

Fig. 2. P-RMSE versus sampled Manning coefficient, constant-n cases (r = −0.97 for Case 1A).

4.2 Water-Surface Elevation

Figure 3 compares the simulated and observed maximum water-surface elevations at the seventeen survey points. The ensemble medians closely reproduce the observed attenuation of the flood wave along the valley, yielding a correlation coefficient of approximately 0.98 and a mean bias of only −0.3 m, indicating excellent agreement with no systematic over- or underestimation. The uncertainty bands, represented by the ensemble minimum and maximum values, are relatively narrow, spanning approximately 2 m at most survey locations and becoming negligible in the downstream reaches where the flow is largely insensitive to Manning's roughness. Consequently, only a limited number of observations fall within the simulated uncertainty envelopes (Table 2). The implications of this limited spread are discussed in Section 5.

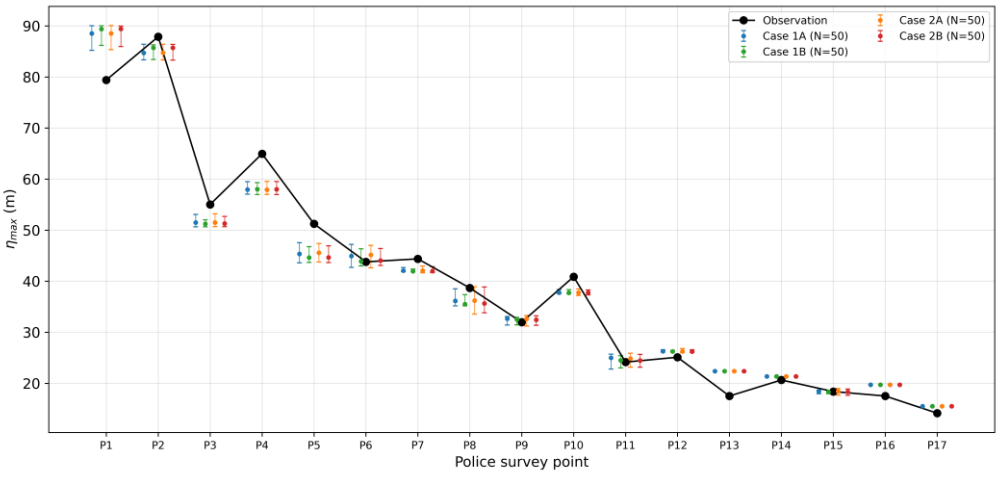

Fig. 3. Maximum water-surface elevation at the survey points: ensemble medians and min-max bands versus field data.

4.3 Inundation Footprint

The mean inundated area at four depth thresholds (h > 0.05, 1, 2 and 5 m) is essentially the same for all four cases, at about 28, 21, 13 and 6 km² respectively, with the four cases differing by at most 1.3 km² at any threshold. The inundation extent is thus geometry-limited: the large release volume fills the Reyran valley and the Fréjus plain to a geometric envelope that is set by the terrain rather than by the roughness. Manning's n modulates the dynamics of the flow (depths, arrival times, and peak elevations) but not the overall area reached by the water.

4.4 Probabilistic Inundation and Uncertainty Maps

The full ensemble is summarized spatially in Figure 4 for the best-performing case (2A). The first two panels show the probability that the local depth exceeds 1 m and 5 m: the valley thalweg and the Fréjus plain are inundated with near-certainty, while the probability decays sharply toward the lateral margins of the flooded envelope, where the wet or dry state depends on the sampled roughness. The third panel maps the ensemble standard deviation of the maximum water-surface elevation, highlighting the margins of the flood and the reaches around the valley bends as the zones of largest predictive uncertainty. Together these maps translate the parameter uncertainty into a spatially explicit hazard product that a single deterministic run cannot provide.

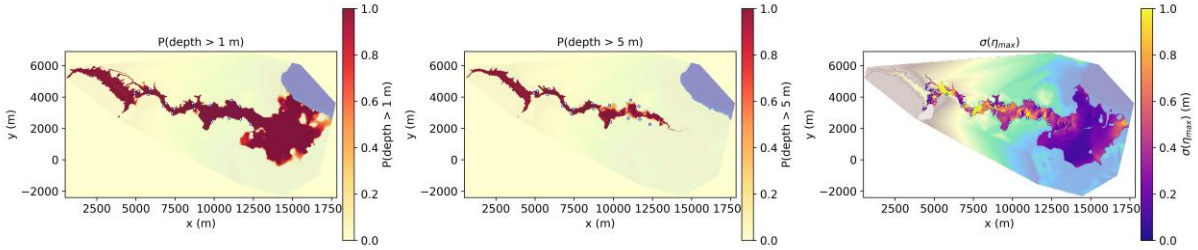

Fig. 4. Ensemble summary for Case 2A: probability of the maximum depth exceeding 1 m (left) and 5 m (centre), and the ensemble standard deviation of the maximum water-surface elevation (right).

4.5 Flow Dynamics and Arrival Time

To examine how the roughness uncertainty propagates into the transient flow, water-depth time series were extracted at four gauge locations spanning the valley from the dam to the downstream reach (G6, G9, G12 and G14 in Fig. 1). As stated in Section 2, these positions are not validation targets. Figure 5 shows the ensemble median and min-max band of the flow depth at these gauges for Case 1A. The peak depth decreases strongly downstream, from about 40 m just below the dam (G6) to about 5 m near the coast (G14), consistent with the attenuation of the wave. The spread of the wave arrival time, by contrast, grows steadily along the valley: the arrival is essentially deterministic near the dam (a spread of only a few seconds across the fifty realizations at G6) but widens to about 130 s at G9, roughly 520 s at G12 and about 800 s (some thirteen minutes) at G14. Thus, although Manning's roughness has almost no effect on the flood extent, it exerts a strong control on the timing of the wave in the downstream reach, where arrival-time uncertainty is largest and most relevant for evacuation planning.

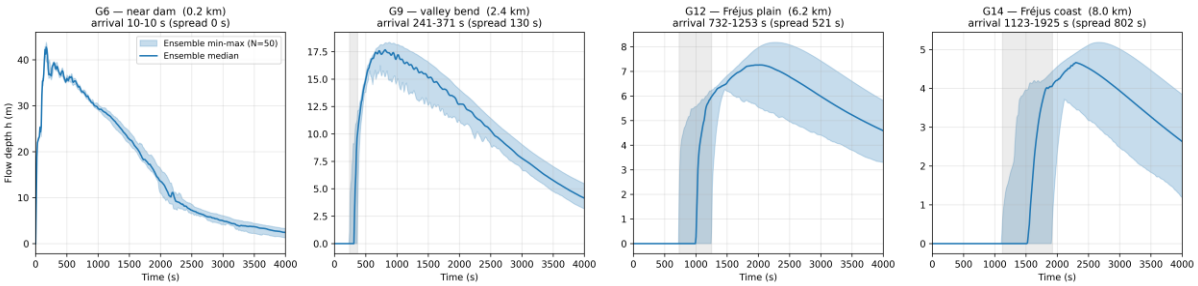

Fig. 5. Ensemble flow-depth time histories at gauges G6, G9, G12 and G14 (Case 1A); grey shading marks the arrival-time spread.

4.6 Comparison with Observed Arrival Times

The simulated arrival times can be compared with the three documented transformer failure times introduced in Section 2 (about 100, 1240 and 1420 s at A, B and C). For Case 1A the two downstream failures fall within the ensemble arrival band, and the near-dam site is reproduced on the same time scale, consistent both with the timing recovered in the deterministic prototype and with the published estimates for this benchmark [10]. This provides an independent, field-based check on the model timing that complements the water-level validation of the previous sections.

5 Discussion

The experiments give a consistent picture of how roughness uncertainty propagates in a 2D dam-break simulation. The inundation footprint is controlled by valley geometry and the release volume and is almost insensitive to Manning's n, whereas the local depths, arrival times and peak elevations are sensitive. For hazard mapping this means that in a terrain-confined valley such as this one the flood extent can be mapped robustly even under substantial roughness uncertainty, but the depth and level estimates that drive structural loading and evacuation timing require the uncertainty to be carried explicitly. The time-history analysis (Fig. 5) sharpens this point: the wave arrival time is almost deterministic near the dam but its ensemble spread grows to about 800 s downstream, so roughness uncertainty translates into a large arrival-time spread precisely in the populated downstream reach where that timing matters most.

Allowing the roughness to vary between sub-regions gives only a marginal gain over a single coefficient (about 0.05 m in median P-RMSE and one extra captured point) because the geometry-limited footprint leaves the additional degrees of freedom acting mainly on local depths. This insensitivity is terrain-regime-dependent: on wider floodplains a distributed roughness has altered the inundated area by about 9% [7], whereas the confined, steep Reyran gorge is terrain-controlled. The uniform prior outperforms the log-normal one, although this partly confounds the prior shape with its range, since the uniform prior also samples the higher n (up to 0.060) where the fit is best; the nominal 0.033 around which the log-normal concentrates is simply sub-optimal in the present configuration.

The ensemble medians reproduce the observed along-valley attenuation closely and without systematic bias, so the central predictions are accurate. The bands from roughness alone are narrow, however, and the coverage in Table 2 should be read as a lower bound obtained from a single uncertainty source. The remaining spread reflects factors not varied here: the reservoir and breach assumptions, the terrain, bathymetry and sea level, the numerical thresholds, the intrinsic uncertainty of the historical high-water marks [19], and the depth-averaged shallow-water approximation in the strongly three-dimensional bends of the valley [14]. This is an expected property of single-source quantification rather than a shortcoming of the model, consistent with the general finding that neglecting structural model uncertainty underestimates the upper tail of flood hazard [20]; the arrival-time check of Section 4.6, which broadly reproduces the transformer records, indicates that the flood is not mis-timed.

The study is deliberately scoped to a single historical event, one solver, and one uncertain input; extending the framework to multiple uncertain inputs and additional dam-break cases is left for future work.

6 Conclusions

A Monte Carlo framework was developed to propagate Manning's roughness uncertainty through GeoClaw simulations of the 1959 Malpasset dam-break event. Four uncertainty scenarios, combining constant and spatially variable roughness representations with uniform and log-normal prior distributions, were evaluated using fifty Latin Hypercube realizations each. The main conclusions are:

- The inundation extent is primarily controlled by valley geometry and exhibits little sensitivity to Manning's roughness, whereas local water depths, peak water levels, and especially wave arrival times are strongly influenced by roughness uncertainty.
- The uncertainty in the wave arrival time grows strongly downstream, from a few seconds near the dam to about 800 s in the downstream reaches, so that roughness uncertainty affects the timing most in the reaches where evacuation planning matters the most.

- A spatially variable roughness field gives a small but consistent improvement over a single domain-wide coefficient, both in median error (3.78 m to 3.73 m) and in observation coverage (24–29%).
- The uniform prior consistently outperforms the log-normal prior, because it also samples the higher roughness values that fit best in the present configuration rather than concentrating on the nominal n = 0.033.
- The ensemble medians closely reproduce the observed maximum water levels, whereas the uncertainty bounds generated from Manning's roughness alone remain relatively narrow. This indicates that roughness is one of the contributors to the overall predictive uncertainty and that additional sources, including terrain uncertainty, breach characteristics, and model structural uncertainty, should be incorporated to fully represent the observed variability.

Abstract. Climate models (CMs) developed by different institutes are widely used to assess flood risks; however, their projections differ because of variations in model structure, spatial resolution, and emission scenarios. These differences propagate through hydrological models and introduce uncertainty into streamflow simulations. This study evaluates the consistency of CMs developed by the same research institutes using Global Climate Models (GCMs) from the Coupled Model Intercomparison Project (CMIP) 5 and CMIP6, as well as Regional Climate Models (RCMs) from CORDEX. A total of 42 CMs from 10 institutes are assessed. Daily streamflow is simulated using a HEC-HMS model developed for the Göksu Basin (E17A014 Stream Gage) for 1970–1986, a period selected due to data availability and the construction of major dams after 1986. Model performance is evaluated by comparing simulated and observed flow duration curves through exceedance probabilities.

Results show substantial variability even among models developed by the same institute. For GCMs, differences between observed and simulated discharges exceed 71% for high-flow quantiles (0.002) and 121% for median-flow quantiles (0.5). For RCMs, these discrepancies increase to approximately 600% and 149%, respectively. Although RCMs provide higher spatial resolution, some produce substantially poorer quantile estimates, with errors reaching approximately 185% relative to observations, compared with more robust GCM estimates. These findings demonstrate that models produced by the same institute can yield markedly different hydrological projections and that higher spatial resolution does not necessarily improve streamflow simulations. Overall, the results highlight the importance of adopting a multi-model approach to obtain a more comprehensive and reliable assessment of flood risk under climate change.

Keywords: Climate Models; Hydrological Model; Exceedance Probability; Peak Discharge

1 Introduction

The assessment of flood risk has become increasingly important due to the growing impacts of climate change on the frequency and intensity of extreme hydrological events. Reliable evaluation of future flood hazards is therefore essential for effective water resources management, infrastructure design, and the development of climate adaptation strategies. Climate models developed by numerous research institutions provide projections of future

meteorological variables, such as precipitation and temperature, which serve as key inputs for hydrological modeling and flood risk assessments. However, these models differ in their structure, parameterizations, spatial resolution, and representation of physical processes, leading to considerable variability in their projections. Consequently, selecting appropriate climate models for hydrological applications remains a significant challenge. Furthermore, many research institutions produce multiple climate models with different configurations and assumptions, resulting in additional variability even among models developed by the same institute. Evaluating the consistency and performance of these models is therefore critical for understanding the uncertainties associated with climate projections and improving the reliability of flood risk assessments under changing climate conditions.

Various types of climate model datasets have been widely used to investigate the impacts of climate change on hydrological and meteorological variables. Among the most commonly employed datasets are the Coupled Model Intercomparison Project Phase 5 (CMIP5) Global Climate Models (GCMs) [1–5], CMIP6 GCMs [6–9], and CMIP5-driven Regional Climate Models (RCMs) produced within the Coordinated Regional Climate Downscaling Experiment (CORDEX) framework [10–13]. These datasets have been extensively applied to evaluate projected changes in meteorological variables such as precipitation (2,6,7,10) and temperature (1,6), which are directly available from climate model outputs. In contrast, studies assessing the impacts of climate change on streamflow remain relatively limited (6,13). This is primarily because streamflow is not a direct output of climate models and must instead be simulated using hydrological models driven by climate model projections. The development, calibration, and validation of hydrological models require extensive hydrological and meteorological data, as well as considerable computational effort and time. Consequently, comprehensive evaluations of streamflow responses to different climate model datasets are less common than studies focusing solely on precipitation and temperature projections.

Despite the widespread application of climate model datasets in hydrological impact assessments, limited attention has been given to the consistency of climate models developed by the same research institute and the implications of their differences for streamflow simulations. Therefore, this study aims to evaluate the performance and consistency of climate models produced by the same institutes using GCMs from CMIP5 and CMIP6 and RCMs from the CORDEX initiative. A total of 42 climate models from 10 research institutes are assessed. Daily streamflow is simulated using a calibrated HEC-HMS model for the Göksu Basin, and model performance is evaluated by comparing simulated and observed flow duration curves across different exceedance probabilities. By systematically comparing climate models developed within the same institution, this study provides insights into the variability of hydrological projections attributable to model selection and examines whether higher-resolution regional climate models consistently provide improved streamflow simulations. The findings are expected to contribute to more informed climate model selection and to support more reliable flood risk assessments under changing climate conditions.

2 Study Area and Data

A hydrological model is developed for the E17A014 Stream Gage (SG) located on the Göksu River, which is approximately 271 km long. The basin area is approximately 10,300 km^2, and hydrological simulations are performed using the HEC-HMS developed by the U.S. Army Corps of Engineers. Five meteorological stations are used in the hydrological model (Fig. 1).

Fig. 1. Study area

The GCMs (Table 1*)* and the RCMs (Table 2*)* are given below. The same color in the tables represents models developed by the same institution.

3 Methods

In this study, precipitation and temperature datasets obtained from the climate models (Table 1 and Table 2) are used as inputs to a hydrological model developed in HEC-HMS. The model is calibrated and validated using observed precipitation and temperature records from five meteorological stations (Fig. 1). To eliminate the influence of human interventions, the hydrological model is developed for a historical period preceding the construction of the first major hydraulic structure in the basin. The calibrated model is then run with the climate model datasets to simulate daily discharge values. Subsequently, discharge values corresponding to selected exceedance probabilities are extracted from the simulated and observed streamflow series to construct flow duration curves (FDCs). The resulting FDCs are then compared with the observed record, while climate models developed by the same modeling institution are evaluated collectively to investigate similarities and differences in their hydrological performance.

4 Results

Discharge values corresponding to selected exceedance probabilities are provided in Table 3. The comparison of FDC values demonstrates considerable variability among the climate models in reproducing the observed discharge characteristics. The largest discrepancies occur at low exceedance probabilities (0.002–0.02), corresponding to extreme high-flow conditions, whereas the differences gradually decrease toward medium-flow conditions (0.2–0.5). This pattern indicates that simulating extreme discharge remains substantially more challenging than reproducing average flow conditions, highlighting the importance of carefully selecting climate model inputs for flood-related hydrological assessments.

Among the GCMs, several simulations consistently overestimate discharges throughout the FDC. MPI-ESM1-2-HR produces the largest discharge values, exceeding the observed discharge by approximately 71% at the 0.002 exceedance probability. Similarly, CMCC-CMS, IPSL-CM5B-LR, MPI-ESM-MR, MRI-ESM2-0, MRI-CGCM3, HadGEM2-CC, and HadGEM2-ES exhibit substantial positive biases, particularly for high-flow events. These models generally preserve the shape of the observed FDC but shift the entire curve upward, indicating a systematic tendency to generate excessive discharge rather than isolated errors during extreme events.

Conversely, several RCM simulations substantially underestimate discharge across the entire flow regime. IPSL-CM5A-MR RCA4 and HadGEM2-ES RCA4, produce the lowest discharge values among all simulations and considerably underestimate observed high flows. Although these simulations reproduce the overall shape of the FDC, they consistently underestimate

discharge magnitude, suggesting that precipitation inputs or runoff generation are systematically reduced during the downscaling process.

A comparison among different generations developed by the same institution reveals that newer climate models do not necessarily outperform their predecessors. The MPI family provides a clear example of this behavior. While MPI-ESM-LR moderately overestimates observed discharge, both MPI-ESM1-2-LR and MPI-ESM1-2-HR generate considerably larger discharge values, with the high-resolution version exhibiting the largest positive bias. Likewise, MPI-ESM-MR also produces substantially larger discharges than MPI-ESM-LR. These results indicate that increased model resolution or updated model physics do not automatically translate into improved hydrological performance.

The MRI models exhibit considerably more consistent behavior. MRI-CGCM3 and MRI-ESM2-0 produce similar FDCs, with MRI-ESM2-0 generating only slightly higher discharge values throughout the flow regime. Similarly, NorESM1-M and NorESM2-LM show only minor differences, indicating that successive model generations preserve similar hydrological characteristics. However, the downscaled NorESM1-M HIRHAM5 simulation substantially reduces discharge, illustrating the significant influence of RCMs.

The EC-EARTH simulations further demonstrate the importance of regional downscaling. The parent EC-EARTH model moderately overestimates discharge, whereas HIRHAM5, RACMO22E, and RCA4 substantially reduce discharge and produce relatively similar FDCs. In contrast, CCLM4-8-17 maintains considerably larger discharge values than the other regional models. Similar behavior is observed within the IPSL family, where the driving GCMs exhibit moderate to large overestimations, while different RCMs produce markedly different discharge characteristics. WRF381p increases discharge relative to the parent model, RCA4 produces one of the strongest underestimations. These findings indicate that the choice of RCM may introduce uncertainties comparable to those associated with the selection of the driving GCM.

The Canadian Earth System Models exhibit relatively stable behavior across generations. CanESM2 and CanESM5 produce very similar FDCs, with only modest differences in high- and medium-flow conditions, suggesting consistent model development between CMIP5 and CMIP6. Likewise, the MIROC family demonstrates relatively stable performance. MIROC-ESM and MIROC-ESM-CHEM generate nearly identical discharge values, while MIROC6 consistently reduces the positive bias observed in MIROC5, indicating a moderate improvement in reproducing observed discharge characteristics.

The HadGEM and CNRM families illustrate the considerable influence of RCMs. Both HadGEM2-CC and HadGEM2-ES substantially overestimate discharge, whereas the RACMO22E and particularly RCA4 downscaled simulations considerably reduce these biases. A similar pattern is observed for CNRM-CM5, where RCA4 produces one of the closest agreements with observations, while ALADIN63 substantially increases discharge. These comparisons demonstrate that regional downscaling can either amplify or reduce the biases inherited from the driving GCM, depending on the selected RCM.

Overall, the comparisons reveal that differences among RCMs frequently exceed those between successive generations of GCMs. Models developed by the same institution often exhibit markedly different hydrological behavior after regional downscaling, emphasizing that RCM selection represents a major source of uncertainty in climate impact assessments. Furthermore, no individual model consistently reproduces the observed FDC across all exceedance probabilities. Some models better represent extreme flows, whereas others more accurately reproduce medium-flow conditions, supporting the use of multi-model approaches rather than reliance on a single climate model for hydrological impact studies.

Table 3. Discharge Values Corresponding to Selected Exceedance Probabilities

	Exceedance Probability

5 Conclusion

This study compared the ability of a wide range of CMIP5, CMIP6, and dynamically downscaled climate models to reproduce the observed FDC across different exceedance probabilities. The results demonstrate substantial variability among the simulations, particularly for extreme high-flow conditions, where model uncertainties are considerably larger than those observed for medium-flow conditions.

Most climate models preserve the general shape of the observed FDC but differ substantially in discharge magnitude. Several GCMs, including MPI-ESM1-2-HR, CMCC-CMS, IPSL-CM5B-LR, and HadGEM2-CC, systematically overestimate discharge throughout the flow regime, whereas several RCM simulations, particularly those driven by CCLM4-8-17, and RCA4 configurations, tend to underestimate discharge. These results indicate that model bias is generally systematic rather than restricted to a particular portion of the FDC.

Comparisons among climate models developed by the same institution show that newer model generations do not consistently provide better agreement with observations. In several model families, including MPI and MRI, updates in model generation or spatial resolution resulted in only limited improvements or even larger deviations from observed discharge. Conversely, the CanESM and MIROC families exhibit relatively consistent behavior between CMIP5 and CMIP6 generations, suggesting greater stability in hydrological performance.

The analyses also demonstrate that the selection of the RCM can substantially modify the hydrological response simulated by the driving GCM. In several model families, including EC-EARTH, HadGEM, IPSL, and CNRM, differences introduced by regional downscaling are comparable to or greater than those between different GCM generations. Consequently, uncertainty associated with RCMs should receive equal consideration when selecting climate model inputs for hydrological impact assessments.

Overall, the findings indicate that no single climate model consistently reproduces observed discharge characteristics across the entire FDC. Therefore, relying on an individual model may introduce substantial uncertainty into climate change impact studies. Multi-model ensemble approaches remain the most robust strategy for representing climate uncertainty and improving the reliability of future hydrological projections, particularly for flood-related applications where accurate representation of high-flow conditions is essential.

Abstract. This study evaluates the effects of DEM selection and spatial resolution on RUSLE-based erosion predictions. Accurate assessment of sedimentation is essential for addressing sediment dynamics that directly influence water quality, aquatic ecosystems, and the stability of infrastructure such as dams and bridges. In this study, the LS factor was derived from Digital Elevation Models (DEMs) obtained from various sources: Shuttle Radar Topography Mission (SRTM) and Advanced Land Observing Satellite (ALOS) at 30m resolution, and TerraSAR-X TanDEM-X DEMs at 12m and 5m resolutions provided by the State Hydraulic Works of Türkiye (DSI). A GIS-based RUSLE method was implemented, incorporating R, K, C, and P factor datasets and validated using measured data. The influence of DEM selection and spatial resolution on erosion predictions was analyzed to assess the sensitivity of RUSLE outputs to differences in topographic input data. The result of RUSLE is validated by using Sediment Yield determined by the reservoir bathymetric survey (SY_{RS}) of Borçka Dam (8.695 t/ha/yr). Sediment Delivery Ratios (SDR) of the reservoir is calculated by using Vanoni (1975) and USDR-SCS (1971) methods to relate RUSLE results with that of reservoir sediment yield. The results showed that, RUSLE soil erosion estimates are in good agreement for several DEM–K combinations for Borçka Dam, even when relatively coarse-resolution input datasets are used. Overall, RUSLE can provide reasonable erosion estimates despite differences in the spatial resolution of the input datasets, provided that the accuracy and consistency of the model inputs are considered collectively.

Keywords: RUSLE, Sediment Yield, Reservoir Sedimentation

1 Introduction

Sediment accumulation poses a significant challenge for reservoirs associated with dams. Various factors, such as the geological characteristics of the river basin, topography, climatic conditions, drainage density, and patterns, along with urban development and forest clearance, collectively contribute to an increased sediment load within the basin. Consequently, the sedimentation process leads to a decrease in the storage capacity of the reservoirs. Although historical data on sediment flow and water levels have been utilized to estimate the sediment storage levels and the economic longevity of dams, inaccuracies persist due to the fluctuating nature of meteorological, hydrological, and anthropogenic factors. This has resulted in reservoirs filling up with sediment faster than initially projected. Particularly during brief, high-intensity flood events, a substantial volume of sediment can be carried into the reservoir, leading

to a rapid reduction in storage capacity and overall lifespan of the dam. As dams play a crucial role in providing water for domestic and agricultural purposes, as well as generating hydroelectric power, the determination of sediment load transported by rivers remains essential for effectively managing sedimentation in dam reservoirs ([1-2]).

Determining the quantity of sediment transported by rivers is essential for the estimation of sediment transport within a watershed. As outlined by Walling [3], there exist three approaches for acquiring sediment yield data: (1) the utilization of continuously recorded discharge data along with their application to a previously established sediment rating curve, (2) the integration of continuously recorded discharge and sediment data, and (3) the utilization of data from reservoir surveys. Among these techniques, the periodic collection of data from reservoir surveys is viewed as a more reliable indicator of long-term sediment yield in a given basin ([1], [4-5]). In a research endeavor by Munthali et al [6], employing Geographic Information System (GIS) and the PanEuropean Soil Erosion Risk Assessment model, the scholars sought to ascertain the hydrological potential for sediment, pinpoint regions characterized by significant sediment generation within the Songwe River watershed, and evaluate the probability of sediment accumulation in a proposed reservoir.

In recent years, advances in remote sensing, Geographic Information Systems (GIS), and hydrological modeling have provided valuable tools for studying sediment transport in river systems. Integrating field observations with these technological advancements allows for a more comprehensive assessment of sediment dynamics, which is essential for developing effective management strategies. The Revised Universal Soil Loss Equation (RUSLE) is a widely used method for estimating soil erosion and sediment yield, offering valuable insights into sediment transport processes and sediment delivery ratio (SDR) estimation.

The primary objective of this study is to investigate how DEM selection and spatial resolution influence LS-factor calculation and subsequent RUSLE-based soil erosion estimates in the Çoruh River Basin. The resulting erosion estimates are further evaluated against sediment yield derived from bathymetric survey of the Borçka reservoir. Furthermore, it is aimed to present the spatial distribution of annual soil loss within the Çoruh River Basin for further studies.

2 Study Area and Data

The Çoruh River, a significant waterway in Türkiye renowned for its hydroelectric potential, has seen the construction of multiple dams along its main course to harness this energy resource. However, unlike its energy-producing capacity, the river itself presents challenges due to its supercritical flow regime and sediment-carrying capacity, which is particularly problematic for dam reservoirs. While studies have focused on sedimentation within reservoirs on a micro-scale basis, basin-wide sediment analysis remains unexplored.

Assessing sediment transport at a basin level is pivotal for determining the effective capacity of hydroelectric dams. Unconventionally, dams in the Çoruh River Basin were built downstream to upstream, driven partly by trans boundary nature of the basin. This sequencing commenced with the Muratlı Dam in 2005, followed by the Borçka Dam in 2008, the Deriner Dam in 2012, and others.

The initial sedimentation of Muratlı Dam reservoir began in 2005, followed by Borçka Dam reservoir in 2008, filling their dead volumes more rapidly than anticipated. Bathymetric survey conducted in 2017 for the Borçka Dam revealed significant reduction in its dead volumes, by 28% over a span of 10 years. Further mitigating sedimentation, a cascade of dams, including Deriner, Artvin, Yusufeli, Arkun, Güllübağ, and Laleli, regulated the river's flow, reducing sediment accumulation to some extent. Nonetheless, runoff from precipitation in the basin's high-erosion environment continues to contribute to sedimentation. To quantify sediment yield, bathymetric map from Borçka Dam is analyzed. Fig. 1 illustrates the study area.

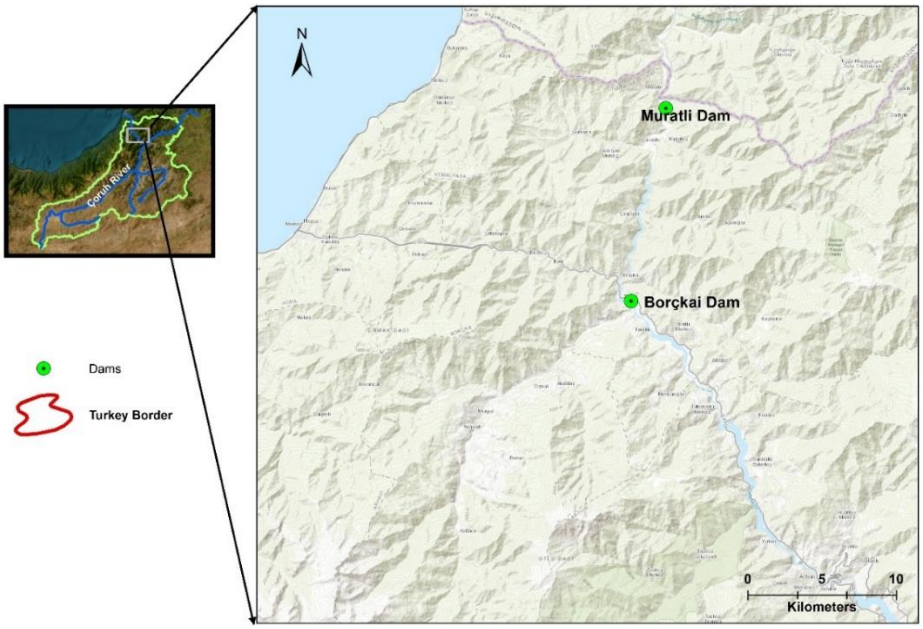

Fig. 1. Study area and location of Borçka Dam.

3 Erosion Prediction By RUSLE

Erosion occurs as a natural phenomenon driven by both wind and water forces. Research from the State Planning Organization (DPT) of Türkiye in 2001 shows that water and rainfall are responsible for 99% of erosion within the country, with wind playing a minor role in the remaining 1%. In order to determine erosion resulting from the rainfall and surface runoff process, the Revised Universal Soil Loss Equation (RUSLE), was used. The RUSLE method, in particular, integrates various key variables contributing to erosion dynamics, including rainfall erosivity (R), soil erodibility (K), topographical attributes like slope length (L) and steepness (S), as well as considerations for crop management (C) and support practices (P). Expressed as an equation, the RUSLE model embodies the relationship as in Eq. (1):

$$A = R \times K \times LS \times C \times P \tag{1}$$

Here, 'A' signifies the annual soil loss (t/ha/yr), 'R' represents the rainfall-runoff erosivity factor (in MJ/mm/ha/h/yr), 'K' denotes the soil erosion sensitivity factor, 'L' corresponds to the slope length factor, 'S' embodies the slope steepness factor, while 'C' and 'P' encapsulate the cover management and support practices factors respectively. Fig. 2 illustrates the flow chart of data needed for a RUSLE model.

3.1 Rainfall Erosivity

The rainfall erosivity factor (R) in the RUSLE equation is considered within the rainfall-runoff interactions framework and is a key determinant influencing soil erosion mechanisms. This factor, denoted as R, is characterized as the product of kinetic energy and the peak 30-minute intensity, serving as an indicator of the erosive potential inherent in rainfall events.

There are numerous methods in the literature to calculate the R factor. In this study, The R factor map is obtained from the European Soil Data Centre (ESDAC) ([7-9]). The map was prepared in 2017 and at resolutions of 30 arc-sec (~1 km at the Equator). Fig. 3 illustrates the R factor for the Çoruh basin.

As illustrated in Fig. 2, the rainfall erosivity (R-Factor) values in the Çoruh River Basin show notable regional variation. The northern portion of the basin, especially the regions with steep slopes and significant precipitation, has the greatest R-Factor values (surpassing 4000 MJ

mm/ha/h/yr) whereas, the southern and central regions of the basin exhibit much lower R-Factor values; the lowest (257 MJ mm/ha/h/yr) indicating comparatively lesser rainfall erosivity.

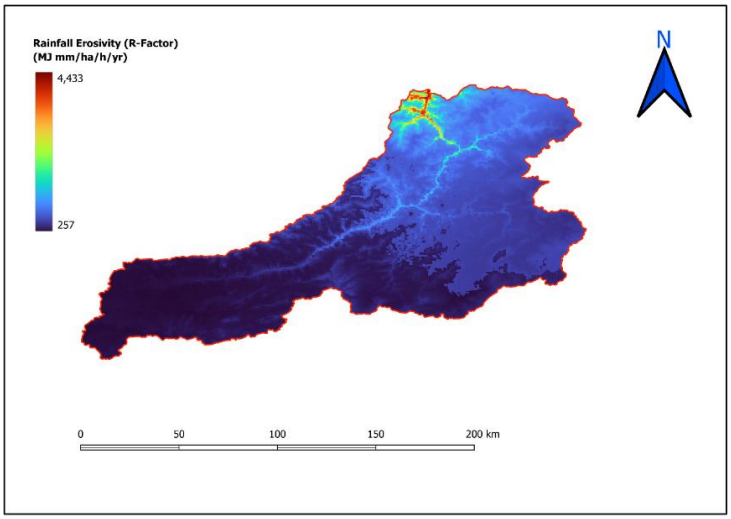

Fig. 2. Rainfall erosivity (R Factor) of Çoruh basin.

3.2 Cover Management Factor (C Factor)

The coverage factor spans from 0 (complete soil coverage) to 1 (no soil coverage). The C factor signifies the impact of soil-disturbing practices, vegetation, crop rotation, productivity level, soil covering, and sub-surface biomass on soil erosion. Natural vegetation primarily contributes to mitigating water erosion [10].

To calculate the C factor, first, a Land Cover map is needed. This map is provided by Copernicus Corine 2018 Land Cover data with 100 m resolution [11]. For each land cover type, C factor values are collected from literature and set to obtain the C factor map ([12-14]. C factor map for the Çoruh basin is provided in Fig. 3 shows the changes of land cover in the Çoruh River Basin, therefore affecting the area's erosion vulnerability. With their lowest C values (0–0.05), densely vegetated areas, whereas places with higher C values (0.1–1.0) mostly agricultural land or barren areas, the northern and middle regions of the basin have lower C values because of better vegetative cover, but the southern and western sections often have higher values, suggesting more exposed terrain.

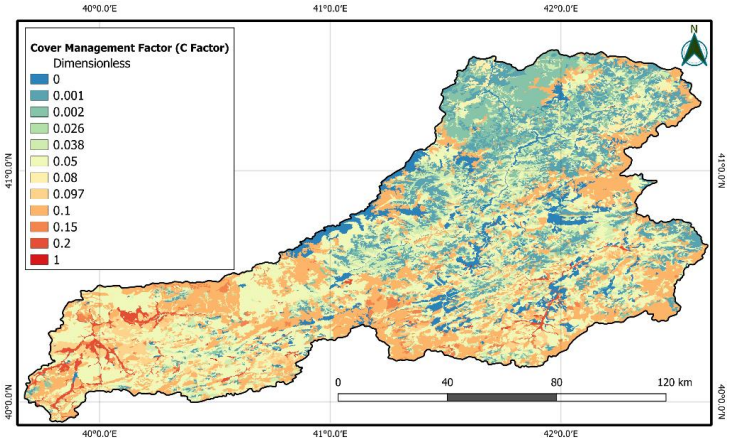

Fig. 3. Cover management factor (C Factor) of Çoruh basin

3.3 Support Practices Factor (P Factor)

The P factor represents the ratio of soil loss under a specific support practice to soil loss under conventional up and down slope tillage. Typically, the conservation practice factor adjusts the

estimation made by the Revised Universal Soil Loss Equation (RUSLE) to account for management and tillage practices that safeguard the soil from erosion.

To provide a P factor map, first, a slope map of the study area with categorized percent units is provided (Fig. 4) using the DEM map. In this study, the P factor map was created using land use/land cover data and support factors. The P values are collected from literature for different land cover and slope values ([13],[15]) were used for the Çoruh river basin and the P Factor map, created using these values was created as shown in Fig. 7. In general, higher P values are assigned to areas lacking conservation practices, such as steep agricultural lands, rangelands, and bare soil, where erosion risk is greater.

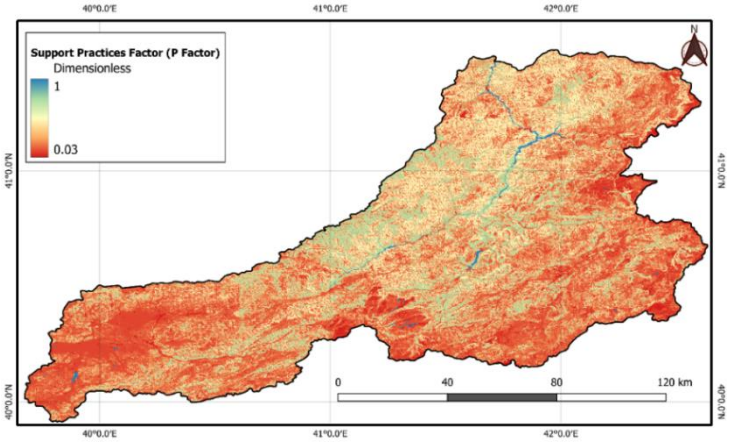

Fig. 4. Support practices factor (P Factor) of the Çoruh basin.

3.4 Soil Erodibility (K Factor)

The soil erodibility factor (K) pertains to how a particular soil and its profile respond over time to the erosive forces caused by rainfall and runoff. It reflects the rate at which soil is lost per unit of rainfall erosion for a given soil type. In the RUSLE model, Wischmeier's method is employed to assess the K factor of a soil type [15]. This method encompasses various soil properties such as particle size (silt, clay, and sand), organic matter content, soil structure, and permeability. The K factor map is provided by the European Soil Data Centre (ESDAC) ([7-9]). Fig. 8 illustrates the soil erodibility map for the Çoruh River Basin.

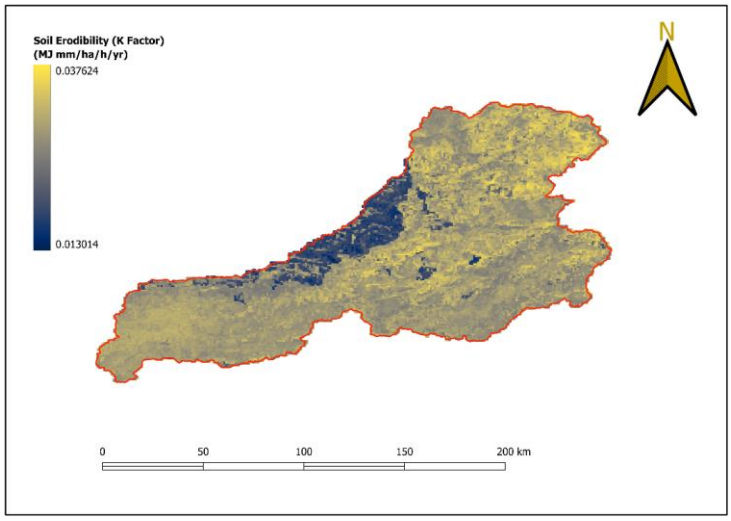

Fig. 5. Soil erodibility (K Factor) of Çoruh basin.

The K Factor values, of the Çoruh River Basin as shown in Fig. 8. The analysis of this figure shows that the K values in the northwestern part are rather high, meaning soils are more prone to erosion The center of the basin reveals moderate K values, meaning mixed soil were here with varying resistance to erosion. On the contrary, the eastern and southeastern areas supply lower K values, meaning these are more stable soils entailing lower susceptibility to detachment by rainfall and runoff.

To enhance the spatial accuracy of the study, the K factor was also calculated using high-resolution soil data based on the EPIC (Erosion-Productivity Impact Calculator) model [16]. Unlike the Wischmeier method [15], which requires soil structure and permeability codes that are often unavailable in high-resolution spatial datasets, the EPIC model estimates K utilizing only organic carbon content and soil particle size distribution (sand, silt, and clay). This approach allowed the integration of finer-scale soil grids to capture local variations in erodibility that coarser data sets might miss.

3.5 Slope Length and Steepness Factor (LS Factor)

The L and S factors within the RUSLE framework represent how topography influences erosion. Research has confirmed that increases in both slope length and steepness lead to higher overland flow and, consequently, increased erosion. Furthermore, it has been noted that changes in slope steepness have a greater impact on gross soil loss compared to changes in slope length. Therefore, topography, especially when the ground slope exceeds a critical angle, emerges as a significant factor in soil loss, primarily because it governs the rate of surface runoff.

The combined LS factor for the Çoruh basin was provided from a Digital Elevation Model (DEM) obtained from three different sources, Shuttle Radar Topography Mission (SRTM) with 30m resolution (SRTM 30m), Advanced Land Observing Satellite (ALOS) with 30m resolution (ALOS 30m), and TerraSAR-X, TanDEM-X satellite provided by State Hydraulic Works (DSI) with 12- and 5-meters resolutions (DSI 12m and DSI 5m). These DEMs differ not only in spatial resolution but also in data source and acquisition characteristics; therefore, the analysis reflects the combined influence of DEM selection and spatial resolution on LS-factor estimation. LS factor was calculated by using Moore & Burch method [17]. Moore and Burch [17] developed an LS factor estimation method using DEM for complex terrain, based on unit stream theory, requiring flow accumulation and slope data. In this study, the previously mentioned DEM data was processed in QGIS to calculate the LS factor. The LS factor was calculated using Eq. (2), which incorporates flow accumulation, and slope steepness.

$$LS = \frac{(FlowAccumulation \times CellSize)^{0.4}}{22.13} \times \frac{(\sin slope)^{1.3}}{0.0896} \quad (2)$$

Here, flow accumulation represents the accumulated upslope contributing area for a given cell, LS denotes the combined slope length and steepness factor, cell size indicates the size of the grid cell (30, 12, and 5 meters in this study), and sin(slope) represents the sine of the slope degree value. The LS factor values across the study area calculated for four different DEM data using the method of Moore and Burch [17] is shown in Fig. 6.

Fig. 6 shows the LS factor's geographical distribution in the Çoruh River Basin, which was obtained from four distinct DEMs (SRTM 30m, ALOS 30m, DSI 12m, and DSI 5m). Because of the steeper slopes and longer slope lengths seen in mountainous areas, the maps constantly display higher LS values there, whereas the western and eastern parts display lower values. The influence of DEM selection and spatial resolution on LS-factor estimation is demonstrated by the fact that higher resolution DEMs (DSI 12m and DSI 5m) show more detailed fluctuations and generally higher LS values when compared to lower resolution DEMs (SRTM 30m and ALOS 30m). The Moore and Burch method [17], which considers flow accumulation, offers a more realistic representation, especially in complex areas. Thus, the Moore and Burch method

is generally preferred for RUSLE, particularly with high-resolution DEMs, for more accurate erosion assessments.

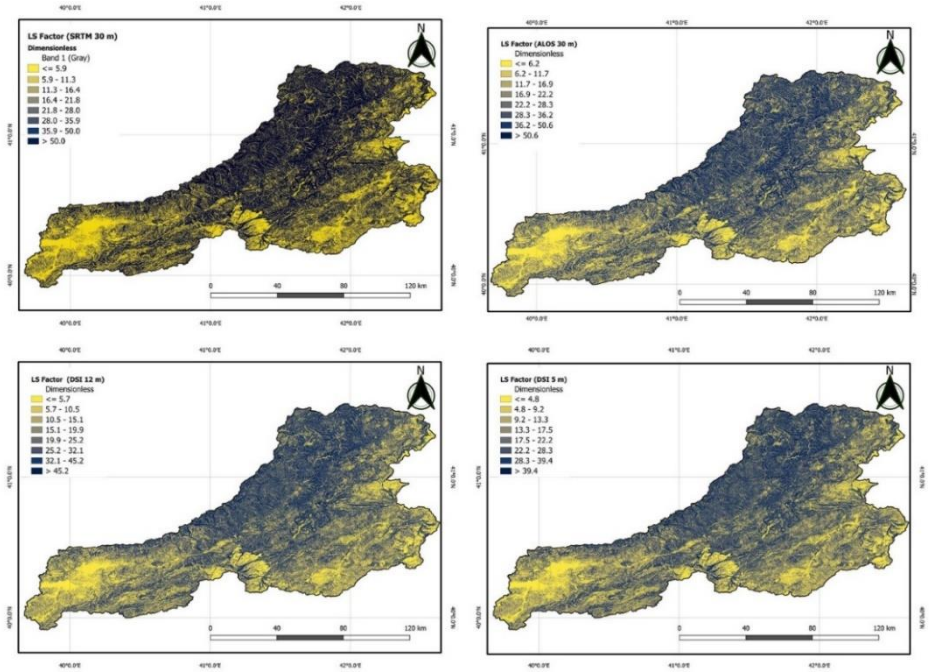

Fig. 6. LS Factor maps of Çoruh River Basin

3.6 Average Annual Soil Loss

The data layers (maps) extracted for the K, LS, R, C, and P factors of the RUSLE model were combined using Eq. (1) within the raster calculator tool of QGIS. This integration aimed to assess, evaluate, and produce maps depicting soil erosion risk and severity for the Çoruh basin. As a result of analyzing, arranging, and making calculations the data obtained from open sources, the spatial distribution and amounts of erosion in the Çoruh basin were obtained by applying the RUSLE method in the GIS environment and are presented in Fig. 7. Understanding the spatial variation of soil erosion, the complex challenges posed by sediment transport could be addressed in the Çoruh River Basin in further studies.

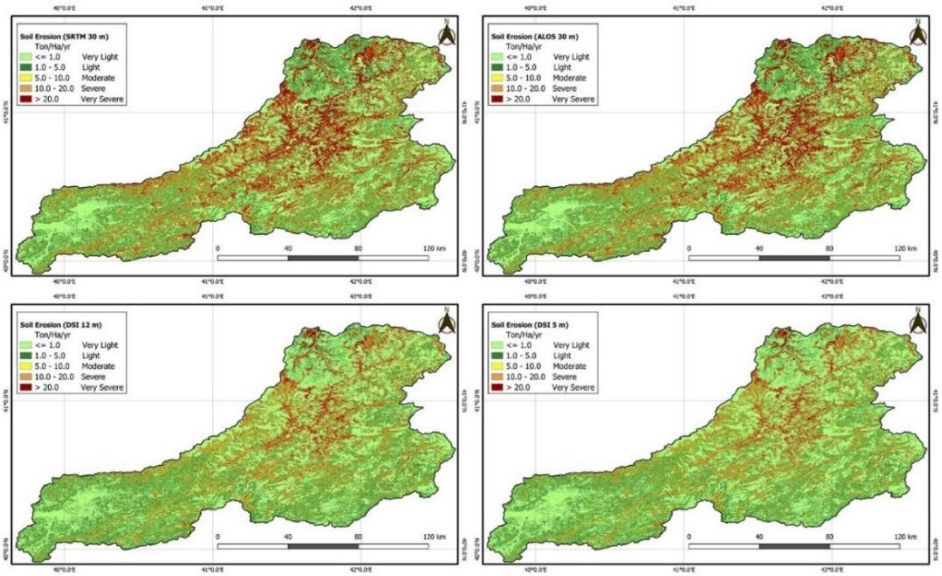

Fig. 7. Average annual soil loss of Çoruh basin.

Accordingly, the average annual soil loss of the basin is shown in Table 1. The total erosion in t/yr for entire basin is also shown in Table 1 for all calculated soil loss on four different resolution DEM, considering all RUSLE parameters.

Table 1. Average annual soil loss (t/ha/yr) and total erosion (t/yr) of Çoruh basin.

	SRTM 30m	ALOS 30m	DSI 12m	DSI 5m
Average annual soil loss (t/ha/yr)	8.76	9.12	8.45	7.47
Total erosion (t/yr)	17,691,220	18,432,007	17,078,041	15,098,590

4 Reservoir Sediment Yield (SY) Calculation

Sediment yield (SY) refers to the amount of sediment transported from a watershed by runoff and delivered to a stream over time. It can also be thought of as the total amount of sediment entering a reservoir at the downstream end of the watershed. SY can be estimated by reservoir surveys or stream sediment measurement programs. However, reservoir surveys are generally considered to be the more reliable method for long-term sediment yield [18].

In this study, sediment yield for the catchment area of Borçka Dam reservoir was calculated using reservoir survey. SY can be calculated with Eq. (3) with reservoir survey ([1-2]).

$$SY_{RS} = \frac{SV\,\gamma_s}{TE\,A} \times 100 \tag{3}$$

Where SY_{RS} is the sediment yield calculated by reservoir survey (t/yr/km²), SV is the annual sediment accumulation rate (m³/yr), γ_s is the unit weight of sediment in the reservoir (t/m³), TE is the sediment retention efficiency of the reservoir (%), and A is the catchment area (km^2).

In this study, the sedimentation process was analyzed using survey conducted for Borçka reservoir in 2017. The sediment accumulation information of the reservoir area of the dam obtained from State Hydraulic Works (DSI) is presented in Table 2.

Table 2. Reservoir area sediment accumulation for Borçka Dam

Years in Op.	Area (ha)	Projected Volume (hm^3)	Volume at Year of Survey (hm^3)	Difference (hm^3)	Annual Avg. Sediment Amount (hm^3)	Design Dead Storage Volume (hm^3)	Dead Storage Volume at Survey (hm^3)	Dead Storage Difference (hm^3)	Annual Avg. Sediment in Dead Storage (hm^3)
9	1014	418.98	323.9	95.08	10.56	268.2	194.69	73.51	8.168

Accordingly, during the 9-year period in which Borçka Dam was in operation, a total of 95.08 hm^3 of sediment accumulated in the reservoir area and formed dead volume. SV was obtained as 10.56 hm^3 for Borçka Dam from DSI data, and the average of the values obtained by taking sediment samples from ground stations in the region was taken for density. Accordingly, the unit weight of the sediment in the reservoir was determined as 1.3 tons/m^3. The sediment trap efficiency (TE) of the reservoir is defined as the ratio of the amount of sediment accumulated in the reservoir against the total sediment input.

One of the most widely used methods for this calculation is the curve developed by Brune [19]. Brune's model assumes that TE depends on the ratio of reservoir capacity (V_{res}) and annual mean inflow (Q_{inflow}) as in Eq. (4).

$$TE = f\left(\frac{V_{res}}{Q_{inflow}}\right) \quad (4)$$

For V_{res}/Q_{inflow} = 418.98/5660=0.074 in sediment trap efficiency calculation (annual average flow of Borçka Dam is 5660 hm³), TE is taken as 82% from Brune's median curve. Accordingly, reservoir sediment yield is SY_{RS} = 8.695 t/ha/yr as shown in Table 3.

Table 3. Reservoir area sediment yield of Borçka Dam

Catchment area, A (km²)	Annual sediment accumulation rate, SV (m³/yr) × 10⁶	Unit weight of sediment in the reservoir, γ_s (t/m³)	Sediment retention efficiency of the reservoir, TE (%)	Reservoir sediment yield, SY_{RS}	
				(t/yr/km²)	(t/yr/ha)
19,255	10.56	1.3	82	869.46	8.695

5 Validation of RUSLE Results by Reservoir Sedimentation

Since RUSLE calculation depends on several variables and data quality, its validation is crucial. To achieve this goal, reservoir sediment yield calculations are considered for validation. The Borçka Dam deposits 8.695 t/ha/yr sediment in the reservoir considering the reservoir survey. To relate RUSLE results with reservoir sediment yield, it's required to calculate sediment delivery ratio (SDR). In literature, several methods are presented for determining SDR which are closely related to basin characteristics. In Türkiye, DSI prefer either USDA-SCS equation (Eq. (5)) or equation proposed by Vanoni [20] (Eq. (6)) due to the similar basins characteristics that are considered in the methods.

$$SDR = 0.51(A)^{-0.11} \quad (5)$$

$$SDR = 0.42(A)^{-0.125} \quad (6)$$

The watershed of Borçka Dam is generated in GIS environment and presented in Fig. 8. The SDR values were calculated using the USDA-SCS and Vanoni equations. Due to the varying watershed area and considering the contribution of each watershed to erosion, the SDR prediction of both equations is close to each other so that the average of SDR values is taken into consideration. Therefore, SDR is determined as 0.26 for Borçka Dam.

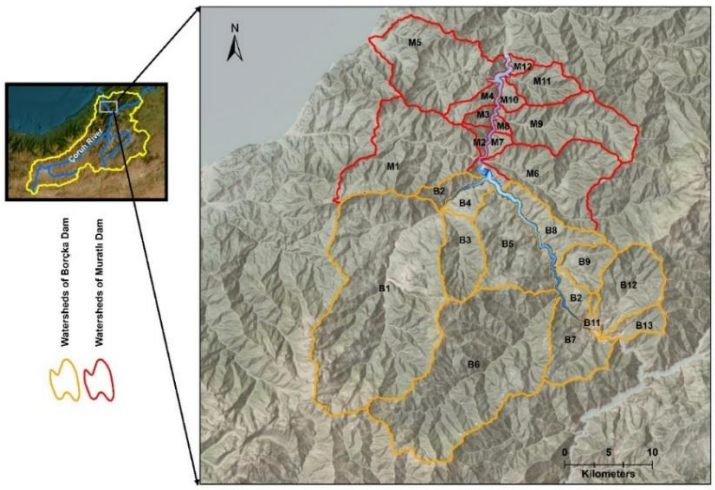

Fig. 8. Watersheds of Borçka Dam (yellow lines).

After having determined the SDR values of the reservoir, reservoir sediment yield is calculated by considering the RUSLE results which are given in Table 4.

Table 4. Sediment Yield (SY_{RS}) for Borçka Dam and RUSLE results

	Reservoir Sediment Yield Considering RUSLE and SDR (t/ha/yr)				
	SRTM 30m	**ALOS 30m**	**DSI 12m**	**DSI 5m**	**SY_{RS}**
K is obtained from ESDAC	8.34	**8.84**	7.71	7.16	8.695
K is obtained by EPIC model	9.33	9.89	**8.78**	8.09	

6 Results and Discussion

Even though the uncertainties and sensitivity resulting from determination of its parameter (R, K, C, LS, P) and due to its empirical formulation, the RUSLE equation is still one of the most used models for estimating long-term soil erosion rates.

Since the DEM is a basic data set in RUSLE, its resolution directly affects the computation of the LS factor, which considers the impacts of slope length and steepness on erosion processes. Erosion estimates were calculated in this study using four DEMs with different spatial resolutions: SRTM 30m, ALOS 30m, DSI 12m, and DSI 5m. Since the DEM is a fundamental input to the calculation of the LS factor, both DEM selection and spatial resolution can influence erosion estimates. The findings demonstrated the model's sensitivity to DEM selection by revealing insignificant variations in the projections of total soil loss as shown in Table 4. In general, also earlier studies showed that erosion estimates from coarser-resolution DEMs (like SRTM 30m) were higher than those from finer-resolution DEMs (like DSI 5m) due to lower-resolution DEMs have tendency to smooth out terrain characteristics which could lead to an overestimation of LS factor and in turn, erosion rates, however, this case was not seen in this study. This may be the topographic characteristics of the catchment of the Borçka Dam.

C and P factors were derived at relatively high spatial resolutions (100m), allowing these parameters to better reflect local land-cover, management, and conservation conditions. In contrast, the R and K factors derived from ESDAC are based on globally produced datasets and therefore have substantially coarser spatial resolutions, generally expressed at the kilometer scale. Moreover, the K factor was additionally estimated using the EPIC model at a higher spatial resolution to investigate the influence of data resolution on the RUSLE results. It should be noted that for the RUSLE calculations, the lowest-resolution results were not differed from the results of the higher-resolution. The results indicate that both DEM selection and spatial resolution did not substantially affect RUSLE-based erosion. It was determined from this study that the results obtained for the Borçka Reservoir indicated that erosion estimates derived from both higher and lower resolution DEMs were consistent with the observed reservoir sediment yield data.

Overall, the results suggest that RUSLE can provide reasonable erosion estimates despite differences in the spatial resolution of the input datasets, provided that the accuracy and consistency of the model inputs are considered collectively.

Acknowledgments

We would like to express our sincere gratitude to the General Directorate of State Hydraulic Works (DSİ) for generously providing the data used in this study, particularly regarding the Çoruh River Basin. We also gratefully acknowledge the financial support provided by The Scientific and Technological Research Council of Türkiye (TÜBİTAK) under project number 121Y456, funded through the TÜBİTAK 1001 Scientific and Technological Research Projects

Support Program. Their support has been instrumental in the successful completion of this research.

Economic Feasibility Of Rainwater Harvesting Systems In Trabzon, Türkiye: A Water Balance And Cost–Benefit Analysis

Osman Tuğrul BAKİ[1]
[1] 0000-0001-8694-0543, Karadeniz Technical University, Civil Engineering Department, Trabzon, Türkiye, tbaki@ktu.edu.tr

Abstract. Rainwater harvesting and recycling systems (RHRS) offer a promising means of reducing municipal water demand in regions facing increasing water stress. This study presents a daily water balance model combined with a cost-benefit analysis to evaluate the economic feasibility of residential RHRS in Trabzon, Türkiye, one of the country's highest-precipitation provinces, receiving an annual average of 870 mm. Using nine years of daily rainfall data (2014–2022) from the Turkish State Meteorological Service and real Turkish market installation costs, tank sizes of 1–20 m^3 are evaluated across four water price scenarios (0.69–1.50 $/$m^3$). Results reveal a systemic oversizing effect: tanks larger than 5 m^3 yield no additional water savings, making 1–3 m^3 configurations consistently optimal. The break-even water price threshold for these small tanks is 0.71–0.76 $/$m^3$, only 3–10% above the current local tariff, indicating that near-term economic viability is imminent, with the 2 m^3 configuration already nearly at parity under current 2026 pricing. The findings offer an evidence-based framework for infrastructure planning and incentive policy design.

Keywords: rainwater harvesting; water balance model; cost–benefit analysis; Trabzon; economic feasibility; oversizing effect.

1 Introduction

Freshwater scarcity is increasingly recognised as one of the most critical infrastructure challenges of the 21st century. In Türkiye, per capita renewable water availability has declined to below 1,400 m^3/year, approaching the internationally defined water stress threshold [1]. Rapid urbanisation, population growth, and the compounding effects of climate change are projected to intensify this pressure, particularly in regions where precipitation is irregular or declining [2].

Rainwater harvesting and recycling systems (RHRS), which collect rooftop runoff for non-potable uses such as toilet flushing, garden irrigation, and fire suppression, offer a technically straightforward means of reducing dependence on centralised water supply networks. The international literature on RHRS is substantial and spans hydrological performance, tank sizing optimisation, and life-cycle economics. Ghisi et al. [3] demonstrated that even modest tank capacities can achieve meaningful potable water substitution in southeastern Brazil, while Imteaz et al. [4] and Khastagir & Jayasuriya [5] developed optimisation frameworks showing that water savings from RHRS follow strongly diminishing returns beyond a threshold tank size, a pattern closely related to what this study terms the oversizing effect. Roebuck et al. [6] extended this analysis to whole-life costing in the United Kingdom, finding that economic viability depends heavily on local water tariffs and installation costs rather than harvesting potential alone. Ward et al. [7] further showed, through monitored performance data from a large United Kingdom building, that real-world savings often diverge from theoretical estimates, underscoring the value of empirically calibrated, site-specific models such as the one developed here. A recent comprehensive review by Campisano et al. [8] confirms that despite decades of RHRS research, robust economic assessments grounded in local hydroclimatic and

market data remain the exception rather than the rule internationally, and are especially scarce for the Eastern Mediterranean and Black Sea climate regions.

Within Türkiye specifically, most existing rainwater harvesting studies remain limited to single-site case assessments, such as Ertop et al.'s [9] evaluation of harvesting potential in Antalya, and have generally relied on generalised climatic averages rather than long-term daily precipitation records, and have not incorporated real market installation costs or region-specific tariff structures. Trabzon presents a compelling case study to address this gap: with a long-term annual rainfall averaging 870 mm, it ranks among Türkiye's wettest provincial capitals. However, the economic viability of RHRS in high-precipitation settings is not self-evident. High rainfall may paradoxically reduce system efficiency if tank capacity is over-specified relative to demand, a phenomenon this study identifies as the oversizing effect.

This paper addresses three research questions: (1) What is the water-saving potential of residential RHRS in Trabzon under observed daily rainfall patterns? (2) What tank size minimises capital investment while maximising cost-effectiveness? (3) At what water price do these systems become economically viable, and how does this relate to current and projected tariffs?

2 Material and Methods

2.1 Study Area and Data

Daily precipitation records for Trabzon (Station No. 17249; 41.00°N, 39.72°E; elevation 39 m a.s.l.) covering the period 2014–2022 were obtained from the Turkish State Meteorological Service. The dataset comprises 3,272 daily observations with zero missing values; standard quality control procedures (range checks and temporal consistency checks) were applied prior to analysis. Annual summary statistics are presented in Table 1.

Table 1. Annual precipitation statistics for Trabzon station, 2014–2022.

Year	Annual (mm)	Max Daily (mm)	Min Daily (mm)	Mean Daily (mm)	Peak Months
2014	915.0	82.4	0.0	2.39	Jan & Oct
2015	1,007.6	55.2	0.0	2.76	Nov & Dec
2016	1,044.6	67.8	0.0	2.86	Oct & Nov
2017	804.4	61.3	0.0	2.20	Jan & Sep
2018	928.2	72.1	0.0	2.54	Nov & Dec
2019	745.0	58.4	0.0	2.04	Sep & Oct
2020	839.4	64.9	0.0	2.30	Oct & Nov
2021	792.6	59.7	0.0	2.17	Jan & Oct
2022	759.6	53.1	0.0	2.08	Sep & Nov
Mean	870.7	63.9	0.0	2.38	—

Note: Peak months identified as those with the highest mean monthly accumulation in each year.

The data reveal substantial interannual variability, with annual totals ranging from 745 mm (2019) to 1,045 mm (2016), a 40% difference. October and November consistently emerge as the wettest months, collectively accounting for approximately 35% of annual precipitation. The

observed daily maximum of 82.4 mm confirms the presence of intense convective events characteristic of the eastern Black Sea climate regime.

2.2 Methodology

A daily water balance model simulates tank storage behaviour over the full observation period, with the tank assumed empty at the start of the simulation and any inflow exceeding available capacity treated as overflow (lost) rather than stored. On days when stored volume is insufficient to meet demand, the shortfall is assumed to be met by the municipal supply. Harvestable runoff on each day is computed as (m^3):

$$Q = \frac{(P-F)xAxC}{1000} \quad (1)$$

where P is daily rainfall (mm), F is the first-flush loss (2.0 mm), A is rooftop catchment area (150 m^2), and C is the runoff coefficient (0.85). Dividing by 1000 converts the result from litres to cubic metres, consistent with the units used for tank capacity and water pricing throughout this study. Tank storage is updated daily subject to the capacity constraint, and a constant daily non-potable demand of 0.1 m^3 is withdrawn from available storage.

Economic feasibility is assessed using Net Present Value (NPV) over a 20-year horizon at a 5% real discount rate, assumed to reflect typical financing conditions for residential infrastructure investment in Türkiye. Water tariffs are held constant in real terms within each scenario, and reported prices reflect water charges only; wastewater fees, which are billed separately alongside water charges in Turkish municipal tariffs, are excluded (see Discussion for the implications of this simplification). Annual monetary savings equal annual water savings (m^3) multiplied by the prevailing water tariff ($/$m^3$). Installation costs are drawn from Turkish market surveys conducted in 2024 and are treated as $-indexed given the dollar-denominated cost structure of system components, ranging from $64 (1 m^3) to $638 (20 m^3), with $15/year for maintenance. Four price scenarios are evaluated: S1 = 0.69 $/$m^3$ (current Trabzon Tier-1 residential water tariff, [10]); S2 = 0.75 $/$m^3$; S3 = 0.87 $/$m^3$ (current Istanbul Tier-1 residential water tariff, [11]); S4 = 1.50 $/$m^3$ (medium-term projection). ₺-denominated tariffs were converted to $ at an exchange rate of 48 ₺/$. S3 is included not as a literal Istanbul deployment scenario, but as a proxy for the tariff level Trabzon may reach if regional convergence with higher-tariff metropolitan markets continues, consistent with observed trends in Turkish municipal water pricing. Break-even threshold prices (the tariff at which NPV equals zero) are derived analytically for each tank size.

3 Results

Table 2 presents the cost-benefit analysis across all tank sizes and price scenarios. Configurations identified as optimal (★) deliver the highest cost-efficiency under viable economic scenarios.

Table 2. Cost–benefit results by tank size and water price scenario

Tank (m^3)	Install. ($)	Annual Saving (m^3)	Coverage (%)	S1 NPV ($) 0.69$/m	S2 NPV ($) 0.75$/m^3	S3 NPV ($) 0.87$/m^3	S4 NPV ($) 1.50$/m^3
1 ★	64	26.5	72.5	-23	-3	+36	+244
2 ★	96	32.2	88.1	-6	+18	+66	+319
3 ★	128	34.1	93.5	-22	+4	+55	+323

Tank (m^3)	Install. ($)	Annual Saving (m^3)	Coverage (%)	S1 NPV ($) 0.69$/m	S2 NPV ($) 0.75$/m^3	S3 NPV ($) 0.87$/m^3	S4 NPV ($) 1.50$/m^3
5	191	35.9	98.3	-69	-42	+11	+293
8	298	36.2	99.2	-174	-147	-92	+192
10	362	36.2	99.2	-238	-211	-156	+128
15	511	36.2	99.2	-387	-360	-305	-21
20	638	36.2	99.2	-514	-487	-432	-148

★ = *optimal configurations.*

Two patterns are immediately apparent. First, annual water savings plateau at 36.2 m^3/year for tanks of 5 m^3 and above, confirming the oversizing effect: beyond this threshold, additional storage capacity does not translate into additional savings because daily demand (36.5 m^3/year at 0.1 m^3/day) is fully met on virtually every rainy day. The 1–3 m^3 range captures 72–94% of maximum achievable savings at a fraction of the cost.

Second, under the current Trabzon tariff (S1 = 0.69 \$/m^3), no configuration yields a positive NPV, though the 1–3 m^3 range comes close, with the 2 m^3 tank reaching -\$6. Under S2, the 2 m^3 tank turns marginally positive at +\$18. Under S3 (0.87 \$/m^3, the price level currently charged in Istanbul), 1–3 m^3 tanks generate NPVs of +\$36 to +\$66, with the 2 m^3 option now delivering the highest return. Under S4, all tanks up to 5 m^3 produce meaningful positive returns, with the 3 m^3 option delivering the highest NPV at +\$323.

Table 3 shows that 1–3 m^3 tanks reach break-even at water prices of 0.71–0.76 \$/m^3, only 3–10% above the current Trabzon tariff, with the 2 m^3 configuration standing just 2.9% below its break-even threshold. Given that Turkish municipal water tariffs have historically increased at rates well above general inflation, this near-parity suggests that economic viability for small-tank RHRS in Trabzon may already be within reach, rather than requiring a multi-year horizon.

Table 3. Break-even water price thresholds by tank size and feasibility assessment.

Tank (m^3)	**Install. ($)**	**Annual Saving (m^3)**	**Threshold (\$/m^3)**	**Feasibility Assessment**
1	64	26.5	0.76 ✓	Achievable imminently
2	96	32.2	0.71 ✓	Nearly at parity today
3	128	34.1	0.74 ✓	Achievable imminently
5	191	35.9	0.84	Achievable near-term
8	298	36.2	1.07	Requires subsidy
10	362	36.2	1.22	Requires subsidy
15	511	36.2	1.55	Not recommended
20	638	36.2	1.83	Not recommended

4 Discussion

The oversizing effect documented here carries a clear practical message: in high-precipitation settings such as Trabzon, specifying larger tanks to maximise harvested volume is economically counterproductive. A 1 m^3 tank recovers 72.5% of maximum possible savings at $64, whereas a 10 m^3 tank recovers 99.2% of savings at a cost nearly six times higher ($362). For residential construction standards, promoting small and affordable systems is therefore more cost-effective than incentivising large-capacity installations. This finding is broadly consistent with Roebuck et al.'s [6] whole-life costing analysis in the United Kingdom, which similarly found that RHRS economic viability is driven primarily by local tariff levels rather than by maximising harvested volume.

The proximity of the break-even threshold to the current tariff is a significant finding for Turkish infrastructure policy. A modest 30% installation subsidy reduces the break-even threshold to 0.63–0.65 \$/m^3 for 2–3 m^3 tanks, bringing them below the current Trabzon tariff (0.69 \$/m^3) and rendering these configurations immediately viable; the 1 m^3 tank's subsidized threshold (0.70 \$/m^3) sits almost exactly at parity with current pricing. Alternatively, the introduction of block tariff structures that penalise high-volume consumption, such as İSKİ's tiered residential pricing already applied in Istanbul, could accelerate adoption without direct fiscal expenditure.

The study has several limitations worth acknowledging. The 150 m^2 roof and 0.1 m^3/day demand are representative residential assumptions; commercial rooftops and higher demand scenarios would improve system economics. The analysis also assumes constant real water prices within each scenario, whereas actual tariff trajectories are uncertain. The runoff coefficient and first-flush allowance, while representative of typical residential roofing, were not varied parametrically; a formal sensitivity analysis would clarify the robustness of the reported thresholds to these assumptions. The tariff figures used in this study reflect water charges only; wastewater fees, which are typically billed alongside water charges in Turkish municipal tariffs, were excluded from the analysis. Since RHRS reduces potable water withdrawal but does not necessarily reduce wastewater discharge proportionally, incorporating wastewater tariffs would likely increase the effective avoided cost per cubic metre, making the reported break-even thresholds conservative. Water quality treatment and system maintenance costs beyond the assumed $15/year were also not modelled in detail. Future work should extend this framework to multiple climatic zones across Türkiye to map regional variation in both harvesting potential and economic viability.

5 Conclusions

This study evaluated the economic feasibility of residential RHRS in Trabzon using a calibrated daily water balance model and real Turkish market costs. Three principal conclusions emerge:

(1) Oversizing effect: for a 150 m^2 rooftop with 0.1 m^3/day non-potable demand, tanks larger than 3–5 m^3 provide no additional water savings, making small tanks the rational choice in Trabzon's high-rainfall setting.

(2) Near-term threshold: 1–3 m^3 tanks break even at water prices of 0.71–0.76 \$/m^3, only 3–10% above the current local tariff, with the 2 m^3 configuration standing just 2.9% below its break-even threshold, indicating that economic viability is imminent rather than a distant, multi-year prospect.

(3) Policy implication: a 30% installation subsidy would bring 2–3 m^3 RHRS below the current Trabzon tariff (break-even thresholds of 0.63–0.65 \$/m^3 versus a current tariff of 0.69 \$/m^3), making them economically viable immediately, while the 1 m^3 configuration would sit at approximate parity; this offers a low-cost, low-risk policy lever for municipal authorities to accelerate adoption ahead of further tariff increases.

These findings provide an evidence-based foundation for integrating decentralised water management into residential construction practice and urban water policy in Türkiye's Black Sea region.

Abstract. Prediction of jet length is essential for the hydraulic design of high-speed spillway aerators, since jet development influences cavity formation, reattachment location, air entrainment, and cavitation protection. This study investigates the use of machine learning algorithms for estimating jet length in spillway aerator flows. Four models, namely Gaussian Process Regression, Adaptive Neuro-Fuzzy Inference System, Polynomial Regression, and Regression Tree Ensembles, were developed using dimensionless hydraulic and geometric input parameters. The Froude number, geometric slope parameter, relative aerator geometry, and combined aerator angle-area ratio were used as input variables, while dimensionless jet length was selected as the output. Model performances were assessed using R^2, RMSE, MAE, and AAPE. The results indicated that ANFIS achieved the best overall performance, with an R^2 of 0.98878, RMSE of 0.72459, MAE of 0.44154, and AAPE of 4.3459%. GPR also provided highly accurate predictions, with an R^2 of 0.98579 and AAPE of 4.6784%. Polynomial Regression and Regression Tree Ensembles exhibited lower prediction accuracy. The findings suggest that ANFIS and GPR can successfully represent the nonlinear relationship between hydraulic and geometric parameters and dimensionless jet length. Therefore, these models can be considered useful alternatives to conventional empirical methods for predicting jet length in spillway aerator flows.

Keywords: High-speed spillway aerator; Jet length; Machine learning algorithms

1 Introduction

Spillways are essential hydraulic structures used to safely convey excess water from reservoirs during flood events. In high-head spillways, the flow may reach very high velocities, increasing the risk of cavitation and subsequent damage to the chute surface. Aeration is one of the most effective methods used to reduce cavitation damage in high-speed spillway flows. By introducing air into the lower region of the flow, spillway aerators increase the air concentration near the chute surface and provide protection against cavitation [1].

A spillway aerator generally consists of a deflector, offset, groove, or a combination of these elements. As the flow passes over the aerator, it separates from the chute surface and forms a free jet before reattaching to the downstream surface. An air cavity develops beneath the jet, allowing atmospheric air to enter the flow. Rutschmann and Hager [2] investigated the air entrainment mechanism of spillway aerators and showed that aerator performance is governed by both hydraulic conditions and aerator geometry. Among the main characteristics of this flow, jet length represents the distance between the flow separation and reattachment points and is closely associated with cavity development and air entrainment. The hydraulic characteristics of jets formed by spillway aerators have subsequently been investigated through several experimental studies. Kökpınar and Göğüş [3] examined high-speed jet flows over spillway

aerators and investigated the effects of hydraulic and geometric parameters on jet length, cavity subpressure, and air entrainment. Pfister and Hager [4] conducted systematic experiments on chute aerators and proposed an explicit relationship for jet length based on approach-flow conditions, aerator geometry, and chute bottom angle. Their results also showed the importance of jet length in describing the different flow regions downstream of an aerator. These investigations indicate that jet length results from the combined effects of several hydraulic and geometric parameters and therefore requires reliable prediction methods for aerator design.

Besides experimental and empirical approaches, numerical methods have also been used to investigate the complex air–water flow occurring around spillway aerators. Tokyay and Kurt [5] applied the Volume of Fluid (VOF) method together with the k−ε turbulence model to simulate flow over a bottom-aerated ramp and step structure. Their numerical analyses focused particularly on air entrainment and the jet length between the separation and reattachment points and considered parameters such as Froude number, discharge, aerator arrangement, and ramp geometry. Shayanseresht and Manafpour [6] compared different turbulence models for air–water flow over a chute aerator and reported that the RNG k−ε model provided jet-length predictions close to experimental measurements. He et al. [7] further investigated three-dimensional aerated deflector-generated jets and evaluated the effects of numerical and physical parameters on the predicted aeration characteristics. Their results demonstrated that numerical approaches can successfully reproduce important characteristics of aerated jets, while also showing the sensitivity of predictions to parameters such as wall roughness and multiphase-flow modelling assumptions.

In recent years, data-driven and soft-computing methods have provided another approach for modelling complex hydraulic processes. These techniques are particularly useful when the relationship between the governing variables and the desired output is nonlinear and difficult to represent using a single empirical expression. Their application has therefore expanded to different aeration and air–water flow problems. Li et al. [8], for example, used embedded multi-gene genetic programming to estimate the air demand of spillway aerators. Kumar et al. [9] investigated soft-computing approaches for predicting the oxygen transfer performance of plunging hollow jets, whereas Puri et al. [10] evaluated different soft-computing techniques for predicting aeration effectiveness based on jet geometry and hydraulic parameters. These studies demonstrate the potential of data-driven approaches for representing complex interactions among hydraulic and geometric variables. Machine learning has also been directly applied to the prediction of air entrainment. Alazmi and Al-Anzi [11] evaluated different machine-learning algorithms for predicting air entrainment rates in a confined plunging liquid jet system. Their results showed that machine-learning models could successfully represent the nonlinear relationship between experimental hydrodynamic parameters and air entrainment. More importantly for spillway aerators, Hekmat et al. [12] applied ANFIS and hybrid ANFIS models combined with different metaheuristic optimization algorithms to estimate aerator design parameters, including dimensionless jet length. This study demonstrated that neuro-fuzzy and optimization-based data-driven approaches can provide high prediction accuracy for spillway aerator parameters. Although previous studies have demonstrated the capability of soft-computing techniques for aeration-related problems and the potential of ANFIS-based approaches for predicting spillway aerator parameters, the predictive performance of different classes of machine-learning algorithms may vary depending on the experimental database, input parameters, and modelling approach. A comparison of algorithms with substantially different learning structures using the same dataset can therefore provide useful information on their ability to represent the nonlinear relationship between hydraulic conditions, aerator geometry, and jet length.

In the present study, experimental data originally reported by Demiröz [13] are used to develop data-driven models for the prediction of jet length in spillway aerator flows. Four

different approaches, namely Gaussian Process Regression (GPR), Adaptive Neuro-Fuzzy Inference System (ANFIS), Polynomial Regression (PR), and Regression Tree Ensembles (RTE), are comparatively evaluated. The Froude number, geometric slope parameter, relative aerator geometry, and combined aerator angle- area ratio are used as dimensionless input parameters, while dimensionless jet length is selected as the output. Model performances are evaluated using the coefficient of determination (R^2), root mean square error (RMSE), mean absolute error (MAE), and average absolute percentage error (AAPE). The comparative assessment aims to identify the model that provides the most accurate prediction of dimensionless jet length under the investigated conditions and to evaluate the applicability of different data-driven approaches as predictive tools for spillway aerator design.

2 Materials and Methods

2.1 Dimensional Analysis and Input Parameters

The experimental data used in this study were obtained from the spillway aerator experiments conducted by Demiröz [13]. In these experiments, the lower nappe length was measured under different hydraulic and geometric conditions. For the present analysis, the jet length was expressed in dimensionless form by normalizing the lower nappe length with the flow depth. The dimensionless jet length, denoted by L_{jet} , was defined as

$$L_{jet} = \frac{L_n}{h} \tag{1}$$

where L_n is the lower nappe length and h is the flow depth.

The dimensionless jet length is influenced by the hydraulic characteristics of the approaching flow and the geometry of the spillway aerator. Accordingly, the general functional relationship can be expressed as

$$L_{jet} = f(V, g, h, \alpha, \theta, T_r, H_s, A_a, A_w) \tag{2}$$

where V is the approach flow velocity and g is the gravitational acceleration, α is the chute-related geometric parameter, θ is the aerator angle, T_r is the ramp height, H_s is the step height, A_a is the aerator opening area, and A_w is the water-flow area.

Using dimensional analysis, the hydraulic and geometric variables were represented by four dimensionless parameters. The first parameter was the Froude number, which represents the relative effects of inertial and gravitational forces:

$$\pi_1 = Fr = \frac{V}{\sqrt{gh}} \tag{3}$$

The second parameter represents the effect of the chute-related geometry:

$$\pi_2 = 1 + \alpha \tag{4}$$

The third parameter represents the aerator geometry relative to the flow depth:

$$\pi_3 = \frac{T_r + H_s}{h} \tag{5}$$

and the fourth parameter combines the effects of the aerator angle and area ratio:

$$\pi_4 = (1 + tan\theta)\frac{A_a}{A_w} \tag{6}$$

Accordingly, the dimensionless jet length can be expressed in terms of these four dimensionless parameters as

$$L_{jet} = f\left(Fr, 1 + \alpha, \frac{T_r + H_s}{h}, (1 + tan\theta)\frac{A_a}{A_w}\right) \tag{7}$$

The four dimensionless parameters π_1, π_2, π_3 and π_4 were used as the input variables for the machine learning models, while L_{jet} was used as the target output. The same input-output structure was used for all models to allow their prediction performances to be compared under identical conditions.

2.2 Machine Learning Models

2.2.1 Gaussian Process Regression (GPR)

Gaussian Process Regression (GPR) is a non-parametric probabilistic regression method used to model nonlinear relationships between input and output variables. In GPR, the response is assumed to follow a Gaussian process defined by a mean function and a covariance function. The covariance function, also referred to as the kernel function, determines the relationship between data points and controls the smoothness of the predicted response.

For a set of input variables x, the regression function can be expressed as

$$f(x) \sim GP\big(m(x), k(x, x')\big) \tag{8}$$

where $m(x)$ is the mean function and , $k(x, x')$ is the covariance function. The theoretical background of Gaussian process regression is given in Rasmussen and Williams [14].

In the present study, GPR was used to predict the dimensionless jet length from the four dimensionless input parameters defined in Section 2.1. A squared exponential kernel function was used, and the input variables were standardized before model training. These settings were applied directly in the MATLAB GPR model. The squared exponential covariance function can be written as

$$k(x, x') = \sigma_f^2 exp\left[-\frac{\|x-x'\|^2}{2l^2}\right] \tag{9}$$

where σ_f^2 is the signal variance and l is the characteristic length scale.

2.2.2 Adaptive Neuro-Fuzzy Inference System (ANFIS)

The Adaptive Neuro-Fuzzy Inference System (ANFIS) combines the learning capability of artificial neural networks with the rule-based structure of fuzzy inference systems. ANFIS establishes nonlinear relationships between input and output variables through fuzzy membership functions and a set of if–then rules. The parameters of the fuzzy inference system are adjusted during the training process to minimize the prediction error.

For a first-order Sugeno fuzzy model, a typical rule can be expressed as

$$Rule\ i\text{:}\ If\ x_1\ is\ A_{i1}, \dots, x_n\ is\ A_{in},\ \ then\ f_i = p_{i1}x_1\ \cdots + p_{in}x_n + r_i \tag{10}$$

where A_{ij} represents the fuzzy set associated with the jth input, and p_{ij} and r_i are consequent parameters.

In the present study, the initial fuzzy inference system was generated using the subtractive clustering method. A cluster influence range of 0.6 was adopted, and the ANFIS model was trained for 100 epochs. The four dimensionless parameters defined in Section 2.1 were used as inputs, while L_{jet} was used as the target output.

2.2.3 Polynomial Regression (PR)

Polynomial Regression (PR) extends conventional linear regression by including polynomial and interaction terms of the input variables, allowing nonlinear relationships between the predictors and the target variable to be represented. For the four input variables considered in this study, a second-order polynomial model was used and can be expressed in the general form

$$L_{jet} = \beta_0 + \sum_{i=1}^{4} \beta_i x_i + \sum_{i=1}^{4} \beta_{ii} x_i^2 + \sum_{i<j} \beta_{ij} x_i\, x_j + \varepsilon \tag{11}$$

Where x_i represents the dimensionless input variables, β_0 is the intercept, β_i , β_{ii} , and β_{ij} are the regression coefficients for the linear, quadratic, and interaction terms, respectively, and ε is the residual error.

In the present study, the PR model included the four linear terms, their corresponding quadratic terms, and all pairwise interactions between the input variables. Accordingly, the model was developed using Fr, $1+\alpha$, $\frac{T_r+H_s}{h}$ and $(1+tan\theta)\frac{A_a}{A_w}$ as predictors of L_{jet}. This model structure corresponds directly to the second-order polynomial formulation implemented in MATLAB.

2.2.4 Regression Tree Ensembles (RTE)

Regression Tree Ensembles (RTE) combine the predictions of multiple regression trees to improve predictive performance and reduce the sensitivity associated with a single decision

tree. In the bagging approach, individual regression trees are trained on different bootstrap samples of the training dataset, and their predictions are combined to obtain the final output. The ensemble prediction can be expressed as

$$\hat{L}_{jet} = \frac{1}{M}\sum_{m=1}^{M} f_m(x) \tag{12}$$

Where M is the total number of regression trees, $f_m(x)$ is the prediction obtained from the m th tree, and $\hat{L}_{jet}$ is the predicted dimensionless jet length.

In the present study, the RTE model was developed using the bagging method with 200 regression trees. The minimum leaf size of each tree was set to 2. The four dimensionless parameters defined in Section 2.1 were used as predictor variables, while L_{jet} was used as the target output. These model settings correspond to those implemented in MATLAB.

2.3 Model Development and Performance Evaluation

The dataset consisted of 177 observations, including the four dimensionless input parameters defined in Section 2.1 and L_{jet} as the target output. A random holdout procedure was used to divide the dataset into training and testing subsets. A fixed random seed was applied to ensure reproducibility. 20% of the observations were used for model training, while the remaining 80% were used for model testing. The same data partition was applied to all four machine learning models to provide a common basis for performance comparison.

The predictive performances of the models were evaluated using the coefficient of determination (R^2), root mean square error (RMSE), mean absolute error (MAE), and average absolute percentage error (AAPE). These statistical measures were calculated as

$$R^2 = 1 - \frac{\left\{\sum_{i=1}^{N}\left(L_{jet,i} - \hat{L}_{jet,i}\right)^2\right\}}{\left\{\sum_{i=1}^{N}\left(L_{jet,i} - \bar{L}_{jet}\right)^2\right\}} \tag{13}$$

$$RMSE = \sqrt{\left\{\frac{1}{N}\sum_{i=1}^{N}\left(L_{jet,i} - \hat{L}_{jet,i}\right)^2\right\}} \tag{14}$$

$$MAE = \frac{1}{N}\sum_{i=1}^{N}\left|L_{jet,i} - \hat{L}_{jet,i}\right| \tag{15}$$

$$AAPE = \frac{100}{N}\sum_{i=1}^{N}\left|\frac{L_{jet,i} - \hat{L}_{jet,i}}{L_{jet,i}}\right| \tag{16}$$

3. Results and Discussion

The prediction performances of the GPR, Polynomial Regression, Regression Tree Ensembles, and ANFIS models were evaluated using R^2 , RMSE, MAE, and AAPE. The obtained performance metrics are presented in Table 1.

As shown in Table 1, ANFIS and GPR provided considerably better prediction performance than Polynomial Regression and RTE. ANFIS achieved the highest value (0.98878) and the lowest RMSE (0.72459) and AAPE (4.3459%), indicating close agreement between the experimental and predicted L_{jet} values. GPR showed a similarly high predictive performance, with an R^2 of 0.98579 and an AAPE of 4.6784%. GPR produced a slightly lower MAE (0.44086) than ANFIS (0.44154).

Polynomial Regression showed lower predictive performance, with an R^2 of 0.74873 and an AAPE of 10.234%. This result indicates that the second-order polynomial formulation was less successful in representing the relationship between the hydraulic and geometric input parameters and L_{jet}. RTE provided a higher R^2 value (0.86479) than Polynomial Regression; however, it produced the highest AAPE (22.595%) and MAE (1.8546) among the investigated models.

Table 1. Performance comparison of the machine learning models for prediction.

Model	R^2	**RMSE**	**MAE**	**AAPE (%)**
GPR	0.98579	0.81537	0.44086	4.6784
Polynomial Regression	0.74873	3.4291	1.1962	10.2340
Regression Tree Ensembles	0.86479	2.5154	1.8546	22.5950
ANFIS	0.98878	0.72459	0.44154	4.3459

The considerably better performance of ANFIS and GPR suggests that the relationship between the selected dimensionless parameters and jet length is strongly nonlinear. ANFIS can represent such relationships through its fuzzy rule-based structure, whereas GPR provides a flexible nonlinear mapping through its kernel-based formulation. In contrast, the predefined mathematical structure of the second-order Polynomial Regression model restricts its ability to represent more complex interactions between the input parameters. The RTE model captured part of the nonlinear behavior but showed larger prediction errors than ANFIS and GPR.

The comparison between the experimental and predicted L_{jet} values obtained using the GPR model is presented in Figure 1. Most of the predicted values are located close to the perfect agreement line, with relatively small deviations over the investigated range. This close agreement is also reflected in the statistical performance of the model, with an R^2 of 0.98579, RMSE of 0.81537, MAE of 0.44086, and AAPE of 4.6784%. These results indicate that GPR effectively represents the relationship between the selected dimensionless hydraulic and geometric parameters and L_{jet}.

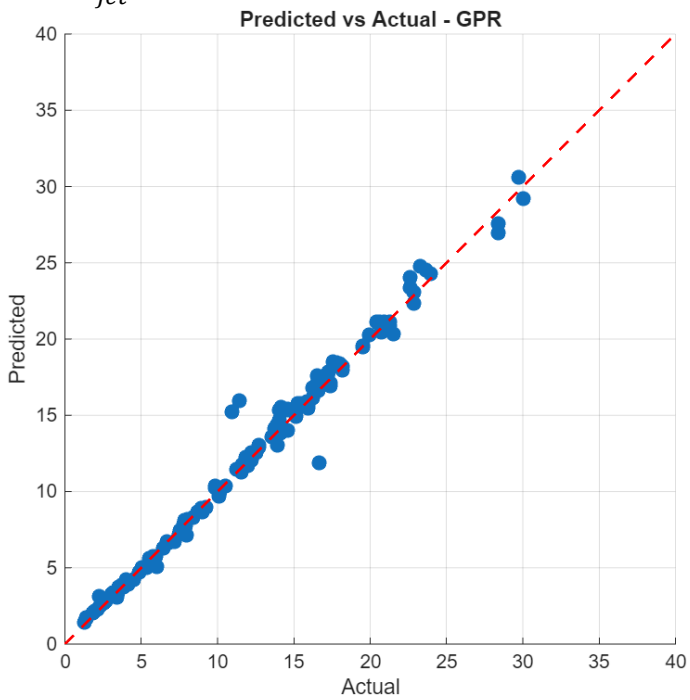

Fig. 1. Actual and predicted jet length values for the GPR model

Figure 2 presents the experimental and predicted L_{jet} values obtained using Polynomial Regression. Compared with GPR, the predicted values show greater scatter around the perfect agreement line. The model yielded an R^2 of 0.74873, RMSE of 3.4291, MAE of 1.1962, and AAPE of 10.234%. The lower prediction accuracy indicates that the second-order polynomial formulation was less effective in representing the relationship between the selected input parameters and L_{jet}.

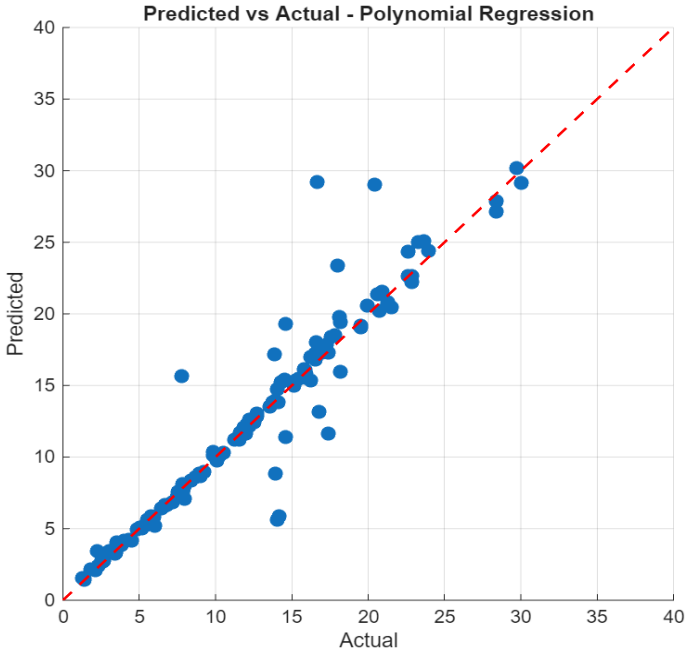

Fig. 2. Actual and predicted jet length values for the Polynomial Regression model.

The prediction results of the RTE model are shown in Figure 3. The model achieved an R^2 of 0.86479, which was higher than that obtained using Polynomial Regression. However, greater deviations between the experimental and predicted values are observed, particularly at larger L_{jet} values, where the model tends to underestimate the experimental values. This behavior is also reflected in the RMSE, MAE, and AAPE values of 2.5154, 1.8546, and 22.595%, respectively. Therefore, although RTE captured part of the nonlinear relationship between the input parameters and L_{jet} , its prediction errors were considerably higher than those obtained using GPR and ANFIS.

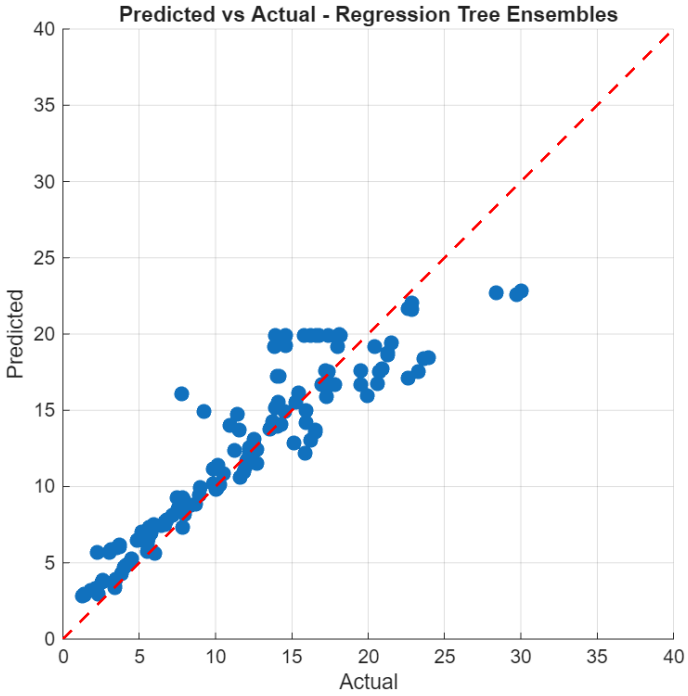

Fig. 3. Actual and predicted jet length values for the Regression Tree Ensembles model.

Figure 4 shows the experimental and predicted L_{jet} values obtained using ANFIS. The predicted values are closely distributed around the perfect agreement line, indicating good agreement with the experimental values. ANFIS achieved the highest R^2(0.98878) and the lowest RMSE (0.72459) and AAPE (4.3459%) among the investigated models. Its MAE of 0.44154 was also

very close to the lowest value obtained using GPR (0.44086). These results show that ANFIS provided the best overall prediction performance, while GPR produced similarly accurate predictions.

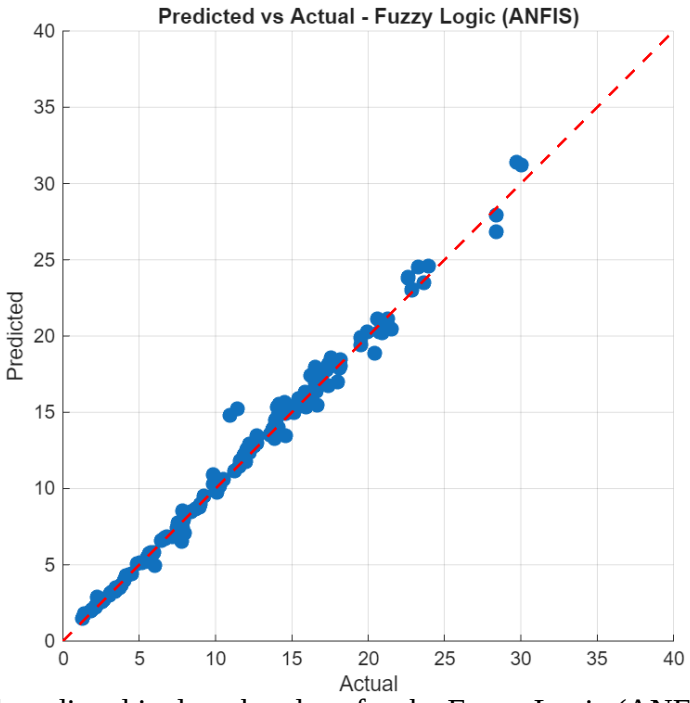

Fig. 4. Actual and predicted jet length values for the Fuzzy Logic (ANFIS) model.

The superior performance of nonlinear data-driven models observed in the present study is in agreement with previous applications of soft computing techniques to aeration-related hydraulic problems. Hekmat et al. [12] investigated hybrid ANFIS models for predicting important spillway aerator design parameters, including the dimensionless jet length. Their best-performing ANFIS-DE model predicted the dimensionless jet length with an R^2 of 0.963, demonstrating the ability of ANFIS-based approaches to represent the complex interactions between hydraulic and geometric parameters. In the present study, the conventional ANFIS model achieved an R^2 of 0.98878 and an AAPE of 4.3459%, further indicating the suitability of neuro-fuzzy modelling for jet length prediction. However, direct comparison of the numerical performance metrics should be made with caution because the datasets, input parameters, and model configurations differ between the studies.

Data-driven approaches have also shown promising performance for other spillway aerator parameters. Li et al. [8] developed an embedded multi-gene genetic programming model for predicting aerator air demand and obtained a coefficient of determination of 0.95. Their model improved prediction accuracy compared with the investigated empirical relationships, showing the potential of data-driven methods for representing complex aerator-flow relationships. Similar observations have been reported for other jet aeration problems. Puri et al. [10] compared several soft computing techniques, including Gaussian Process, Random Forest, Support Vector Machine, and Artificial Neural Network models, for predicting jet aeration efficiency. Their results showed that nonlinear machine learning approaches could successfully represent the effects of hydraulic and geometric variables on aeration performance.

From a hydraulic perspective, the importance of considering both flow conditions and aerator geometry is also supported by earlier experimental investigations. Kökpınar and Göğüş [3] showed that high-speed jet behavior over spillway aerators is influenced by aerator geometry and flow conditions and developed empirical relationships for dimensionless jet length and other aeration parameters. The present results extend this approach by using dimensionless hydraulic and geometric parameters as inputs to machine learning models rather than

prescribing a single empirical functional form. The considerably better performance of ANFIS and GPR compared with Polynomial Regression suggests that flexible nonlinear models are more capable of representing the interactions among these parameters within the investigated dataset. Nevertheless, the developed models are data-driven and their predictive capability should be considered within the range of hydraulic and geometric conditions represented in the experimental database. Further studies using additional experimental datasets and different aerator configurations would be useful to examine the generalization capability of the models.

4. Conclusions

In this study, the applicability of four machine learning approaches, namely Gaussian Process Regression (GPR), Adaptive Neuro-Fuzzy Inference System (ANFIS), Polynomial Regression (PR), and Regression Tree Ensembles (RTE), was investigated for the prediction of dimensionless jet length in spillway aerator flows. Four dimensionless parameters representing the hydraulic and geometric characteristics of the flow and aerator were used as model inputs, while L_{jet} was selected as the target output.

The results showed clear differences among the predictive performances of the investigated models. ANFIS provided the best overall performance, with an R^2 of 0.98878, RMSE of 0.72459, and AAPE of 4.3459%. GPR also showed high prediction accuracy, achieving an R^2 of 0.98579 and an AAPE of 4.6784%. In comparison, PR and RTE produced lower prediction performances, particularly in terms of prediction errors. The better performances of ANFIS and GPR indicate that these models are more capable of representing the nonlinear relationship between the selected dimensionless hydraulic and geometric parameters and jet length.

The findings demonstrate the potential of data-driven approaches for estimating jet length in spillway aerator flows and support previous studies reporting successful applications of ANFIS-based methods to aerator design parameters. However, the developed models were evaluated using a specific experimental database, and their predictive capability should therefore be considered within the range of hydraulic and geometric conditions represented by the available data. Further studies using additional experimental datasets and different aerator configurations would be useful for evaluating the generalization capability of the developed models.

Abstract. This study aims to examine the performance of various machine learning methods in modeling hydrological processes involving nonlinear relationships and in calculating parameters that directly influence hydrological events. To this end, monthly average flow data measured at Flow Observation Station (FOS) No. D01A003 on the Meriç River in the Meriç-Ergene Basin, along with monthly total precipitation and temperature data measured at İpsala Meteorological Observation Station (MOS) No. 17632, were used to evaluate the performance of LSBoost, Multivariate Adaptive Regression Splines (MARS), Model Tree (M5-tree), and Artificial Neural Networks (ANN) were employed to develop four distinct rainfall-runoff models. In this context, the performance of the models developed separately using each machine learning technique was evaluated based on an NSE of ≥ 0.85, and the best models obtained were ANN and LSBoost models with 0.920 and 0.960, respectively. Final models for all machine learning methods under investigation were created using the determined hyperparameters. Based on the performance metrics, the model demonstrating the highest performance was identified as the best model. In conclusion, given the critical importance of future flow forecasts in the planning, design, and operation phases of hydraulic infrastructure projects, it is anticipated that the models developed in this study will be useful for future watershed planning and will also provide effective solutions for the sizing of flood protection structures, a significant risk in our country.

Keywords: Rainfall-Runoff Modeling; Machine Learning; Model Performance.

1 Introduction

As living beings depend on water, people have sought to understand water and water-related issues throughout history. Accordingly, various scientific disciplines have been developed to harness water and manage water resources. Within the field of hydrology, one of these scientific disciplines, rainfall-runoff models are developed to simulate the process by which rainfall falling within a river basin is converted into runoff. By forecasting future flow based on meteorological parameters (precipitation, temperature, etc.), these models provide insights for the design of water infrastructure, particularly in relation to flood events, determining optimal locations and ensuring the effective use of project budgets. As global water resources continue to dwindle, accurately predicting surface runoff has become increasingly important, necessitating the application of ever more precise methods to model the rainfall-runoff process. However, due to the complex relationship between rainfall and surface runoff, accurately forecasting surface runoff is challenging [1-5].

Many researchers have conducted studies on rainfall-runoff modeling, which is based on identifying the relationship between complex and long time series. A review of research in this field reveals that machine learning methods developed in tandem with advances in computer technology have found widespread application among rainfall-runoff modeling techniques. Artificial neural network models have been successfully applied in literature to identify optimal relationships. In one such study, the goal was to develop a point-source rainfall-runoff model using an optimal artificial neural network (ANN) architecture, based on daily average discharge data from Flow Observation Station No. D22A116 on the Aksu Creek in Giresun Province and daily total precipitation data from Giresun Meteorological Station No. 17034. The performance of the models was evaluated by calculating various metrics. The results of the analyses indicated that, although all ANN architectures produced satisfactory results, the best performance was achieved by the ANN-QN architecture trained using the Quasi-Newton (QN) training algorithm [6].

Another study aimed to perform short-term rainfall-runoff modeling using three years' (2014, 2015, and 2016) of synchronized hourly rainfall and runoff data obtained from the Samoggia River basin in Italy. The researchers compared four basic machine learning methods (ANFIS-PSO, ANFIS-FCM, MARS, and M5Tree) with the Multiple Model Simple Average (MM-SA) ensemble method and the EBA4SUB conceptual event-based hydrological model. Among the machine learning methods, the ANFIS-PSO, ANFIS-FCM, and MARS models exhibited similar accuracy and performed better than the M5Tree model. Furthermore, it was concluded that the machine learning methods generally outperformed the conceptual EBA4SUB model [1].

In a study conducted in the Meric River basin, which is also the subject of this study, the statistical relationships between the river's daily flow data and the daily average temperature and daily total rainfall data were examined. Using the methods employed in the study, correlation coefficients between the variables were first calculated, and linear regression analysis was performed by evaluating these coefficients bidirectionally within a 95% confidence interval. According to the results of the study, it was observed that the relationship between daily average temperatures and daily average river flow in the Meriç River is stronger than the relationship with daily total precipitation [7].

Upon reviewing the rainfall-runoff modeling processes examined in the studies cited in the literature, no study was found that aimed to develop a rainfall-runoff model for the Meriç River basin using machine learning methods. Machine learning methods have distinct advantages over traditional statistical and linear methods in hydrological time series modeling. The most significant advantage of these methods is their ability to capture the complex and nonlinear nature of hydrological processes; simple regression cannot model this complexity. Thanks to these advantages, machine learning models produce better results across all scenarios compared to linear methods, offering higher prediction accuracy by providing lower error rates and higher efficiency coefficients.

In this work, a rainfall-runoff model analysis was conducted for the Meriç River basin to determine the optimal solution, using monthly total precipitation and temperature data. In addition to the machine learning methods most frequently used in the literature, this study applied the LSBoost method which has found less application in precipitation-runoff modeling to the Meriç River. The aim was to contribute to the high-accuracy prediction of future flow in this region and in areas with similar flow characteristics. In developing the models, various advanced machine learning methods including Multivariate Adaptive Regression Splines (MARS), Model Tree (M5-tree), and Artificial Neural Networks (ANN) were used in addition to the LSBoost method, and the method with the highest prediction performance was determined.

The main objective of this study is to develop machine learning-based rainfall-runoff models capable of simulating complex and nonlinear hydrological processes. To this end, models that accurately and efficiently predict discharge using monthly total rainfall and temperature data from the Meriç River basin as input will be developed using LSBoost, MARS, M5-tree, and Artificial Neural Network techniques.

2 Methodology

This study is based on a three-phase research design. These phases are data definition, training of the models, and determination of the model with the best performance.

2.1 Data definition

For the preparation of the datasets, the input data, monthly total precipitation and monthly average temperature, were obtained from the İpsala Meteorological Observation Station (MOS) No. 17632, located at 40°53'21.7"N, 26°23'27.5"E. The flow data used cover the period from 1996 to 2021 and were obtained from Flow Observation Station (FOS) No. D01A003 (Table 1; Fig. 1). To ensure the longest continuous data set, the FOS that was operational and the MOS located near the Meriç River were selected. All MOSs in the study basin are shown on the map in Figure 1, and information on the FOS from which flow data will be obtained is presented in Table 1.

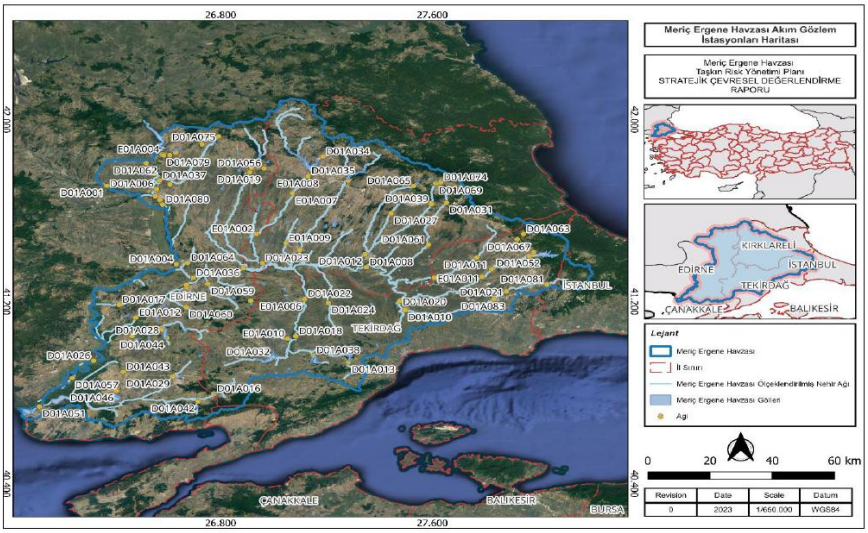

Fig.1. Map of Flow Observation Stations (FOS) in the Meriç-Ergene Basin [8].

Table 1. Flow Observation Station (FOS) used for dataset

Station No	Station Name	Location	Rainfall Area (km²)	Average Elevation (m)	River System
D01A003	Kirişhane	26°34'14" E 41°38'50" N	34990	30	Meriç River

2.2 Development and Training of the Prediction Models

As part of the model development process, four different machine learning approaches will be evaluated. These approaches are presented below.

LSBoost is a regression algorithm based on the gradient-boosted trees method and uses least squares loss. It operates iteratively to improve predictive accuracy by minimizing mean squared errors. In this regard, it is defined as a sequential-correction-based ensemble method that primarily aims for high accuracy by reducing bias. LSBoost stands out for its robust handling

of missing data, scalability on large datasets through histogram-based optimization, and strong capability to model nonlinear, non-monotonic relationships and complex feature interactions. These capabilities enable it to provide accurate and stable hydrological forecasts [9]. Key advantages of the algorithm include its ability to produce consistent and reliable results on both training and test datasets, as well as its low tendency toward overfitting. These characteristics make LSBoost a fast, robust, and computationally efficient method, particularly for prediction and modeling applications in the field of engineering [10]. There are numerous studies in the literature comparing the performance of the LSBoost algorithm with other machine learning methods, such as Support Vector Regression (SVR), Random Forest (RF), and various empirical models. These comparative analyses demonstrate that the LSBoost algorithm exhibits higher prediction accuracy and lower error metrics (RMSE, MAE, etc.), consistently showing superior performance in this regard [11].

MARS is a nonlinear and nonparametric regression method capable of estimating a continuous dependent parameter in high-dimensional data. This method operates through a forward-backward procedure. In the forward step, multiple basis functions are added to the model to overfit the data. These basis functions are based on a spline function that divides the data set into piecewise linear segments. In the backward step, unnecessary basis functions are removed from the model and pruned using a generalized cross-validation criterion. This pruning procedure improves prediction accuracy. MARS falls under the category of regression-based machine learning models and has been successfully used in numerous hydrological applications for decades [1, 12]. MARS is a data-driven technique used to model complex hydrological processes [13]. By automatically optimizing model complexity, the method eliminates the need for additional tuning; and thanks to its feature selection mechanism, it demonstrates superior performance compared to classical linear models in addressing multicollinearity issues [14].

The M5-tree is a machine learning and data mining method frequently used in hydrological modeling. It falls under the category of regression decision trees and aims to estimate the values of numerical variables. Unlike other decision tree algorithms, this algorithm fits a multivariate linear regression model rather than assigning a fixed value to the terminal leaf node. Because of this feature, it is likened to piecewise linear functions. This positions the M5-tree as a multivariate linear model, situated between linear and nonlinear models. The M5-tree uses a hierarchical classification method to partition the dataset into classes. It measures error using the standard deviation of the class values reaching a node and selects the split that maximizes the expected error reduction. This method partitions the nonlinear data space of the input dataset into multiple classes (subspaces), each represented by a simple linear regression. The M5 model has distinct advantages, particularly when compared to complex models. To list a few, the relationships it provides are simpler and more understandable for non-expert users than those of complex nonlinear methods. The training processes are simpler and do not require trial and error, testing, or error evaluation. It is robust in handling incomplete data. Furthermore, thanks to the M5 algorithm's ability to manage non-convergence issues, it does not require the data normalization necessary for models such as ANN. The M5-tree demonstrates satisfactory performance on large datasets and in multidimensional problems, while also being effectively calibrated using a small number of training examples, that is, it is not dependent on the amount of data. In summary, the M5-tree (or M5P) is an efficient tool designed to model complex and multidimensional rainfall-runoff problems by partitioning the data space into manageable subspaces using piecewise linear functions [15–17].

ANN models typically consist of an input layer, one or more hidden layers, and an output layer. The layered feedforward network is the most common and easiest-to-implement architecture. Three-layer feedforward neural networks are widely used for simulation and prediction in engineering problems. Transfer Functions: Sigmoid functions are the most popular transfer functions used to calculate the outputs of nodes. ANN has the ability to learn complex

relationships between input and output data through a training process. During training, the error between the output and the desired value is calculated, and the weights are adjusted using the back-propagation procedure. The Levenberg Marquardt back propagation algorithm is a common technique used in training ANN models. ANN is classified as system-theoretical models or black-box models that rely primarily on precipitation and runoff data, without paying much attention to the details of physical processes. These models have garnered global interest due to their ability to capture the highly nonlinear and complex relationships among hydrological variables. Viewed as a more promising alternative to traditional statistical rainfall-runoff models and conceptual models, ANN is useful in watersheds without hydrometric stations or in areas with limited data [1, 18–20].

2.3 Determination of the Model with the Best Performance

At this stage of the study, final models were generated for each machine learning method for which optimal hyperparameters had been determined, using the entire training and validation datasets. The generated models were tested using a test dataset that had not been used at all during the training and validation phases. Root Mean Square Error (RMSE), Pearson Correlation Coefficient (R), Nash-Sutcliffe Efficiency Coefficient (NSE), Performance Index (PI), and the A10 Index were used to evaluate the performance of the machine learning methods. These metrics were calculated for the test data according to Equations 1–5.

$$RMSE = \left[\frac{1}{n}\sum_{i=1}^{n}(S_i - T_i)^2\right]^{\frac{1}{2}} \tag{1}$$

$$R = \frac{\sum(T_i - \bar{T})(S_i - \bar{S})}{\sqrt{\sum(T_i - \bar{T})^2 \sum(S_i - \bar{S})^2}} \tag{2}$$

$$NSE = 1 - \frac{\sum_{i=1}^{n}(S_i - T_i)^2}{\sum_{i=1}^{n}(S_i - \bar{S})^2} \tag{3}$$

$$\mathrm{PI} = \frac{RRMSE}{1 + r} \tag{4}$$

$$\mathrm{A10} = \frac{M10}{T} \tag{5}$$

In these equations, S_i represents the output value obtained from the current observation stations, $\bar{S}$ represents the average of these values, T_i represents the output value obtained from the model, RRMSE represents the square root of the relative root mean square error, R represents the Pearson correlation coefficient, and n represents the total number of test data points. The root mean square error (RMSE) quantifies the average magnitude of prediction errors, providing information about the absolute deviation between observed and predicted values. The Pearson correlation coefficient (R) evaluates the linear relationship between predictions and observations, with values close to ±1 indicating a strong directional fit. The Nash-Sutcliffe Efficiency Coefficient (NSE) measures the model's relative predictive power compared to the mean of the observed data. An NSE of 1 indicates perfect performance. The Performance Index (PI), a composite metric, combines these measures to provide a holistic assessment of the model's effectiveness. The A10, a useful metric for evaluating the predictive accuracy of regression models within a specific margin of error, enables a more comprehensive assessment of the model's performance when used in conjunction with other performance metrics.

3 Results and Discussions

In this phase of the study, the prediction performance of the developed MARS, M5-tree, LSBoost, and ANN prediction models was analyzed by comparing them. To determine the model with the most effective prediction performance, several performance metrics such as RMSE, R, NSE, PI, and A10 were used. The models were not used during the training and validation phases and were therefore evaluated on test data that the models had not previously seen. The performance metrics obtained from the test data are shown in Table 2. In this table, the ANN model achieved the smallest error value, and based on the condition that NSE ≥ 0.85, both the LSBoost and ANN models demonstrated superior prediction accuracy.

Table 2. Performance metrics obtained from the models for the test dataset.

Models	RMSE	NSE	R	PI	A10
MARS	94.928	0.696	0.894	0.295	0.143
M5-tree	119.859	0.515	0.869	0.378	0.286
LSBoost	48.714	**0.920**	0.975	0.145	0.214
ANN	34.632	**0.960**	0.987	0.103	0.143

Fig. 2 shows scatter plots to determine which of the MARS, M5-tree, LSBoost, and ANN methods used in rainfall-runoff modeling has the most effective prediction performance. As can be seen in Fig. 2, the ANN and LSBoost models exhibit low dispersion, indicating that these two models perform well. This finding is consistent with the data in Table 2.

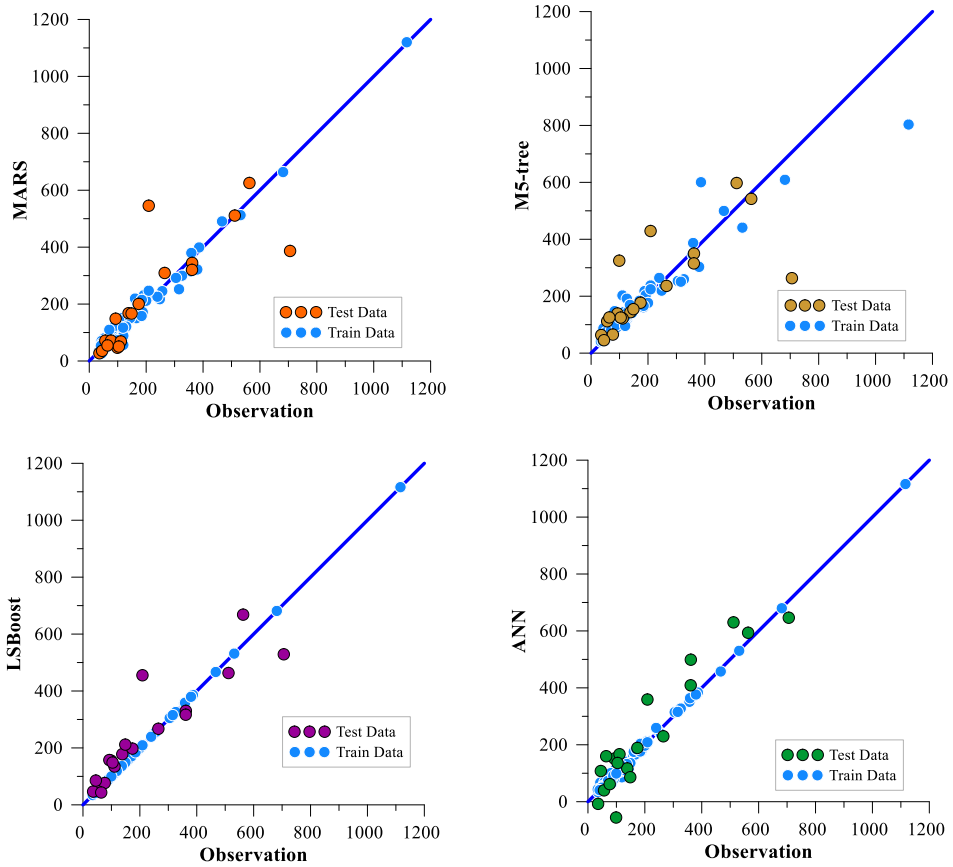

Fig. 2. Scatter graph of observation data with estimated data from the models for the test dataset.

4. Conclusion

In this study, the complex and nonlinear rainfall-runoff relationship in the Meriç River basin was successfully modeled using monthly meteorological and hydrological datasets spanning from 2002 to 2021. Four prominent machine learning techniques, Least-Squares Boosting (LSBoost), Multivariate Adaptive Regression Splines (MARS), Model Tree (M5-tree), and Artificial Neural Networks (ANN), were implemented and compared to predict monthly average river flow at the Kirişhane Flow Observation Station (FOS No. D01A003) based on temperature and precipitation inputs from the İpsala Meteorological Observation Station (MOS No. 17632).

The evaluation of these optimized models on an independent test dataset revealed significant differences in their predictive capabilities. Based on the established performance threshold of NSE ≥ 0.85, both the ANN and LSBoost models demonstrated superior prediction accuracy, exhibiting highly stable performance with minimal dispersion. Among all investigated methods, the ANN model achieved the highest overall performance, yielding the lowest prediction error and the strongest directional fit with an RMSE of 34.632, NSE of 0.960, R of 0.987, PI of 0.103, and A10 of 0.143. The LSBoost model also provided excellent predictive capability, ranking as the second-best model with an RMSE of 48.714, NSE of 0.920, R of 0.975, PI of 0.145, and A10 of 0.214. Conversely, the MARS (NSE of 0.696) and M5-tree (NSE of 0.515) models showed considerably lower performance, indicating limited capacity in fully capturing the complex, non-linear dynamics of the watershed.

The findings of this study confirm that machine learning approaches, particularly ANN and LSBoost, are highly effective tools for simulating complex hydrological processes in the Meriç-Ergene Basin. Given the critical role of accurate streamflow forecasting, the developed models are anticipated to be highly beneficial for future watershed planning, water resource management, and hydraulic infrastructure design. Furthermore, these high-accuracy predictions provide a reliable scientific foundation for optimizing the design and sizing of flood protection structures, which remains a vital necessity in mitigating flood risks in the region.

Abstract. Predicting river flows is a highly complex issue, nonlinear and dependent on numerous parameters, making it crucial for watershed and flood management. This study aims to evaluate the performance of various machine learning methods in modeling the rainfall-runoff interaction, a hydrological process involving nonlinear relationships, and in calculating the parameters that directly influence this hydrological phenomenon. Accordingly, using monthly average flow data measured at Flow Observation Station on the Çağlayan Creek and monthly total precipitation and temperature data recorded at Fındıklı Meteorological Observation Station, four distinct rainfall–runoff models were developed through LSBoost, Multivariate Adaptive Regression Spline (MARS), Model Tree (M5-tree), and Artificial Neural Networks (ANN) methods. To this end, the performance of the models created using each machine learning technique was evaluated based on the condition NSE ≥ 0.85, and optimal hyperparameters were determined for the most successful models. Using these hyperparameters, final models were generated for these methods; these models were not used during the training and validation phases and were therefore tested on test data that the models had not previously seen. Performance metrics such as RMSE, Pearson correlation coefficient (R), Nash–Sutcliffe Efficiency Coefficient (NSE), Performance Index (PI), and A10 Index were analyzed for the test data to measure the predictive performance of each model and conduct a comparative evaluation. Given that future flow forecasts play a critical role in the planning, design, and operation of hydraulic structures, this study anticipates that the models to be developed can be effectively utilized in watershed planning efforts.

Keywords: Rainfall-Runoff Modeling; Machine Learning; Performance Metrics.

1 Introduction

Climate change, which has been increasing in Turkey in recent years, is leading to a rise in the frequency and intensity of floods. This increase in flood events is resulting in serious, life-threatening consequences, such as loss of life and property. Floods are the natural disasters that cause the most loss of life and property in our country, second only to earthquakes. Rainfall-runoff modeling plays a vital role in hydrology for flood disaster management and for determining available water quantities in the planning of drinking water, agricultural, and hydroelectric power plants. In recent years, due to water scarcity, the accurate prediction of surface runoff has become a critical issue for hydrologists to conserve available water resources. Rainfall -runoff modeling is one of the most complex problems in hydrological research due to factors such as the constantly variable nature of precipitation regimes, their occurrence over very large areas, the inability to observe them continuously, their susceptibility to varying topographic conditions within a watershed, and the influence of numerous variables [1-5].

A review of research on rainfall-runoff modeling reveals that studies employing machine learning methods have produced more successful results than those based on empirical and physical models [2]. In the study evaluating the use of Artificial Neural Networks (ANN) to model the complex relationship between precipitation and runoff in the Middle Fırat Basin, the researchers examined the relationship between the monthly average discharge data from discharge observation station No. 2122 and the monthly total precipitation data from precipitation observation station No. 17099. The methodological focus of the study was to predict discharge values using the Feedforward Backpropagation Neural Network (FFBNN) method—one of the ANN methods—and to compare these results with those obtained using Multiple Linear Regression (MLR), a more classical method. The study concluded that the FPRNN method, a black-box model, yielded better results than the MLR method in all cases [6].

Another study investigated the accuracy of short-term hourly rainfall-runoff forecasts, which are critical for flood mitigation and the safety of hydraulic structures in the Ilme River basin in Germany. As part of the study, four machine learning methods (Optimally Pruned Overfitting Machine (OPELM), Multivariate Adaptive Regression Splines (MARS), M5 Tree (M5Tree), and the newly developed hybrid MARS-Kmeans) were compared with a conceptual event-based model called EBA4SUB and the Multiple Linear Regression (MLR) method. In analyses conducted using precipitation and runoff data, the hybrid MARS-Kmeans method was found to demonstrate superior performance compared to other ML methods. Event-based comparisons with the conceptual EBA4SUB model, however, showed that all machine learning models provided better accuracy and yielded better results than EBA4SUB [1].

In the study conducted in Mersin on the Lamas (Limonlu) River, researchers compared Artificial Neural Networks (ANN), Support Vector Machines (SVM), and Deep Learning (DL) methods to solve a nonlinear hydrological problem in a study aimed at predicting river flow using monthly average flow data from 1967 to 2020. Upon examining the comparison criteria, it was observed that Deep Learning (DL) was the best method for solving the problem [7].

In Şen (2019)'s study-which aims to determine flood risk under current conditions and various climate change scenarios in the watersheds located within the boundaries of Rize Province (Turkey's rainiest region) and including the Çağlayan Creek, the subject of this study-basin and flood modeling studies were conducted using daily precipitation outputs from the A2 emission scenario, derived from the ECHAM5 global circulation model dynamically downscaled with the RegCM3 regional model. The results of the 100-year flood modeling studies concluded that there is a flood risk for the Çağlayan Creek under the current conditions scenario [8].

Although machine learning-based rainfall-runoff models have been developed in various watersheds in the existing literature, no study has been found that aims to develop a rainfall-runoff model using these machine learning methods in the Çağlayan Creek watershed in Rize, which is the subject of this study. In this study, a rainfall-runoff model was developed to predict future discharge in the Çağlayan Creek watershed using monthly total precipitation and temperature data. This study represents the first application of rainfall-runoff modeling for this watershed and aims to contribute to the high-accuracy prediction of future discharge in this region and in areas with similar flow characteristics. Various advanced machine learning methods, such as LSBoost, Multivariate Adaptive Regression Splines (MARS), Model Tree (M5-tree), and Artificial Neural Networks (ANN), were used in the development of the models to identify the one with the highest prediction performance.

This work is the first to systematically compare various advanced machine learning methods such as LSBoost, Multivariate Adaptive Regression Splines (MARS), Model Tree (M5-tree), and Artificial Neural Networks (ANN) which have not previously been applied to the Çağlayan Creek watershed, in the context of developing a rainfall-runoff model. By determining which

of the machine learning methods used is more accurate, stable, and efficient for predicting future discharge-using appropriate performance metrics-the study will make a significant contribution to researchers and practitioners.

2 Methodology

The Çağlayan Creek, also known as the Abunoğa River or Fındıklı Creek, is a river located in the Fındıklı district of Rize Province that flows into the Black Sea. The river's source is approximately 2600 meters above sea level, and the river is approximately 34.7 km long. The river's channel gradient is 75%. In management plans prepared by the General Directorate of Water Management under the Ministry of Agriculture and Forestry, the coastal streams in the Fındıklı and Arhavi regions, along with valley systems such as the Çağlayan Creek, have been grouped under the Kabısra Creek Sub-Basin (TR22.M5.1) due to their geographical proximity (Fig. 1, Fig. 2). The Çağlayan Creek has its own independent, micro-scale coastal watershed of 174 km² (the Çağlayan Watershed). However, in the official macro-level sub-basin classification, it is classified within the Kabısra group [9].

Fig. 1. Sub-basins of the Eastern Black Sea Basin [9].

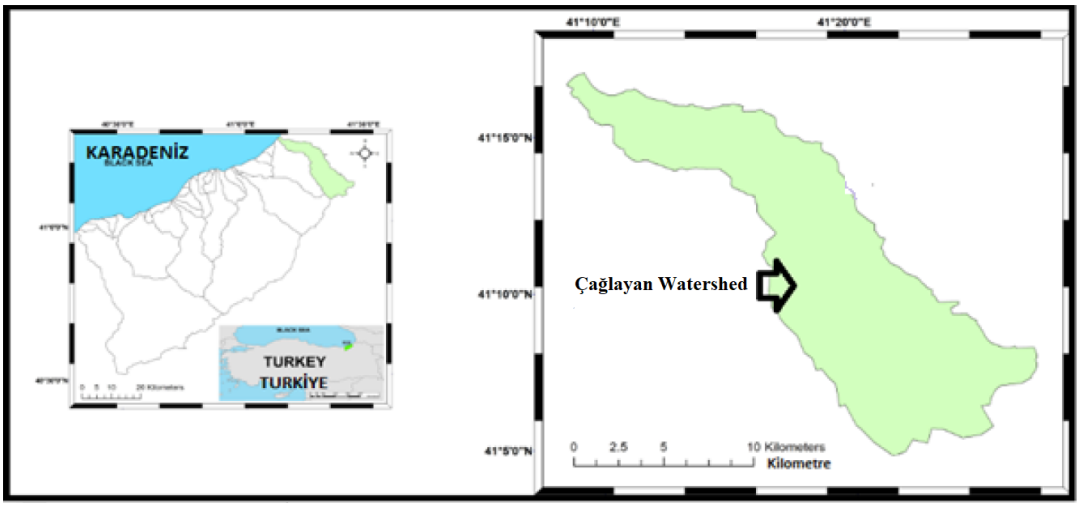

Fig.2. Geographic (locational) representation of the Çağlayan watershed [5].

During the preparation of the datasets, monthly total precipitation and monthly average temperature data were used as input variables. These data will be obtained from the Fındıklı Meteorological Observation Station (MOS) No. 18934, located at coordinates 41°13'44.8"N–41°15'04.8"E. The discharge data to be used in the study cover the years 1992–2021 and were

obtained from the D22A006 Flow Observation Station (FOS) (Table 1). To ensure a continuous and long-term dataset, the FOS, currently active, and the MOS, located near the Çağlayan Creek, were selected. Detailed information concerning FOS from which the flow data was obtained is presented in Table 1.

Table 1. Flow Observation Station (FOS) providing data

Station No	Station Name	Location	Rainfall Area (km²)	Average Elevation (m)	River System
D22A006	Köprübaşı	41°15'3"E 41°15'0"N	156	60	Çağlayan Creek

2.1 Development and Training of the Prediction Models

The four different machine learning methods were applied during the model-building phase to enable comparative analyses. These methods are as follows:

LSBoost (Least-Squares Boosting) is a machine learning algorithm being studied among data-driven models for medium- and long-term flow forecasting. LSBoost is one of the ensemble techniques being evaluated to address the issue of imbalanced datasets that data-driven flow forecasting models face when predicting high flows (floods). It uses a least-squares loss function to weigh the predictions. The LSBoost algorithm proceeds by training models sequentially. Models following the initial model are trained to predict the residual errors of the previous model in the sequence. The prediction at a given training iteration is calculated as the weighted sum of the models trained in previous iterations. Its primary objective is to iteratively train a series of weak learners to minimize the squared error loss [10-12]. Comparative analyses show that the LSBoost algorithm consistently yields higher prediction accuracy and lower error metrics (RMSE, MAE, etc.) [13]. Furthermore, the algorithm stands out for producing stable and reliable results on both training and test datasets and for its low tendency toward overfitting. These characteristics make LSBoost a fast, robust, and computationally efficient method, particularly for prediction problems in engineering applications [14].

MARS (Multivariate Adaptive Regression Splines) is a soft computing model widely used in the field of hydrology. MARS is a nonparametric regression approach introduced by Friedman (1991). It is known as a robust and suitable tool for modeling high-dimensional data. MARS has the capability to examine the effect of each input parameter on the model's output estimate. The model is based on a combination of a series of linear functions known as basic functions. By combining these linear basis functions, a nonlinear model is constructed to determine the functional relationship between the dependent and independent parameters. Input parameters are divided into consecutive segments, and a linear function is defined for each segment; these are referred to as basic functions [1, 15-16].

The M5-tree, a machine learning modeling method in the regression tree category, is based on two steps. The first step is decision tree construction: A decision tree is constructed using a splitting criterion. In the second step, the model tree is designed, the overgrown tree is pruned, and the subtrees are replaced with linear regression functions. The M5-tree uses the binary decision tree concept to split the data, but instead of class labels, it uses linear regression functions that predict continuous numerical attributes at the nodes. The splitting criterion treats the standard deviation of class values reaching a leaf as a measure of error. Standard Deviation Reduction calculates the expected reduction in this error, and M5 selects the split that maximizes the expected error reduction [1]. By combining the intuitiveness of decision trees with the accuracy of linear regression, this hybrid model effectively models piecewise linear and multidimensional relationships by partitioning the data space into homogeneous regions and applying linear regression at each leaf [17]. The M5 Tree is both computationally efficient

and robust against data quality issues in large and complex datasets, and it can successfully model processes at low cost when working with multidimensional numerical variables [18].

Artificial Neural Networks (ANN) are known as systems theory models that aim to capture the relationships between input and output variables in a physical process without considering the underlying physical process itself. An ANN is a highly interconnected network consisting of many simple processing units called neurons, which are modeled after biological neurons in the human brain. ANN typically consists of an input layer, one or more hidden layers, and an output layer. ANN is frequently used by researchers working in the field of hydrology. The ANN technique has proven to be an excellent tool for modeling the complex, dynamic, nonlinear, and piecewise rainfall-runoff process and has demonstrated better performance than traditional modeling techniques. While models developed to simulate the rainfall-runoff process are categorized as empirical, black-box, conceptual, or physically based distributed models, ANN fall under the category of theoretical/black-box models. The primary advantage of ANN is their ability to learn previously unknown relationships between input and output data through a training process, without requiring prior knowledge of watershed characteristics. ANNs are also defined as mathematical structures capable of representing arbitrarily complex nonlinear processes. The most used transfer function for neurons in the hidden layers and the output layer is the sigmoid function; therefore, the network's output range is limited to between zero and one. Consequently, the observed output must be normalized (typically to the range [0.1, 0.9]). In rainfall-runoff modeling, past rainfall (P) and past runoff (Q) amounts are typically used as input variables. Studies have shown that when only past rainfall data are used as input, the models exhibit very low accuracy and low NSE values in hourly runoff forecasting. In contrast, including past flow data as input variables has significantly improved the accuracy of the models [1, 19-20].

2.2 Evaluation of Model Performance and Determination of the Best Model

At this stage, final models were created for each machine learning method with its hyperparameters optimized using the entire training and validation datasets. These models were then evaluated on the test dataset, which was not used at all during the training or validation process. To measure model performance, the following metrics were used: Root Mean Square Error (RMSE), Pearson Correlation Coefficient (R), Nash-Sutcliffe Efficiency Coefficient (NSE), Performance Index (PI), and the A10 Index. These metrics were calculated for the test data based on Equations 1–5.

$$RMSE = \left[\frac{1}{n}\sum_{i=1}^{n}(S_i - T_i)^2\right]^{\frac{1}{2}} \quad (1)$$

$$R = \frac{\sum(T_i - \bar{T})(S_i - \bar{S})}{\sqrt{\sum(T_i - \bar{T})^2 \sum(S_i - \bar{S})^2}} \quad (2)$$

$$NSE = 1 - \frac{\sum_{i=1}^{n}(S_i - T_i)^2}{\sum_{i=1}^{n}(S_i - \bar{S})^2} \quad (3)$$

$$PI = \frac{RRMSE}{1 + r} \quad (4)$$

$$A10 = \frac{M10}{T} \quad (5)$$

In equations (1–4), S_i indicates the output value obtained from the current observation stations, $\bar{S}$ is the average of these values, T_i is the output value obtained from the model,

RRMSE is the square root of the relative root mean square error, r is the Pearson correlation coefficient, and n is the total number of test data points. The root mean square error (RMSE) reflects the average magnitude of prediction errors and provides information about the absolute deviation between observed and predicted values. The Pearson correlation coefficient (R) measures the linear relationship between model predictions and observations; a coefficient approaching ±1 indicates a strong directional fit. The Nash-Sutcliffe Efficiency Coefficient (NSE), on the other hand, evaluates model performance relative to the mean of the observed values; an NSE of 1 indicates that the model has perfect predictive accuracy. The Performance Index (PI), a composite performance metric, evaluates the model's overall effectiveness by combining these metrics into a holistic framework. Also, the A10 index, used to examine the prediction accuracy of regression models within a specific error tolerance range, enables a more comprehensive evaluation of model performance when used alongside other performance metrics. The A10 takes values between 0 and 1; a value closer to 1 indicates that the vast majority of the model's predictions fall within a 10% margin of error relative to the actual values, while a value closer to 0 indicates that only a very small portion of the predictions fall within this range. By using these metrics together, the predictive performance of models is validated in a systematic, detailed, and multifaceted manner, taking into account both the magnitude of error and directional consistency.

3 Results and Discussions

This section presents a comparative analysis of the prediction performances for various models utilized in this study, including the MARS model , M5-tree model, LSBoost model and ANN model. The objective is to identify the models with the most effective prediction performance among those tested.

The evaluation of these models was conducted by examining RMSE, R, NSE, PI and A10 values for training, testing, and all data sets. Table 2 provide these metrics for observed runoff of Çağlayan Creek. In the table, the results that demonstrate the lowest error value and the highest NSE value for test data sets are highlighted in bold.

When evaluating the error and NSE values from the machine learning methods applied in this study, it is evident that for runoff prediction model, the ANN model outperforms other methods in terms of prediction accuracy. Nonetheless, the NSE value for ANN method exceeds 0.85, indicating that the model has a strong correlation with the observation data (Table 2).

Table 2. Performance metrics obtained from MARS, M5-tree, LSBoost and ANN methods for the test dataset.

Models	**RMSE**	**NSE**	**R**	**PI**	**A10**
MARS	2.933	0.566	0.783	0.19	0.17
M5-tree	2.924	0.569	0.844	0.18	0.17
LSBoost	3.328	0.441	0.764	0.22	0.25
ANN	**1.699**	**0.854**	0.927	0.10	0.33

Fig. 3 shows the scatter diagrams for the MARS, M5-tree, LSBoost and ANN methods with respect to runoff prediction model. It can be seen from Fig. 3 that the scattering of the ANN model is the lowest denoting, indicating its best performance. This is also consistent with Table 2.

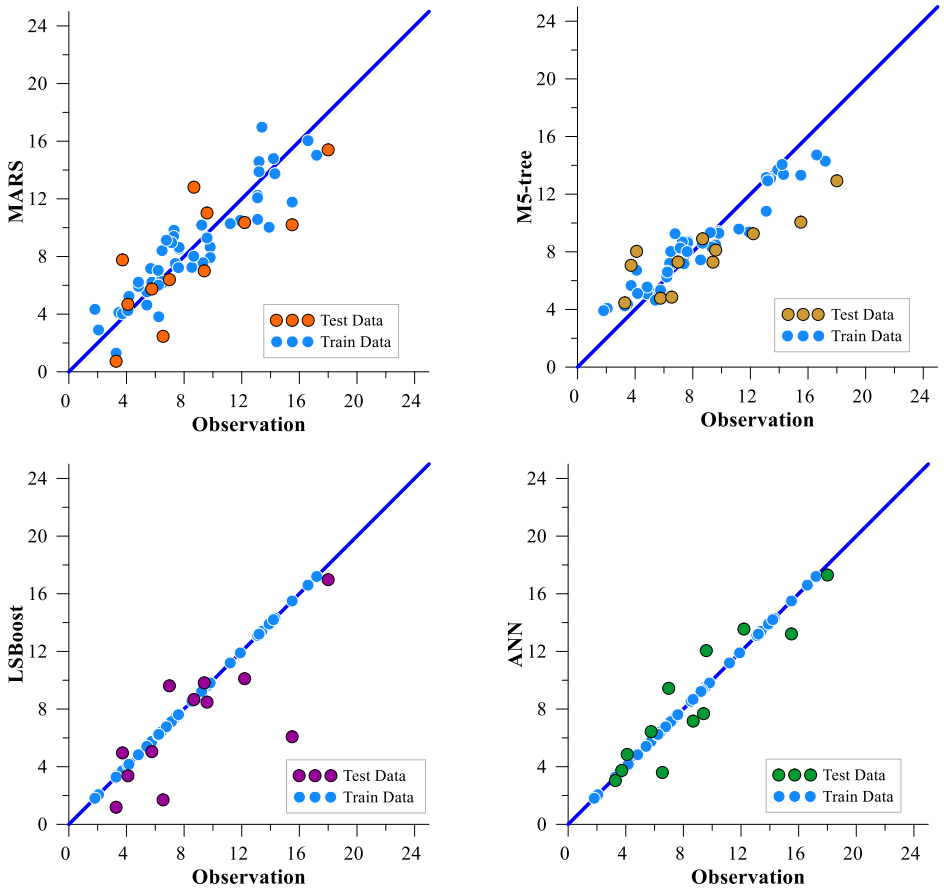

Fig. 3. Scatterplots of observation data with estimated data from MARS, M5-tree, LSBoost and ANN for the test dataset.

4 Conclusion

In this study, the complex and nonlinear rainfall-runoff relationship in the Çağlayan Creek watershed, located in the Fındıklı district of Rize Province, was modeled for the first time using four distinct machine learning methods: Least-Squares Boosting (LSBoost), Multivariate Adaptive Regression Splines (MARS), Model Tree (M5-tree), and Artificial Neural Networks (ANN).

The models were developed using monthly average flow, total precipitation, and average temperature datasets spanning from 1992 to 2021. To assess their generalizability, the performance of each optimized model was evaluated on an independent test dataset that the models had not previously seen during the training and validation phases. Comparing the performance metrics obtained on the test dataset, the Artificial Neural Network (ANN) model demonstrated the highest prediction accuracy, far outperforming the other methods. The ANN model achieved excellent performance with an RMSE of 1.699, NSE of 0.854, R of 0.927, PI of 0.10, and A10 of 0.33, indicating a very strong correlation and robust fit with the observed runoff data. In contrast, the M5-tree (NSE: 0.569) and MARS (NSE: 0.566) models showed moderate predictive performance, while the LSBoost model produced the lowest predictive accuracy with an NSE of 0.441.

As the first application of machine learning-based rainfall-runoff modeling for the Çağlayan Creek watershed, this study provides a crucial tool for high-accuracy future discharge prediction. In a region like Rize, which faces significant flood risks intensified by climate change, these high-performance models can offer invaluable decision support for flood risk management, water resource conservation, and the safe planning, design, and operation of hydraulic structures.

Abstract. Feasibility studies of hydropower plants include technoeconomic, socioeconomic, and environmental analyses. Technoeconomic analysis involves civil works, electrical works, hydromechanics, and electromechanics. Moreover, socioeconomic analysis encompasses employment, flood control, and relocation of structures. Furthermore, environmental analysis comprises reduction of carbon dioxide, losses in carbon sequestration, and in ecology. This study focuses on the development of new software, called HydroFeasibility, which combines all aspects of feasibility in hydropower investments.

Keywords: Feasibility Software; Hydropower Plant; Cost-Benefit Analysis

1 Introduction

Feasibility studies for hydropower investments are usually conducted via computation of spreadsheet formulas, utilization of equipment characteristics charts, and engineering experience. However, these conventional methods may introduce human error and lead to substantial time loss.

In this study, novel software is developed to assembly the three main pillars of feasibility, which are technoeconomic, socioeconomic, and environmental assessments. The software, called HydroFeasibility, is written in C Sharp (C#) programming language. Its graphical user interphase (GUI) enables convenient implementation of embedded data-driven equations.

2 Digital Tools for Feasibility Studies

There are various software for feasibility studies of hydropower plants. These may vary from custom-programmable digital tools to comprehensive feasibility software with optimization and multiple scenario features.

RETScreen Clean Energy Project Analysis Software by Natural Resources of Canada, for instance, can calculate benefits as power, energy yield, carbon offset revenues, and costs as initial and operational expenses. Korkmaz [1] studied technoeconomic viability of Kadincik-4 HPP in Turkey via RETScreen and founded that the penstock diameters calculated by the software were twenty percent greater than the officially accepted feasibility report. Mutlu [2] assessed feasibility of Niksar HPP in Turkey via RETScreen and identified the software's inadequacy to model sediment conditions and expropriation costs in tunnel/channel excavations. Yuce and Yuce [3] evaluated viability of nine hydropower plants in Turkey. They showed the need to adapt North American hydrological data and adjust cost coefficients/export rates to Turkish settings.

Vilela and Reid [4] used HydroCalculator for evaluation of dam projects in Amazon Basin through economic, social, and environmental aspects. The open-access interactivity with quantitative estimation of net present value, internal rate of return, and greenhouse gas emission

costs were identified as the advantages of HydroCalculator, despite its over simplified financial estimates and deficiency of detailed engineering parameters.

Canales and Beluco [5] modeled a hydropower plant in a hybrid configuration using HOMER. They found that HOMER featured satisfactory optimization of net present cost for hydro, solar, wind and electricity storage hybrid systems, however, with intrinsic requirements of constant head and simplified inflow, it lacked modeling reservoir type hydropower plants.

Bayazit, Bakis, and Koc [6] examined hydropower potential using Geographic Information System (GIS) software in displaying and analyzing river catchment features and employing digital elevation models in detecting sites. Via GIS software, potential locations and their environmental compatibility were identified without acquiring field surveying, while the researchers noted the discrepancies between on-site physical features and digital terrains by GIS database.

Moldoveanu and Popa [7] evaluated the feasibility and design parameters of the Cetateni 2 HPP in Romania via a GIS-based digital tool called VAPIDRO-ASTE. Their work confirmed that while VAPIDRO-ASTE extracted river network, investigated catchment hydrology, and computed the residual potential, it required advanced user proficiency in GIS.

With Super Decisions software, using Multi-Criteria Decision Analysis, Saracoglu [8] scrutinized the investment selection and decision-making problems for small hydropower plants in Turkey. The software allowed the graphical control of hierarchal trees to normalize priorities, with qualitative and quantitative parameters, however, modeling pairwise comparisons observed to be challenging and time-consuming.

As the standard international methods and digital tools lack from excellent alignment with the legislative, financial, and structural feasibility studies in Turkey, development of a localized, custom-built, new feasibility software emerges as a necessity.

3 HydroFeasibility – the Newly Developed Software

In this study, new software, HydroFeasibility was developed for feasibility studies of hydropower plants in Turkey.

The software was coded in C#, in terms of modules and submodules. As a part of .NET environment, WinForms was used as the GUI class library. The computational engine, which was based on object-oriented programming principles, featured an extendible architecture enabling incorporation of additional equations and parameters in the future.

On the GUI, the validity of parameters entered is instantly checked. Progressive exception handling (try-catch blocks and data validation algorithms) was integrated to prevent invalid inputs or undefined results. Upon execution, the application initializes the main window, presenting the user with the menu bar (Fig. 1).

The technoeconomic, socioeconomic, and environmental analysis modules were designed as drop-down menus for benefit and cost calculations. In Technoeconomic Module, cost calculations were further detailed in submodules like Electromechanics, Hydromechanics, Civil Works, and Electrical Works (Fig. 2).

While Socioeconomic Module and Environmental Module encapsulate distinct benefit and cost submodules, Benefit – Cost Module acts as the integration layer, aggregating all system-wide calculations. Results from technoeconomic, socioeconomic, and environmental modules are used to compute benefit to cost ratio of the investment on “present values” basis. The process flow diagram of Benefit – Cost Module is shown in Fig. 3.

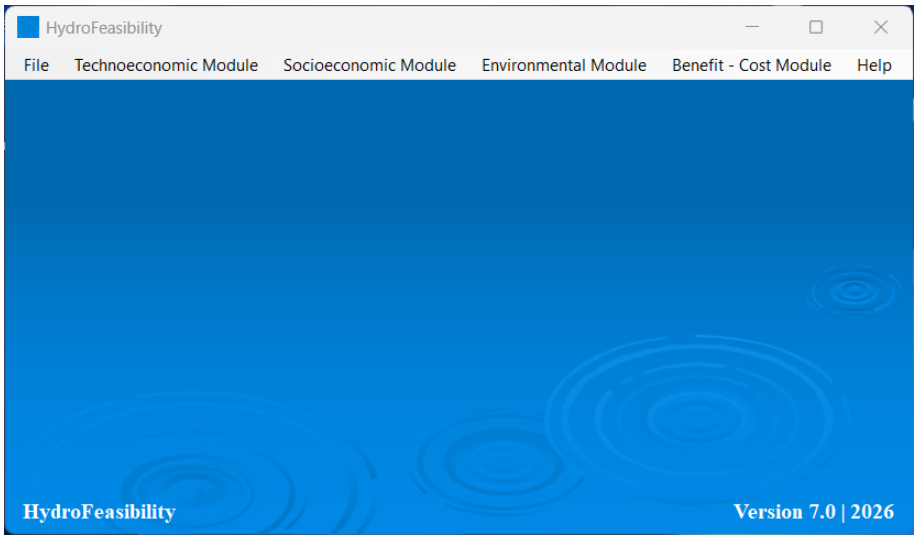

Fig. 1. The main window in HydroFeasibility.

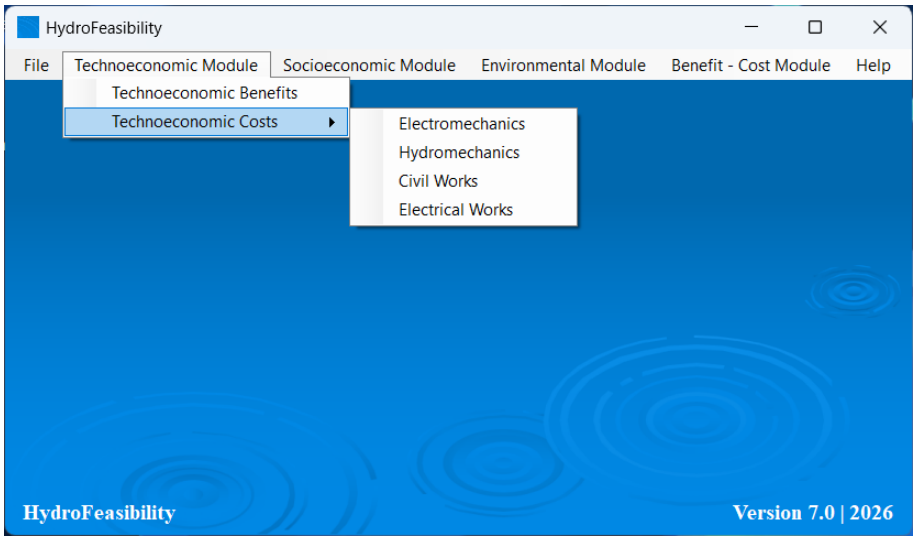

Fig. 2. The Technoeconomic Module in HydroFeasibility.

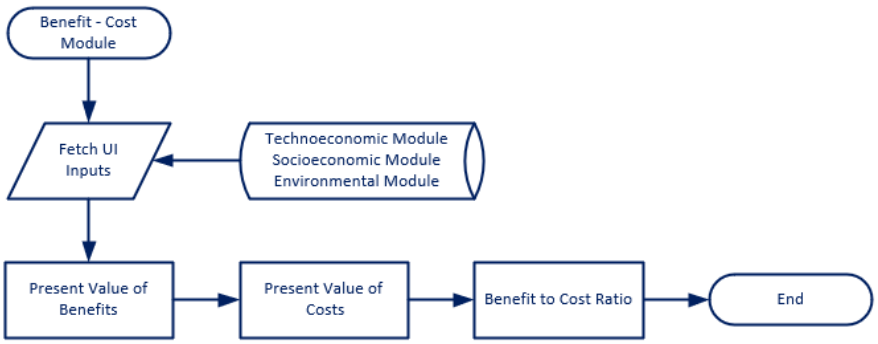

Fig. 3. Process Flow Diagram of Benefit – Cost Module in HydroFeasibility.

4 Case Study – An Application of HydroFeasibility

As an application of the newly developed software, technoeconomic, socioeconomic, and environmental viability of a fictitious hydropower plant is analyzed via HydroFeasibility.

4.1 Technoeconomic Analysis

In this case study, the technoeconomic data for the year 2014 are presented as annual benefits in Table 1, and as initial costs in Table 2.

Table 1. Data for Technoeconomic Annual Benefits.

Item	*Benefit (US $/year)*
Electricity Revenue	4,470,000.00

Table 2. Data for Technoeconomic Initial Costs.

Item	*Cost (US $)*
Civil Works	17,081,900.00
Hydromechanics	2,756,600.00
Electrical Works	352,300.00
Electromechanics	2,936,500.00
Expropriation	599,000.00

The annuities are considered for forty-nine years. The period for construction is taken as two years. The percentage of contingencies, the percentage of feasibility study, project design, engineering, and control are assumed as 15.00 %. The interest rate during construction and the discount rate are adopted as 9.50 %.

Additionally, data for renewal costs of some components are listed in Table 3.

Table 3. Data for Renewal Costs.

Item	*Renewal Cost (US $)*
Concrete Lined Channel	234,920.00
Diversion Structures	4,698.00
Steel Penstock	117,450.00
Power Transmission Line	140,900.00
Powerhouse	196,000.00
Electromechanical Equipment	2,936,500.00
Asphalt Paved Roads	9,278.00
Site Structures	28,190.00
Intake	3,522.00
Weir	14,800.00

Moreover, for operation and maintenance, an annual cost of US $ 70,000.00 is allocated. Similarly, for the project lifespan, miscellaneous annual costs are predicted to be US $ 60,000.00. Then, HydroFeasibility is run for technoeconomic analysis (Fig. 4).

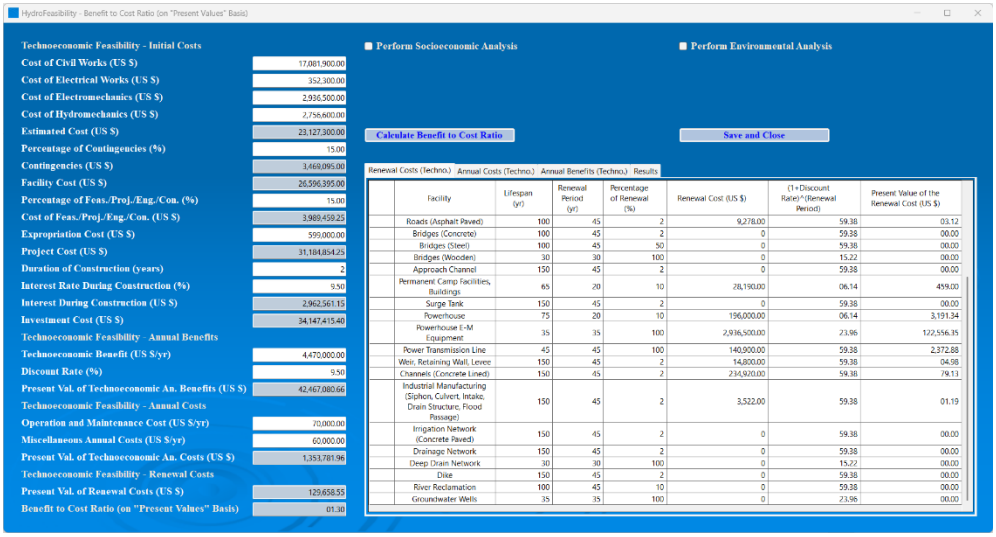

Fig. 4. Technoeconomic Analysis in HydroFeasibility.

The results obtained are shown in Fig. 5, 6, and 7.

Renewal Costs (Techno.) | Annual Costs (Techno.) | Annual Benefits (Techno.) | Results

	Facility	Lifespan (yr)	Renewal Period (yr)	Percentage of Renewal (%)	Renewal Cost (US $)	(1+Discount Rate)^(Renewal Period)	Present Value of the Renewal Cost (US $)
	Roads (Asphalt Paved)	100	45	2	9,278.00	59.38	03.12

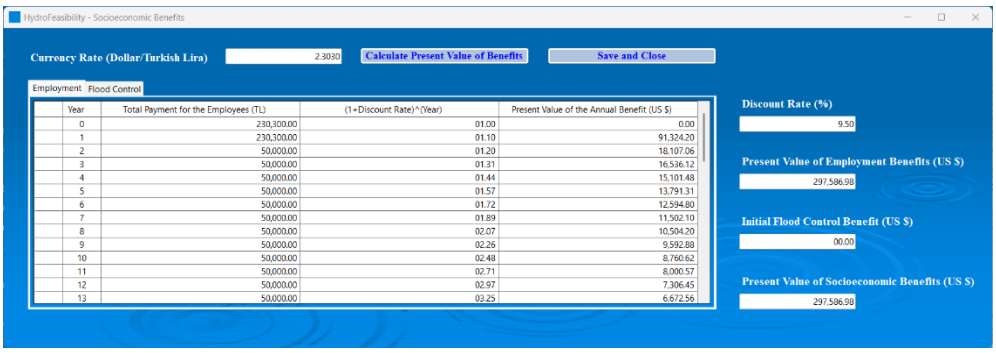
	25	4,470,000.00	09.67	462,332.63
	26	4,470,000.00	10.59	422,221.58

Fig. 7. Calculation of Annual Benefits.

Here, Benefit to Cost Ratio (BCR) by the technoeconomic analysis of the project yielded is calculated as 1.30 on present values basis. With BCR greater than or equal to one, the project seems feasible.

4.2 Socioeconomic Analysis



In this case, the socioeconomic benefits involve employment, and the socioeconomic costs includes the relocation of structures.

In the first two years of the project, all the technical staff and security personnel will be on site, however, beginning from the third year, only the operators and the security personnel will remain. The employment benefits are presented in Table 4.

Table 4. Employment Benefits.

Period (years)	*Total Payment for the Employees (₺)*	*Total Payment for the Employees (US $)*
0 – 2	230,300.00	100,000.00
3 – 49	50,000.00	21,710.81

Upon incorporating Socioeconomic Benefits module of HydroFeasibility, the results given in Fig. 8 are found.

	Year	Total Payment for the Employees (TL)	(1+Discount Rate)^(Year)	Present Value of the Annual Benefit (US $)
	0	230,300.00	01.00	0.00
	1	230,300.00	01.10	91,324.20
	2	50,000.00	01.20	18,107.06
	3	50,000.00	01.31	16,536.12
	4	50,000.00	01.44	15,101.48
	5	50,000.00	01.57	13,791.31
	6	50,000.00	01.72	12,594.80
	7	50,000.00	01.89	11,502.10
	8	50,000.00	02.07	10,504.20
	9	50,000.00	02.26	9,592.88
	10	50,000.00	02.48	8,760.62
	11	50,000.00	02.71	8,000.57
	12	50,000.00	02.97	7,306.45
	13	50,000.00	03.25	6,672.56

Fig. 8. Employment Benefits.

For relocation of structures, two types of buildings are taken into consideration (Table 5).

Table 5. Costs for Relocation of Structures.

Structure to Relocate	*Quantity*	*Cost of Relocation (₺)*
Type – 1	1	24,642.10
Type – 2	1	12,896.80

Furthermore, the socioeconomic costs computed by HydroFeasibility are shown in Fig. 9.

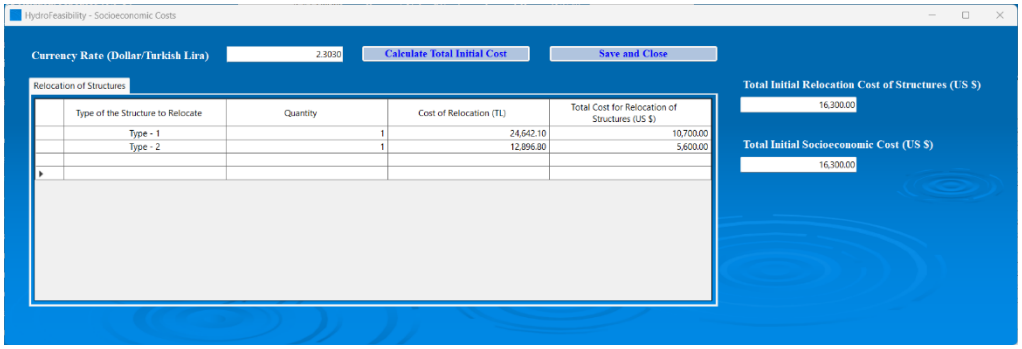


Fig. 9. Costs for Relocation of Structures.

Therefore, after the incorporation of socioeconomic assessment in the feasibility study, the BCR just rose to 1.31 (Fig. 10).

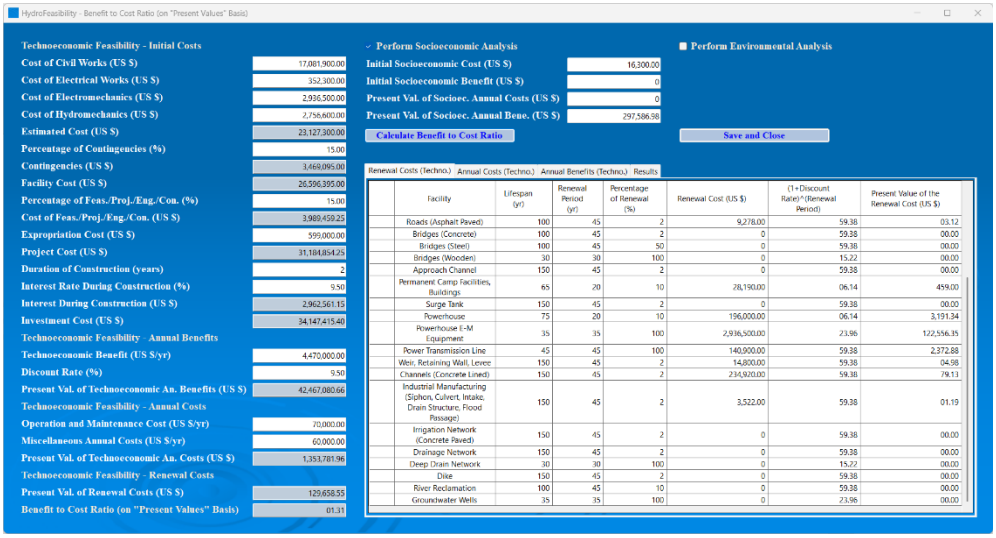

Fig. 10. Technoeconomic and Socioeconomic Assessment.

4.3 Environmental Analysis

Here, the environmental benefits focus on reduction of carbon dioxide with assumption of no harm of the project on vegetation, trees, and crops.

Reduction of carbon dioxide (CO_2) due to hydropower is 45.36 kg per 1 MWh of annual energy [9]. For this case, with energy yield of 30,000.00 MWh/year, CO_2 of 1,360.80 tons/year should be reduced. This reduction is reflected in the Environmental Benefits Module of HydroFeasibility, and the results are illustrated in Fig. 11.

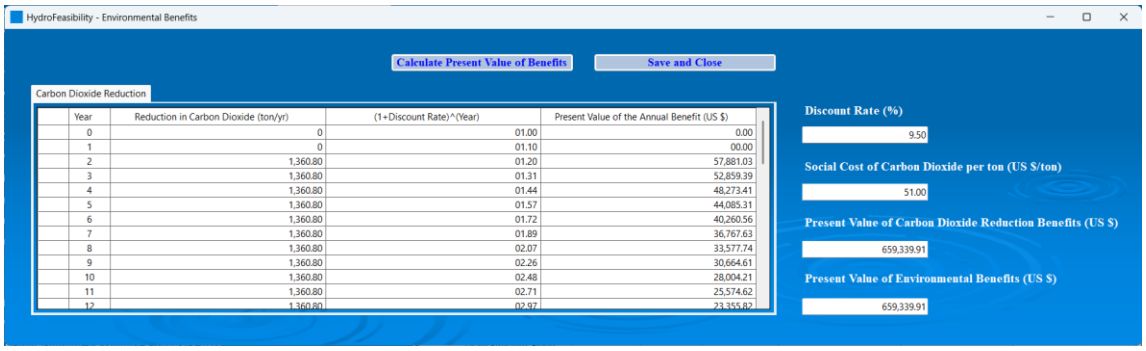

Fig. 11. Environmental Benefits.

After incorporation of environmental assessment, the BCR increased to 1.33 (Fig. 12).

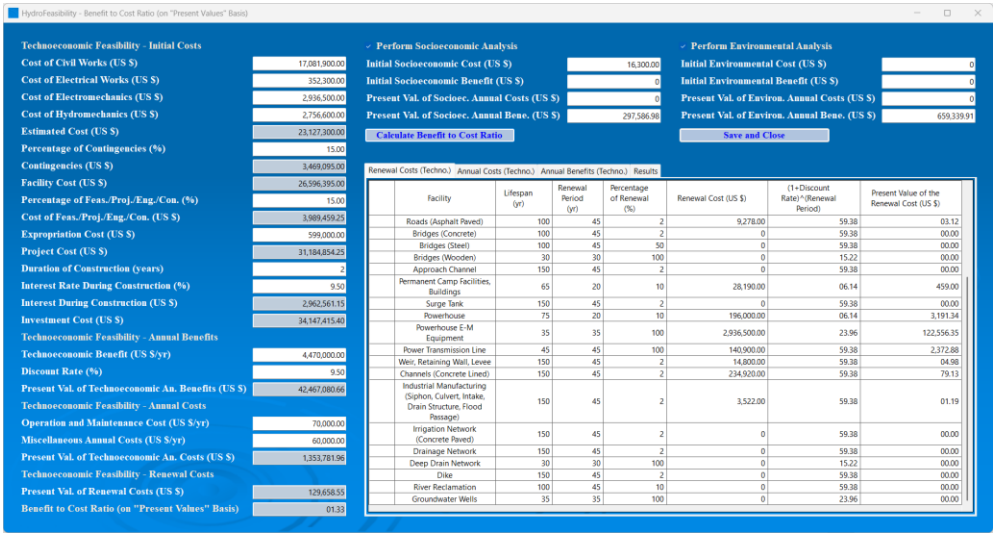

Fig. 12. Technoeconomic, Socioeconomic, and Environmental Assessment.

5 Results and Discussion

In this case study, technoeconomic, socioeconomic, and environmental feasibility of a fictitious hydropower plant with a weir was analyzed.

In technoeconomic analysis, initial costs were costs of civil works, electrical works, electromechanics, hydromechanics, and expropriation. Annual benefits were revenues from electricity generation. Operation and maintenance costs, renewal costs were also considered. BCR calculated for the technoeconomic assessment was 1.30. Since this value was greater than or equal to one, the investment was found to be feasible. Moreover, in socioeconomic analysis, benefits involved employment opportunities, whereas costs comprised relocation of structures. Including the socioeconomic analysis, BCR increased to 1.31. Furthermore, environmental analysis was held with annual benefits of carbon dioxide reduction. Incorporating the environmental aspects, BCR rose to 1.33.

Here, the influences of socioeconomic and environmental parameters on BCR were found to be insignificant. This may be due to small capacity and limited area of the hydropower plant with weir. For a hydropower plant with a dam and substantial reservoir, socioeconomic and/or environmental analyses could have altered the BCR significantly.

6 Conclusion

In this study, the newly developed feasibility software, HydroFeasibility has been presented and used in a comprehensive feasibility analysis of a fictitious hydropower plant with a weir.

The findings highlighted that the progressive inclusion of socio-environmental factors slightly increased the BCR. This exhibited the low-impact characteristics of run-of-river weir plants, compared to facilities with dams and enormous reservoirs.

While the newly developed software, HydroFeasibility, signifies an innovative, localized, multi-dimensional energy planning tool, future versions may require structural updates for adaptation to data transfer attributes and hybrid solutions with electricity storage.

Abstract. Hydraulic gates are critical structures for regulating discharge and water levels in open channels. Unlike conventional planar sluice or radial gates, vertically moving cylindrical gates exhibit hybrid hydrodynamic behavior by combining linear vertical motion with a streamlined curved boundary. This study experimentally investigated the hydraulic characteristics of flow beneath a vertically moving cylindrical gate (D = 125 mm) in a 5.0 m flume and numerically simulated them using 1D HEC-RAS across three steady discharges (Q = 1.24, 1.49, 1.64 L/s) and gate openings (B = 14, 24, 34 mm). Baseline flume tests established an optimal Manning roughness of n = 0.010 (mean absolute error of 2.91%). In HEC-RAS, default radial gate theoretical exponents render the formulation mathematically identical to the classic sluice gate equation. Conventional planar sluice discharge coefficients (Cu = 0.50 - 0.70) significantly overpredicted upstream headwater depths due to exaggerated contraction assumptions. Calibrating the coefficient to Cu = 0.85 successfully accounted for the streamlined curved surface and reduced vena contracta effects, decreasing mean relative errors to -0.61% for headwater and -1.23% for tailwater depths R2 > 0.999). The findings demonstrate that 1D HEC-RAS sluice formulations accurately replicate cylindrical gate hydrodynamics when calibrated with Cu = 0.85.

1 Introduction

Hydraulic gates are movable control mechanisms employed in open channels, dams, and river control structures to regulate water levels, control flow, measure discharge, convey specified flow rates, or completely shut off the flow [1-4]. Unlike weirs that discharge flow over their crests, gates generally achieve flow control by forcing the water to pass underneath or through a defined opening. The design of gates requires analysis of complex hydrodynamic forces that vary with the hydraulic head difference between upstream and downstream water levels, the flow regime (free or submerged), and the structural geometry [3, 5].

Based on their geometric forms and operating mechanisms, gates are categorized into types such as sluice, radial (Tainter), miter, sector, and flap. Among these, sluice and radial gates represent the two most widely utilized control structures in hydraulic engineering and water conveyance systems. While sluice gates move along a vertical plane, transferring the hydraulic load to linear guides, radial gates feature circular arc surfaces rotating around a pivot axis, concentrating the hydrodynamic load onto the trunnion pin and thereby minimizing the load on the hoisting mechanism [2, 3, 5]. Sluice gates are commonly used in vertical water control structures due to their structural simplicity, cost-effectiveness, and operational ease. Flow

beneath a sluice gate accelerates through a converging section, displaying orifice-type flow behavior, which results in energy dissipation accompanied by a characteristic water surface profile variation downstream [1, 2]. Consequently, determining the hydraulic behavior under bottom-discharge structures requires accounting for the geometric boundaries and contraction characteristics specific to each gate type [3, 4].

The gate discharge coefficient and the hydraulics of flow beneath gates have been the subject of numerous scientific studies in the literature. Severi, Masoudian [6] experimentally investigated the discharge coefficients, energy losses, and energy variations of vertically moving cylindrical gates. Using PIV measurements on a rising sector gate model, Song, Park [7] investigated flow velocity and turbulence distributions at varying gate openings, demonstrating that larger openings significantly reduce relative turbulence intensity and establishing a functional relationship between maximum mouth velocity and the Froude number for practical operation. Similarly, Abbaszadeh, Daneshfaraz [8] evaluated the effects of sluice gate openings on hydraulic characteristics, demonstrating that smaller openings increase both the contraction and discharge coefficients as well as hydrodynamic forces, while developing accurate non-linear polynomial regression models to predict discharge coefficients and relative energy loss across varying Froude numbers. Regarding downstream flow phenomena and numerical validation, Şimşek, Kösen [9] compared velocity profiles obtained from numerical simulations using ANSYS-Fluent with experimental data for submerged hydraulic jumps at various submergence ratios downstream of a sluice gate. Likewise, Ateş and Yıldız [10] compared experimental measurements of hydraulic jumps formed under a movable vertical gate with numerical results calculated using HEC-RAS (Hydraulic Engineering Center's River Analysis System).

In this study, the hydraulic behavior of flow beneath a vertically moving cylindrical gate was experimentally investigated under various discharge conditions, and the resulting physical data were compared with numerical modeling results from HEC-RAS[11].

2 Materials and Methods

The methodology adopted in this study consists of a three-step framework. In the first step, the channel bed roughness (Manning's n) was determined under baseline (without gate) flow conditions at a constant discharge and bed slope. In the second step, a vertically moving cylindrical gate was installed at the middle of the channel, and headwater and tailwater depths were measured across three distinct discharge rates and three distinct gate openings (14, 24, and 34 mm). In the final step, identical channel and gate geometries were configured in HEC-RAS.

To evaluate the nature of the gate, gate formulations were implemented, discharge coefficients (C_u) were calibrated, and the predictive performance of both approaches was compared against the experimental dataset.

2.1 Governing Equations and Gate Formulations in HEC-RAS

HEC-RAS (Hydrologic Engineering Center's River Analysis System), developed by the U.S. Army Corps of Engineers (USACE), is a public-domain hydraulic modeling software globally recognized as an industry standard in river hydraulics, flood management, and hydraulic structure design. The software is extensively used to simulate steady and unsteady flow regimes in natural river networks and artificial open channels, to perform flood risk assessments, and to evaluate structural hydraulics [12]. The HEC-RAS modeling suite encompasses four primary one-dimensional river analysis components: (1) steady-flow water surface profile calculations, (2) unsteady-flow hydrodynamic simulations (1D and 2D), (3) movable-boundary sediment transport computations, and (4) water quality analysis [11].

HEC-RAS relies on the conservation of mass and momentum, governed by the Saint-Venant equations. For gradually varied 1D unsteady flow, the Saint-Venant continuity and momentum equations are expressed as Equations (1) and (2), respectively:

$$\frac{\partial \mathrm{A}}{\partial \mathrm{t}}+\frac{\partial \mathrm{Q}}{\partial \mathrm{x}}=0 \tag{1}$$

$$\frac{\partial \mathrm{Q}}{\partial \mathrm{t}}+\frac{\partial\left(\frac{Q^2}{A}\right)}{\partial \mathrm{x}}+\mathrm{gA}\frac{\partial \mathrm{H}}{\partial \mathrm{x}}+\mathrm{gA}S_f=0 \tag{2}$$

Where Q is the total discharge, A is the cross-sectional flow area, t is time, x is the distance along the channel, g is the gravitational acceleration, H is the water depth, and S_f is the friction slope. HEC-RAS calculates the friction slope (S_f) using the Manning equation (Equation 3):

$$\mathrm{Q}=\frac{1}{\mathrm{n}}\ \mathrm{AR}^{2/3}\ \mathrm{S}^{1/2} \tag{3}$$

Where n is the Manning roughness coefficient, and R is the hydraulic radius. HEC-RAS solves these one-dimensional governing equations numerically using an implicit finite difference scheme combined with the Newton-Raphson iteration technique [12].

Despite representing a basic and fundamental control structure, the hydraulics of flow beneath gates constitutes a rich and complex topic in fluid mechanics [3, 5]. Flow passing beneath a gate exhibits distinct characteristics depending on the flow regime and is fundamentally categorized into two main regimes: free and submerged flow. The classification of underflow regimes is illustrated in Fig. 1. While the flow passing beneath the gate in the first two diagrams (a and b) represents free flow, the final diagram (c) illustrates submerged flow.

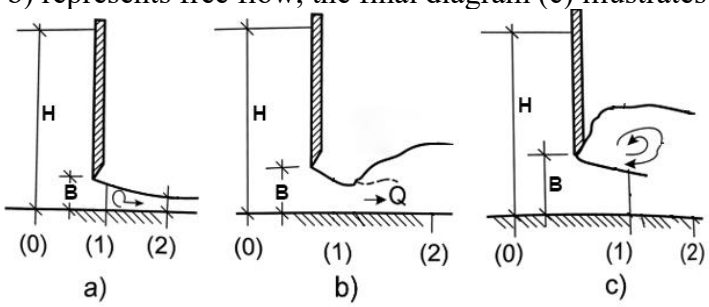

Fig. 1. Flow beneath gates: a) and b) free flow c) submerged flow [2]

In free flow case, the downstream water level has no effect on the high-velocity jet issuing through the gate opening, and the flow beneath the gate discharges freely downstream (Fig 1a & 2b). Based on the channel's hydraulic characteristics, the flow exiting the gate may maintain a supercritical regime or transition to a subcritical state by dissipating energy via a hydraulic jump at a specific distance downstream [2, 5, 13-15].

Sluice Gate Flow Equation

An example sluice gate is presented in Fig. 2.

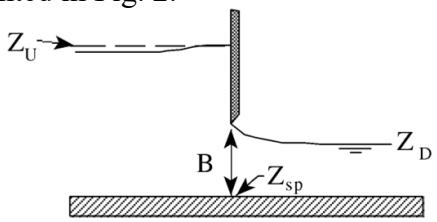

Fig. 2. Sluice gate with broad crested spillway.

In Fig. 2, Z_U is the elevation of the upstream energy grade line (m), Z_D is the elevation of the downstream water surface (m) and Z_{sp} is the elevation of the spillway crest through the gate

(m). The upstream head (H) is the difference of Z_U and Z_D. The equation for a free-flowing sluice gate is as follows [12]:

$$Q = C_u WB\sqrt{2gH} \quad (4)$$

Where, Q is the flow rate (m^3/s), C_u is the unsubmerged discharge coefficient, typically 0.5-0.7, W is the gate width (m), B is the gate opening (m), g is the gravitational acceleration (m/s^2), and H is the upstream head above the spillway crest (Z_U-Z_{sp}). As downstream submergence impairs free flow under the gate, increasing the upstream headwater level for a given flow rate, the program transitions to the following equation [12]:

$$Q = C_u WB\sqrt{2g3H} \quad (5)$$

Flow submergence begins when the tailwater depth to headwater energy ratio over the spillway exceeds 0.67. To bridge free flow and fully submerged regimes, Equation (6) is utilized. This transition ensures a gradual shift toward the fully submerged orifice equation up to a submergence ratio of 0.80.

$$Q = C_s A\sqrt{2gH} \quad (6)$$

Where, Cs is the submerged discharge coefficient (Cs =κ.Cu) The factor κ in this expression always takes a value less than unity and can be derived by formulating the specific force balance between sections (1) and (2) [2]. The default value for the submerged discharge coefficient is 0.8.

Radial Gate Flow Equation

The flow through the gate is considered to be "Free Flow" when the downstream tailwater elevation (Z_D) is not high enough to cause an increase in the upstream headwater elevation for a given flow rate.

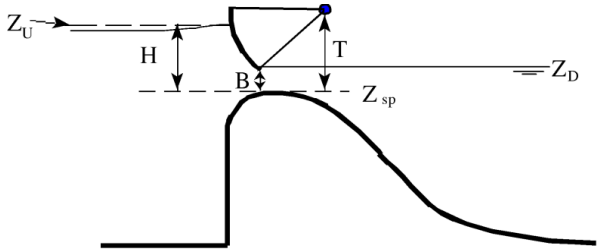

Fig. 3. Typical Radial Gate with an Ogee Spillway Crest [12]

In Fig. 3. Z_U is the elevation of the upstream energy grade line (m), Z_D is the elevation of the downstream water surface (m) and Z_{sp} is the elevation of the spillway crest through the gate (m). The upstream head (H) is the difference of Z_U and Z_D. The equation used for a Radial gate under free flow conditions is as follows [12]:

$$Q = C_u\sqrt{2g}\, WT^{TE}B^{BE}H^{HE} \quad (7)$$

Where, T is the trunnion height (m), TE represents the trunnion exponent, BE is the opening exponent, HE is the head exponent. Upon the onset of downstream submergence, where rising tailwater levels impede free discharge and elevate the required upstream head for a constant flow rate, the formulation transitions to the following expression [12]:

$$Q = C_u\sqrt{2g}\, WT^{TE}B^{BE}(3H)^{HE} \quad (8)$$

Once the ratio of tailwater to upstream energy head over the spillway exceeds 0.67, submergence starts. Equations compute a weighted flow across the transition zone, smoothly shifting the calculation to the fully submerged orifice equation as submergence reaches 0.80. The fully submerged equation is shown in Eq. 6 [12]. When the standard (default) exponents in the interface (TE=0, BE=1 and HE=0.5) are substituted, the equation transforms into the classic orifice/gate flow form where C_s, submerged discharge coefficient is typically 0.8.

2.2 Experimental Setup and Procedure

The TecQuipment H12 – 5 Meter Flow Channel system used in this study (Fig. 4) is an experimental laboratory apparatus designed to investigate the hydraulic characteristics of open-channel flows. The system operates on the principle of continuous closed-loop water recirculation, enabling controlled and precise analysis of various flow conditions. Developed to facilitate the practical observation of open-channel flow theories, the apparatus is widely used in education and research, particularly in hydraulic engineering and fluid mechanics [16].

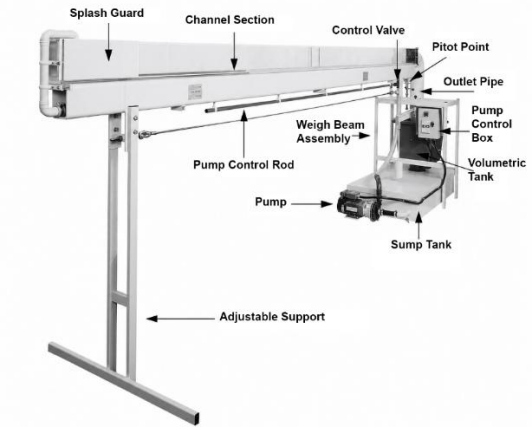

Fig. 4. Tecquipment h12 – 5 Metre Flow Channel

Water from the system's sump tank is delivered to the channel inlet via a centrifugal pump. The flow discharge is regulated by a precision control valve at the inlet section, enabling experiments under various discharge conditions. To promote a more uniform flow pattern along the channel, flow straighteners are employed, thereby mitigating turbulence effects and enhancing measurement accuracy. Additionally, the channel bed slope can be adjusted using an adjustable jacking mechanism, enabling observation of flow behavior across different slope configurations. This feature enables experimental investigation of various flow regimes, including uniform, critical, and supercritical flow [16].

The experiments were conducted using the TecQuipment h12 open-channel flume system, featuring a rectangular cross-section with a length of 5.0 m, a height of 175 mm, a width of 75 mm, and a constant bed slope ($S_o = 0.00506$). Water was supplied via a closed-loop recirculation system powered by a centrifugal pump. The flow discharge (Q) was precisely regulated using an inlet valve and volumetrically verified using the integrated calibration tank combined with time-interval measurements ($\Delta V / \Delta t$).

Prior to installing the gate, baseline experiments were performed in the ungated flume at a constant bed slope ($S_0 = 0.00506$) to determine the channel roughness coefficient. In the second step, a vertically moving cylindrical block (diameter D = 125mm) was installed at the midpoint of the channel (at Station 2.5 m). Headwater and tailwater depths, as well as water surface profiles along the channel, were recorded using point gauges with a measurement precision of ±1mm (Fig. 5).

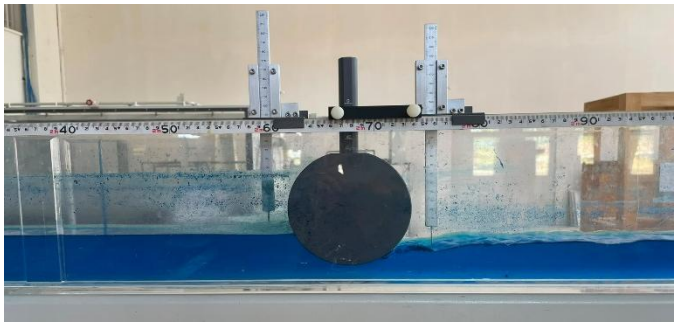

Fig. 5. Experimental setup

2.3 Numerical Modelling and Calibration in HEC-RAS

The un-gated flume model was configured with a length of 5.0 m, a height of 175 mm, a width of 75 mm, and a constant bed slope of S_0 = 0.00506 (Fig. 6-a&c). Cross sections were interpolated at 20 cm intervals along the channel (Fig. 6-b).

In the first phase, the channel bed roughness coefficient (Manning's n) was determined through a combined experimental and numerical calibration process. Baseline physical experiments were initially conducted in the un-gated flume across four distinct discharge rates (Q = 0.69, 1.03, 1.11, and 1.50 L/s), and the corresponding water depths were measured under uniform flow conditions. Subsequently, numerical simulations were executed in HEC-RAS using the same discharge rates with various candidate Manning roughness coefficients (n = 0.010, 0.011, and 0.012). The representative roughness coefficient for the channel was then established by comparing the numerically calculated water depths against the experimentally measured values.

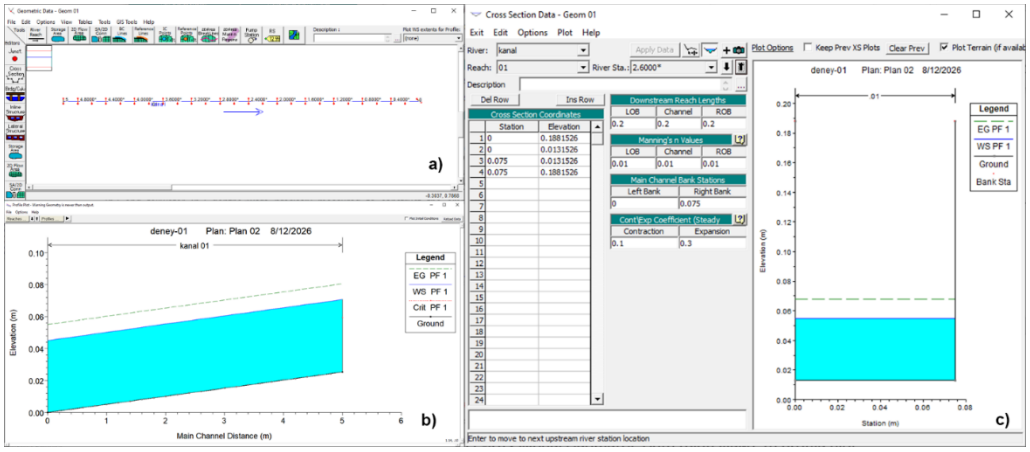

Fig. 6. a) HEC-RAS Model Geometric Data (plan view), b) cross section at 2.60m, c) profile plot

Subsequently, the cylindrical block was incorporated into HEC-RAS as an "Inline Structure" at the channel midpoint (Station 2.5 m; Fig. 7). While HEC-RAS offers standard gate geometries, such as sluice, radial, overflow, and user-defined shapes, the cylindrical obstacle used in this study does not strictly fit any single default category. However, because it combines the vertical movement mechanism of a sluice gate with the circular contact surface of a radial gate, both the sluice and radial-gate formulations can be implemented separately to evaluate their predictive capabilities (Fig. 8).

In HEC-RAS, when default theoretical exponents are adopted for the radial gate configuration, namely, the trunnion exponent (TE = 0), opening exponent (BE = 1), and head exponent (HE = 0.5), the radial formulation mathematically simplifies to the classic sluice gate equation (Eq. 4). Consequently, the numerical simulations were executed using the Sluice Gate methodology. The submerged orifice coefficient (C_s) was retained at its default value of 0.8. Although measured water surface elevations were prescribed at the channel boundaries, HEC-RAS internally computes the upstream energy head based on the specified opening (B) and discharge coefficient (C_u). Standard flat-planar sluice gate guidelines typically recommend C_u values in the range of 0.50 - 0.70. However, this conventional range underestimates the hydraulic efficiency of the curved cylindrical profile, causing the 1D model to significantly overpredict upstream water depths due to exaggerated contraction loss assumptions. To accurately capture the streamlined flow behavior and effectively compensate for the reduced vena contracta effects of the curved cylindrical block, the discharge coefficient was extended

beyond conventional flat-gate limits and systematically evaluated across C_u = 0.70, 0.80, and 0.85.

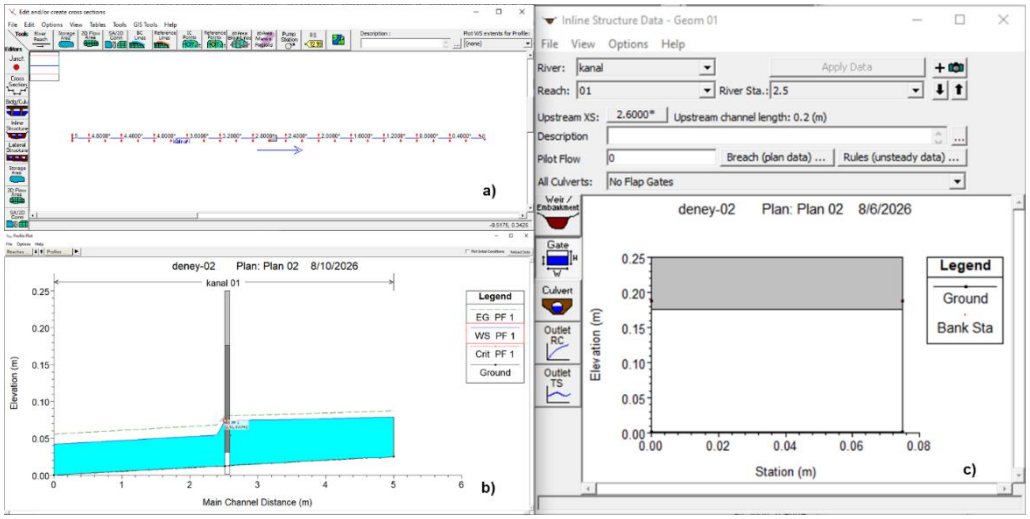

Fig. 7. a) HEC-RAS Model Geometric Data (plan view), b) profile plot and c) Inline structure data window

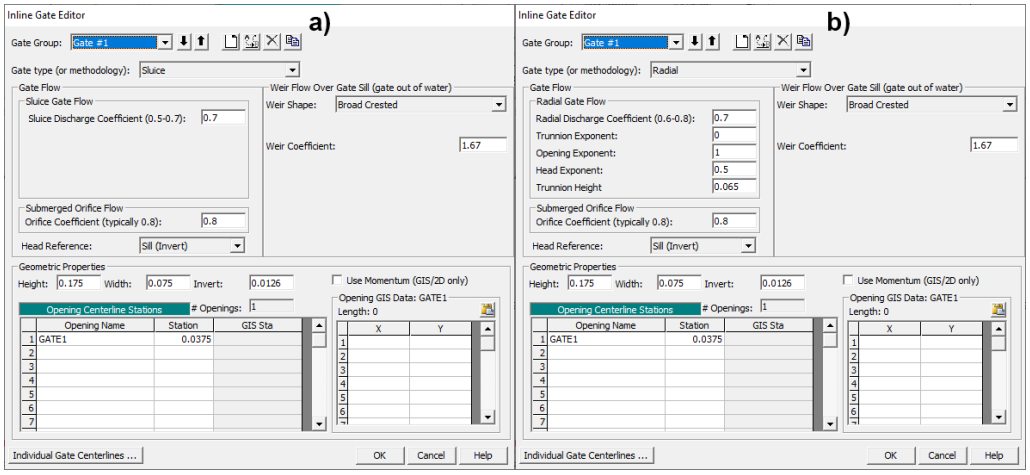

Fig. 8. Comparison of sluice and radial gate editor interfaces in HEC-RAS, a) sluice gate, b) radial gate

The observed discharges (Q1 = 1.64 L/s, Q2 = 1.49 L/s, and Q3 = 1.24 L/s) were prescribed as steady-flow data at the channel inlet. Simulations were executed under mixed flow regime conditions to capture both subcritical and supercritical flow transitions (including hydraulic jumps). The experimentally measured headwater depths and tailwater depths were prescribed as "Known Water Surface Elevations" at the upstream and downstream cross sections, respectively, ensuring that the boundary conditions accurately reflected the physical flume behavior. A total of 27 distinct scenarios were formulated based on discharge, gate opening, and discharge coefficient parameters. Simulation scenarios were named according to the gate type, flow rate, and gate opening configured in the model. The scenario designations based on these parameters are listed in Table 1.

Table 1. Scenario codes, Modeled gate type, discharge, and gate openings

Discharge Coefficient (C_u)	**Discharge (L/s)**	**Gate Openings (mm)**
Cu = 0.70	Q1 = 1.64 L/s	(a): B = 14 mm
Cu = 0.80	Q2 = 1.49 L/s	(b): B = 24 mm
Cu = 0.85	Q3 = 1.24 L/s	(c): B = 34 mm

3 Results and Discussion

3.1 Manning's "n" Calibration Results

Manning roughness calibration results under baseline conditions are shown in Table 2.

Table 2. Manning roughness calibration results under un-gated baseline conditions.

Measured		Calculated			Exact	Relative Error
Discharge Q (L/s)	Depth (mm)	Depth (mm) (n=0.010)	Depth (mm) (n=0.011)	Depth (mm) (n=0.012)	Manning's n (n_{intp})	(n=0.010) (%)
1.50	43	39.48	42.39	45.26	0.0116	8.19%
1.11	32	31.69	33.95	36.17	0.0103	0.97%
1.03	30	29.97	32.09	34.17	0.0100	0.10%
0.69	23	22.45	23.98	25.48	0.0105	2.39%
				Average:	**0.0106**	**2.91%**

As presented in Table 2, the exact interpolated roughness values (n_{intp}) ranged between 0.0100 and 0.0116, yielding a mean Manning coefficient of n_{avg} = 0.0106. Adopting n = 0.010 yielded excellent agreement with experimental depth measurements, with a mean absolute percentage error of only 2.91% and near-perfect predictions for medium-to-low discharges (0.10% error at 1.03 L/s). Consequently, n = 0.010 was selected as the representative bed roughness coefficient for all subsequent gated simulations.

3.2 Water Surface Profile Comparisons Under Various Q and Cu Conditions

To address the overprediction of upstream water depths caused by standard flat-gate assumptions, a systematic sensitivity analysis of the discharge coefficient (C_u) was performed across values of 0.70, 0.80, and 0.85 under different scenarios (Table 3).

Table 3. Measured and HEC-RAS simulated water depths and relative error percentages across different Cu values

Scen.	Discharge (L/s)	Measured			Modelled							
					Cu=0.7		Cu=0.8		Cu=0.85			
		B (mm)	HW (mm)	TW (mm)	HW (mm)	TW (mm)	HW (mm)	TW (mm)	HW (mm)	TW (mm)	HW Err (%)	TW Err (%)
Q1-a	1.64	14	169	43	191.15	41.35	178.55	41.35	168.15	41.35	-0.50%	-3.83%
Q1-b	1.64	24	55	43	82.45	41.85	55.95	41.85	53.45	41.85	-2.81%	-2.67%
Q1-c	1.64	34	55	43	54.85	42.15	56.15	42.15	54.65	42.15	-0.63%	-1.97%
Q2-a	1.49	14	139	38	182.95	37.85	155.95	38.45	137.85	37.85	-0.83%	-0.39%
Q2-b	1.49	24	49	38	67.15	37.95	79.65	38.45	48.95	37.95	-0.10%	-0.12%
Q2-c	1.49	34	49	41	51.45	39.95	68.65	39.45	50.65	39.95	3.37%	-2.55%
Q3-a	1.24	14	96	34	140.95	33.35	107.05	33.35	94.55	33.35	-1.51%	-1.90%
Q3-b	1.24	24	45	34	44.55	34.65	45.75	34.65	44.05	34.65	-2.10%	1.92%
Q3-c	1.24	34	43	36	45.35	36.15	43.15	36.15	42.85	36.15	-0.34%	0.43%
									Average:		**-0.61%**	**-1.23%**

As summarized in Table 3, adopting the conventional sluice gate coefficient (C_u = 0.70) resulted in an overestimation of headwater elevations (HW), as it fails to account for the reduced flow contraction characteristic of cylindrical geometries. Increasing the coefficient to C_u = 0.80 substantially improved the water surface profile agreement. The optimal predictive performance was achieved at C_u = 0.85, yielding near-perfect alignment with physical flume measurements. Under C_u = 0.85, the mean percentage error for upstream headwater (HW) and downstream tailwater (TW) depths was reduced to -0.61% and -1.23%. This demonstrates that

calibrating the discharge coefficient to C_u=0.85 successfully captures the superior hydraulic efficiency and reduced energy head losses of vertically moving cylindrical gates within 1D HEC-RAS formulations.

Fig. 9 illustrates the simulated longitudinal water surface profiles along the 5.0 m flume for the representative discharge Q_2 = 1.49 L/s under three different gate openings (B = 14, 24, and 34 mm) at the calibrated discharge coefficient (C_u = 0.85).

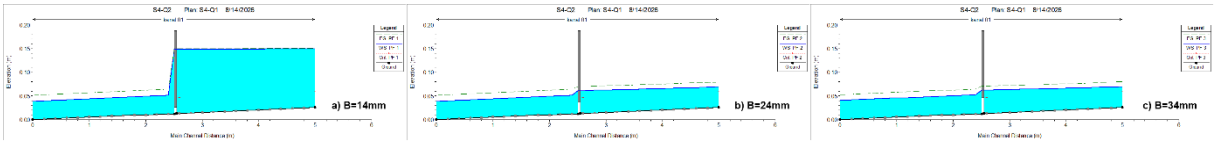

Fig. 9. Profiles for scenarios a) Q2-B=14mm, b) Q2-B=24mm and c) Q2-B=34mm

As observed in Fig 9-a (Scenario Q2-a, B = 14 mm), the constricted gate opening creates a pronounced backwater accumulation upstream (Station 2.5 m to 5.0 m), where the water surface elevates sharply to approximately 137.85 mm. In contrast, downstream of the cylindrical block (Station 0.0 m to 2.5 m), the flow discharges as a supercritical stream before gradually transitioning along the mild slope (S_0 = 0.00506). As the gate opening increases to B = 24 mm (Fig. 9-b) and B = 34 mm (Fig. 9-c), the upstream obstruction is significantly relieved, causing the headwater depth to drop progressively from 137.85 mm to 48.95 mm and 50.65 mm, respectively. This transition highlights that for moderate-to-large gate openings, the cylindrical obstacle exerts minimal choking effects on the channel conveyance capacity, aligning closely with the experimentally recorded water surface profiles.

Fig. 10 illustrates the longitudinal variation of the Froude number (Fr) along the flume for the representative discharge Q2 = 1.49 L/s across three gate openings (B = 14, 24, and 34 mm}$). The abrupt structural transition at the cylindrical inline structure (Station 2.5 m) induces distinct hydrodynamic responses across the channel reaches. For Scenario Q2-a (B = 14 mm, Fig. 10-a), the pronounced upstream backwater accumulation causes a substantial deceleration of flow velocity, resulting in deeply subcritical conditions upstream (Fr = 0.12 - 0.14). As the flow passes beneath the constricted cylindrical opening and discharges downstream (Station 2.4 m to 0.0 m), the velocity accelerates significantly, driving the downstream Froude number up to approximately Fr= 0.83 - 0.85. In contrast, as the gate opening increases to B = 24 mm (Fig. 10-b) and B = 34 mm (Fig. 10-c), the diminished upstream obstruction reduces water depth and accelerates the approach velocity, raising the upstream Froude number to moderate subcritical levels (Fr = 0.60 - 0.68). Across all scenarios, the downstream reach maintains high subcritical to near-critical flow conditions (Fr = 0.82 - 0.85), reflecting stable conveyance behavior under the calibrated Manning roughness (n = 0.010).

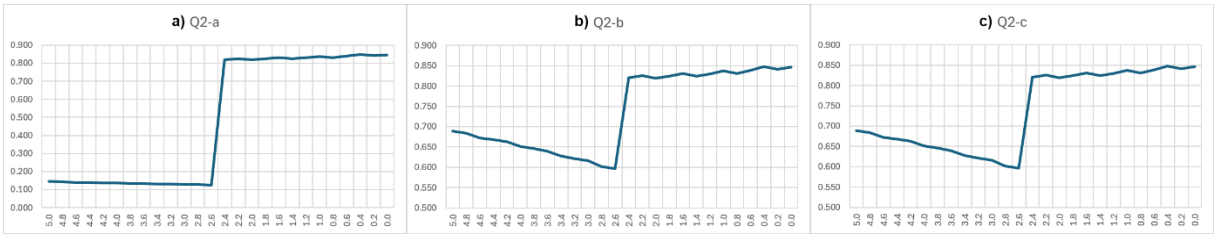

Fig. 10. Froude number distribution along the channel for the scenarios a) Q2-a, b) Q2-b and c) Q2-c

Fig. 11 presents the scatter plots and linear regression relationships between experimentally measured and HEC-RAS simulated water depths for both headwater (HW) and tailwater (TW) across the evaluated discharge coefficients (C_u = 0.70, 0.80 and 0.85). For the upstream

headwater depth (HW, left panel), adopting the standard planar-gate discharge coefficient (C_u = 0.70) resulted in an overestimation slope of y = 1.2334x (R^2 = 0.985). Increasing the coefficient to C_u = 0.80 mitigated this overprediction, improving the regression slope to y = 1.1066x (R^2 = 0.989). The highest degree of correlation and numerical accuracy was achieved at C_u = 0.85, yielding a near-unity slope (y = 0.9928x) and an outstanding determination coefficient (R^2 = 0.999). Conversely, the downstream tailwater depths (TW, right panel) demonstrated consistent, robust agreement across all calibrated coefficients, with regression slopes ranging from y = 0.9853x to y = 0.9869x and determination coefficients exceeding R^2 = 0.999. These regression metrics quantitatively confirm that extending the discharge coefficient to C_u = 0.85 eliminates the artificial upstream head accumulation caused by 1D flat-gate formulations and accurately replicates the physical flow behavior beneath the cylindrical obstacle.

4 Conclusions

In this study, the hydraulic performance and flow characteristics of a vertically moving cylindrical gate were investigated through physical flume experiments and one-dimensional numerical simulations in HEC-RAS. Baseline physical experiments and numerical modeling in the ungated flume demonstrated that a Manning roughness coefficient of n = 0.010 provides excellent agreement with experimental water depths, achieving a mean absolute percentage error of only 2.91%. Under standard theoretical exponents (TE = 0, BE = 1, and HE = 0.5), the HEC-RAS radial gate equation mathematically reduces to the classic planar sluice gate equation. Consequently, adopting the sluice gate methodology in 1D numerical modeling simplifies the computational setup while fully retaining hydraulic validity. Conventional discharge coefficient values recommended for planar sluice gates (Cu = 0.50 - 0.70) significantly overestimate upstream headwater depths (HW) due to exaggerated flow contraction assumptions. Extending the coefficient to Cu = 0.85 successfully captured the streamlined boundary layer and reduced vena contracta effects characteristic of the curved cylindrical surface. At Cu = 0.85, the HEC-RAS model exhibited remarkable agreement with physical measurements across all modeled discharges (Q = 1.24 - 1.64 L/s) and gate openings (B = 14, 24, and 34 mm). The mean relative percentage errors for upstream headwater (HW) and downstream tailwater (TW) were reduced to -0.61% and -1.23%, respectively, with mean absolute errors of less than 1.0 mm and linear correlation coefficients exceeding R^2 = 0.999. The longitudinal Froude number distributions confirmed that the cylindrical obstruction creates

deeply subcritical approach flow upstream (Fr = 0.12 - 0.14) at small openings, which rapidly accelerates to high subcritical and near-critical conditions downstream (Fr = 0.82 - 0.85). Overall, these findings demonstrate that standard 1D HEC-RAS sluice gate formulations can accurately predict the hydraulic behavior of vertically moving cylindrical control structures, provided that the discharge coefficient is calibrated to account for the reduced contraction losses (Cu = 0.85).

Abstract. The frequency and severity of meteorological extremes have increased under climate change conditions. In particular, compound dry hot events caused by the simultaneous occurrence of low precipitation, high temperature, and low relative humidity create significant pressure on hydroclimatic systems. In this study, the spatiotemporal characteristics of compound dry hot stress events were investigated using meteorological stations in Trabzon Province. Monthly precipitation, temperature, and relative humidity data covering the 2012-2025 period were utilized. Compound stress months were identified based on precipitation values below the 25th percentile, temperature values above the 75th percentile, and relative humidity values below the 25th percentile. For the identified compound events, duration, severity, intensity, and peak stress parameters were calculated. In addition, a 90th percentile based rare event frequency analysis was performed to evaluate rare compound event behavior. The SPI-1 benchmark comparison showed that 103 months were jointly detected by both approaches, whereas 46 months were identified only by the compound stress framework. The results indicated that although Trabzon exhibits humid climate characteristics, significant spatial differences exist among the stations in terms of compound stress behavior. Marked differences were observed among the stations in terms of event frequency, duration, severity, and intensity. Higher elevation stations generally exhibited greater compound stress severity and persistence. Rare compound event analysis revealed episodic stress behavior with high severity values at several stations. The findings demonstrate that compound meteorological stress structures may develop even in humid regions and exhibit considerable spatial variability.

1 Introduction

Drought is a natural disaster and climate-related phenomenon that can be observed in any region of the world, and the increasing prevalence of both extreme drought and extreme wet conditions in recent years has further heightened the importance of research in this field [1]. In addition, the simultaneous occurrence of drought and high temperature conditions leads to the formation of compound dry-hot events. Such events can have more severe consequences than the effects of a single drought or heatwave and can challenge the adaptability of natural systems [2,3].

The coverage, quality, and record length characteristics of the data sets used in drought studies directly affect the level of uncertainty in drought index predictions [4,5]. Missing or insufficient data can introduce uncertainty in the representation of drought conditions. Preferences for the dry indicator, threshold, and variable combinations used in compound event analyses can also

create differences in the determined event frequency, severity, and spatial pattern [3]. Therefore, the evaluation of atmospheric dryness indicators along with precipitation deficit and high temperature contributes to a more comprehensive definition of compound stress conditions [8].

In the literature, compound dry-hot events have been evaluated using different temporal scales and variable combinations. Bevacqua et al. [2] have demonstrated the decisive effect of mean precipitation trends on the occurrence of future compound hot-dry events using large ensembles of climate models. Hosseinzadehtalaei et al. [3] have shown that the use of different dry indicators has caused significant changes in the projected event probability and uncertainty results. Wang et al. [6] combined daily SZI and STI values using Copula to develop a daily-scale compound dry-hot index and evaluated the method's applicability across seven different climate regions. Yin et al. [7] examined the vegetation vulnerability under compound heat and drought stress using the Vine Copula approach based on SPI and STI. Zhao et al. [8] have demonstrated the importance of the atmospheric dryness component in compound hazard assessment by evaluating high temperature, low relative humidity, and high wind conditions together.

The aim of this study is to determine the spatial and temporal characteristics of compound dry-hot stress events in the province of Trabzon, which has a humid climate and distinct topographic variability, and to compare the obtained results with SPI-1 based drought conditions. In this context, monthly precipitation, temperature, and relative humidity data for the period 2012-2025 from 17 meteorological stations were used. For compound conditions, it was based on the precipitation value being below the 25th percentile and the temperature value being above the 75th percentile [11]. This bivariate definition has been extended by adding the condition that the relative humidity value is below the 25th percentile to represent the effect of atmospheric dryness [8]. The identified events have been examined using duration, severity, intensity, and peak stress metrics. Additionally, rare event characteristics have been evaluated and elevation dependency analysis has been applied. The original contribution of the study is its expansion of the literature framework based on precipitation deficit and high temperature by incorporating low relative humidity, evaluating compound stress conditions through three meteorological variables, and comparing the obtained results with the SPI-1 benchmark.

2 Materials and Methods

2.1 Study Area and Meteorological Dataset

Trabzon is located on the coast of Turkey's Eastern Black Sea Basin, between the latitudes 40°30′-41°30′ north and the longitudes 38°30′-40°30′ east, and has an area of 4,664 km². The province is characterized by mild climate conditions, where summers are not excessively hot and winters are not excessively cold [9]. A total of 17 meteorological stations located throughout Trabzon were included in the study. The data coverage information for the station codes, observation periods, and the precipitation, temperature, and relative humidity data necessary for compound analysis, calculated from records where these data are present in the same month, is presented in Table 1. Station elevation information was obtained from the Turkish State Meteorological Service together with the station metadata.

Table 1. Characteristics and data coverage of the meteorological stations used in the study

Station	Station code	Elevation m	Observation period	Data coverage %
Trabzon Bölge	17037	25	2012-2025	85.7

2.2 Compound Dry Hot Stress Event Identification and Analysis Framework

Compound dry-hot events are generally defined by the occurrence of dry and hot conditions simultaneously or in close periods [10, 12]. In the identification of these events, percentile-based thresholds that take into account regional climate characteristics are also commonly used alongside absolute thresholds [10]. In a study conducted on a monthly scale, the simultaneous occurrence of precipitation values below the 25th percentile and temperature values above the 75th percentile was considered a compound dry-warm event [11].

Based on this literature framework, in the present study, it was deemed necessary for a month to be classified as a compound dry-hot stress month if the precipitation value is below the 25th percentile, the temperature value is above the 75th percentile, and the relative humidity value is below the 25th percentile simultaneously. Threshold values were calculated separately for each meteorological station and calendar month to account for local and seasonal climate variability effects. Because the percentile thresholds were estimated separately for each calendar month, each threshold was based on approximately 10–14 observations per station depending on data availability. Therefore, some uncertainty may arise from the limited sample size used for monthly percentile estimation. By adding the condition of low relative humidity to the analysis, the traditional precipitation-temperature based bivariate definition was expanded, and the effect of atmospheric dryness was also intended to be represented within the compound stress structure [8]. Months with missing records for any variable were excluded from the evaluation.

In the literature, compound dry-hot events are generally evaluated based on different characteristics such as frequency, severity, duration, and magnitude [10]. In this study, consecutive compound stress months have been grouped as a single compound event. Duration shows the number of consecutive compound months that continue throughout an event. Severity

represents the cumulative stress level during the event, intensity represents the average stress level within the event, and peak stress represents the highest stress level reached throughout the event. These characteristics were used not to create a new index but to compare and summarize the structure of the identified events on a station basis.

For each compound month, the normalized monthly stress score was calculated using the dry, hot, and atmospheric dryness components. The dry component was calculated as the difference between the 25th percentile precipitation threshold and the observed precipitation, normalized by the precipitation interquartile range. Hot component was calculated by dividing the excess of the observed temperature value over the 75th percentile threshold by the temperature interquartile range value. The atmospheric dryness component, on the other hand, is obtained by dividing the difference between the 25th percentile relative humidity threshold and the observed relative humidity by the relative humidity interquartile range value. These three components have been defined to produce a positive stress contribution only in the months when compound conditions occur. The monthly stress score has been calculated as the sum of the three component values. Event severity shows the total of monthly stress score values over consecutive compound months. Event intensity has been calculated as the ratio of the event severity value to the duration value. Peak stress, on the other hand, refers to the highest monthly stress score value obtained during the event.

Station-based event frequency is calculated by expressing the ratio of the number of compound months to the number of valid months for the same station as a percentage. The persistence ratio has been evaluated as the ratio of the number of compound events with a duration value of two months or longer to the total number of compound events. These metrics were used to examine the associations between station elevation and compound stress characteristics.

To compare the results obtained with the compound approach with an independent drought indicator that operates solely on precipitation deficit, SPI-1 was calculated using monthly precipitation data. SPI is based on representing precipitation values with a probability distribution and converting the obtained probability values into a standard normal distribution form [13]. Months with an SPI-1 value of -1 or lower are classified as drought months. The comparison of the compound method and SPI-1 was conducted over the common months where valid data was available for both analyses. The months identified by both methods were defined as overlap months, the months identified only by the compound approach as compound only months, and the months identified only by SPI-1 as SPI only months. The agreement rate has been used to show the overall consistency of the months classified in the same way by both approaches.

WMO recommends at least a 30-year continuous monthly precipitation record for reliable SPI estimation [13]. Due to the current study covering the period from 2012 to 2025, the SPI-1 results have been evaluated not as a long-term drought climatology indicator but as an exploratory benchmark providing a comparison with the compound approach. The SPI-1 comparison was recalculated using the same valid station-month records included in the final compound event analysis.

To determine the upper tail stress conditions among compound events, events where at least one of the severity, intensity, or peak stress metrics exceeds its global 90th percentile threshold value have been classified as rare compound events. This threshold has been used not to produce a long-term return period, but to distinguish the structure of upper tail compound stress events within the current observation period. For each station, rare event count, maximum rare severity, dominant season, and empirical recurrence characteristics within the observation period have been evaluated.

To examine the relationships between topographic variability and compound stress behavior, station elevation was compared with event frequency, event count, total severity, mean intensity, persistence ratio, and rare event count. Pearson correlation was used for linear

association and Spearman rank correlation for monotonic association. The obtained correlations only indicate the level of association between the variables and have not been interpreted as a causal relationship.

3 Results and Discussion

3.1 General Characteristics of Compound Dry Hot Stress Events

The distribution of compound dry hot stress conditions across Trabzon has been evaluated based on station-based occurrence and event characteristics. In the examined period of 2012–2025, a total of 149 compound months were identified for 17 meteorological stations. When consecutive compound months are considered under a single event, a total of 141 compound events have been obtained. The values of valid months, compound months, event count, maximum duration, total severity, and mean intensity on a station basis are provided in Table 2.

Table 2. Station based summary of compound dry hot stress characteristics

Station	Valid months	Compound months	Event count	Max duration	Total severity	Mean intensity
Köprübaşı Beşköy	142	17	15	2	34.539	2.066
Vakfıkebir Hamzalı Köyü	139	12	11	2	22.176	1.883
Maçka Örnekalan Köyü	141	12	11	2	27.955	2.274
Dernekpazarı	142	11	8	4	23.493	1.797
Hayrat Pazarönü	156	12	12	1	21.311	1.776
Çaykara Uzungöl	168	12	11	2	16.251	1.353
Maçka Altındere Sümela	168	11	11	1	15.85	1.441
Sürmene Deniz Bilimleri Enstitüsü	143	8	8	1	15.042	1.88
Beşikdüzü	154	8	8	1	12.084	1.51
Trabzon Havalimanı	167	7	7	1	8.322	1.189
Akçaabat	168	7	7	1	5.665	0.809
Düzköy	154	6	6	1	11.613	1.935
Of Fidanlık	156	6	6	1	9.993	1.665
Arsin	156	6	6	1	10.698	1.783
Çarşıbaşı/Yaroz	140	5	5	1	8.606	1.721
Tonya Kalınçam	158	5	5	1	11.756	2.351
Trabzon Bölge	144	4	4	1	4.586	1.146

The results in Table 2 reveal that the compound stress behavior exhibits significant spatial variability throughout Trabzon. Köprübaşı Beşköy has become the station with the highest occurrence value, with 17 compound months and 15 compound events. The same station ranked first in cumulative stress with a total severity of 34.539. In contrast, the Trabzon Bölge has shown the lowest occurrence value with only four compound months and four events.

It is observed that the station ranking varies according to the used stress metric value. The highest mean intensity value was determined to be 2.351 for the Tonya Kalınçam station, while Maçka Örnekalan Köyü with 2.274 and Köprübaşı Beşköy with 2.066 stood out. In terms of maximum duration, Dernekpazarı stands out with a four-month event compared to the other stations. This result shows that the frequency, duration, severity, and intensity values do not

represent the same compound stress characteristic. In the evaluation of compound dry hot events, considering different event characteristics values together is therefore important [10].

3.2 Severe Compound Event Characteristics

To highlight the most significant stress periods within compound events, they have been ranked according to their severity values. The ten events with the highest severity values are presented in Table 3. This assessment allows for the observation of the difference between cumulative stress resulting from long-duration events and short-duration events that produce high intensity and peak stress.

Table 3. Top severe compound dry hot stress events

Rank	Station	Start	End	Duration	Severity	Intensity	Peak stress
1	Dernekpazarı	2014-03	2014-06	4	12.157	3.039	9.061
2	Köprübaşı Beşköy	2014-03	2014-03	1	9.911	9.911	9.911
3	Vakfıkebir Hamzalı Köyü	2014-03	2014-03	1	7.842	7.842	7.842
4	Maçka Örnekalan Köyü	2020-09	2020-10	2	5.872	2.936	5.312
5	Hayrat Pazarönü	2012-11	2012-11	1	5.583	5.583	5.583
6	Arsin	2012-11	2012-11	1	5.172	5.172	5.172
7	Maçka Örnekalan Köyü	2014-02	2014-02	1	5.084	5.084	5.084
8	Tonya Kalınçam	2012-11	2012-11	1	4.887	4.887	4.887
9	Köprübaşı Beşköy	2020-09	2020-10	2	3.956	1.978	2.722
10	Maçka Örnekalan Köyü	2023-10	2023-10	1	3.724	3.724	3.724

The highest event severity during the examined period was determined for the Dernekpazarı station between March 2014 and June 2014. This four-month event reached values of 12.157 severity, 3.039 intensity, and 9.061 peak stress. The single monthly event determined for the Köprübaşı Beşköy station in March 2014 produced a severity of 9.911 and the same value of intensity with peak stress. When these two results are evaluated together, it is observed that the cumulative severity value is dependent not only on the peak stress level but also on the event duration characteristic.

In the March 2014 period, the simultaneous occurrence of high severity values at the Dernekpazarı, Köprübaşı Beşköy, and Vakfıkebir Hamzalı Köyü stations is noteworthy. Similarly, severe compound events were identified at the Maçka Örnekalan Village and Köprübaşı Beşköy stations during the September and October 2020 period. The structure observed during the same periods at different stations may indicate the influence of larger-scale meteorological conditions. However, since atmospheric circulation or synoptic pattern analysis was not conducted in the study, this situation has not been evaluated as a causal relationship.

Among the single-month events, the Köprübaşı Beşköy, Vakfıkebir Hamzalı Köyü, Hayrat Pazarönü, Arsin, and Tonya Kalınçam stations stood out with high intensity values. In contrast, the long duration of the Dernekpazarı event value has been decisive in producing high severity.

Therefore, in the evaluation of severe compound stress, it is more balanced to examine not only the maximum or mean values but also the duration, severity, intensity, and peak stress characteristics together [10].

3.3 Comparison with SPI Based Drought Conditions

The relationship between the stress months determined by the compound framework and the SPI-1 drought conditions based solely on the precipitation variable has been evaluated comparatively. The purpose of this comparison is to reveal the extent to which the two approaches identify the same stress condition together and in which periods they differ. In this context, only common station-month records with valid precipitation, temperature, and relative humidity data for both analyses were considered. The overlap, compound only, SPI only, and overall agreement values for the compound framework and SPI-1 results are presented in Table 4.

Table 4. Simplified comparison between compound method and SPI-1

Metric	Value	Interpretation
Common station month records	2596	Months with valid data for both approaches
Compound months	149	Low precipitation, high temperature and low relative humidity occurred together
SPI-1 drought months	442	Precipitation based drought months
Overlap months	103	Both approaches detected stress
Compound only months	46	Compound stress detected without SPI-1 drought classification
SPI only months	339	Precipitation deficit without simultaneous compound atmospheric stress
Overall agreement %	85.2	General monthly agreement level

As a result of the SPI-1 benchmark analysis, 442 drought months were identified within the common station month records, while the compound framework defined 149 compound months. Both approaches showed a common stress condition for 103 months. Accordingly, approximately 69.1% of the compound months overlap with the SPI-1 drought classification, while 46 months, or about 30.9%, are identified solely by the compound framework.

In 339 out of the 442 months classified as drought by SPI-1, compound conditions did not occur simultaneously. This result stems from the fundamental conceptual difference between the two approaches. While SPI-1 determines drought conditions solely based on precipitation anomaly, the compound framework is based on the simultaneous occurrence of low precipitation, high temperature, and low relative humidity conditions in the same month. Therefore, compound only months should not be interpreted as drought events missed by SPI-1. Similarly, SPI only months are not events missed by the compound framework either. Two methods evaluate different hydroclimatic stress structures.

Overall agreement has been calculated as 85.2%. However, this value should not be considered as a standalone method agreement indicator since it includes both event and non-event classification values together. The joint evaluation of overlap, compound only, and SPI only results is more explanatory. Additionally, SPI-1 has been calculated using precipitation records only from the period 2012–2025. Since the longer observation period condition recommended by the WMO was not met, the SPI-1 results were used not as an indicator of long-term drought climatology but solely for exploratory benchmarking purposes [13].

3.4 Rare Compound Event Characteristics

In order to evaluate the upper tail stress structure among compound events, rare event characteristics have been examined. Severity, intensity, or peak stress metrics values exceeding the global 90th percentile threshold value were classified as rare compound events. A total of 17 rare compound events were identified during the observation period, and these events were observed at nine different stations. The station-based rare event count, maximum rare severity, and dominant season are provided in Table 5.

Table 5. Rare compound event characteristics during the 2012-2025 observation period

Station	Rare events	Max rare severity	Dominant rare season
Köprübaşı Beşköy	4	9.911	Autumn
Dernekpazarı	2	12.157	Spring
Maçka Örnekalan Köyü	3	5.872	Autumn
Vakfıkebir Hamzalı Köyü	1	7.842	Spring
Tonya Kalınçam	2	4.887	Autumn
Hayrat Pazarönü	1	5.583	Autumn
Arsin	1	5.172	Autumn
Sürmene Deniz Bilimleri Enstitüsü	2	3.642	Spring
Of Fidanlık	1	3.035	Autumn

In terms of rare event frequency, Köprübaşı Beşköy ranks first with four events, while Maçka Örnekalan Village ranks second with three events. Two rare events have been identified for the Dernekpazarı, Tonya Kalınçam, and Sürmene Marine Sciences Institute stations. In contrast, one rare event was observed for the Vakfıkebir Hamzalı Köyü, Hayrat Pazarönü, Arsin, and Of Fidanlık stations. In terms of maximum rare severity, Dernekpazarı reached the highest value with 12.157. Although Köprübaşı Beşköy produced more rare events, the maximum rare severity value was determined to be 9.911. This difference shows that the rare event frequency and rare event magnitude values do not represent the same risk characteristic.

When evaluating the seasonal distribution, Autumn was determined to be the dominant season in six out of the nine station values, while Spring was the dominant season in three. The fact that the rare compound stress structure is not limited to Summer can be explained by the relative threshold approach used. Since threshold values are calculated separately for each calendar month, the definition of a month as hot or dry is based on the local distribution characteristics of that month rather than the absolute climate value. Therefore, conditions of high temperature, low precipitation, and low relative humidity according to seasonal norms can also create compound stress during the Spring or Autumn periods.

3.5 Elevation Dependency of Compound Stress Metrics

To evaluate the relationship between Trabzon's distinct topographic variability and compound stress characteristics, associations between station elevation and frequency, event count, total severity, mean intensity, persistence ratio, and rare event count were examined. Linear relationships were evaluated using Pearson correlation, while monotonic relationships were assessed using Spearman rank correlation. The obtained correlation coefficients and significance levels are presented in Table 6.

Table 6. Relationship between elevation and compound stress metrics

Metric	Pearson (r)	Pearson (p)	Spearman (rho)	Spearman (p)	Interpretation
Frequency (%)	0.570	0.017	0.452	0.068	positive linear association with $p<0.05$
Event count	0.551	0.022	0.462	0.062	positive linear association with $p<0.05$
Total severity	0.629	0.007	0.681	0.003	positive association with $p<0.05$
Mean intensity	0.521	0.032	0.458	0.064	positive linear association with $p<0.05$
Persistence ratio	0.604	0.010	0.562	0.019	positive association with $p<0.05$
Rare events	0.366	0.148	0.239	0.355	positive but not significant

Given the exploratory nature of the elevation analysis and the limited number of stations, p values were interpreted without adjustment for multiple comparisons and should therefore be considered exploratory. Positive correlation coefficients were obtained between elevation and all compound stress metrics examined in Table 6. Pearson correlation indicated positive associations with $p<0.05$ for frequency, event count, total severity, mean intensity, and persistence ratio. The strongest linear relationship was observed for total severity with $r=0.629$ and $p=0.007$, followed by persistence ratio with $r=0.604$ and $p=0.010$. Frequency, event count, and mean intensity also showed moderate positive linear associations with elevation.

Spearman rank correlation produced a similar but more selective pattern. Total severity showed the strongest monotonic association with elevation with $rho=0.681$ and $p=0.003$. Persistence ratio was also positively associated with elevation with $rho=0.562$ and $p=0.019$. In contrast, the Spearman relationships for frequency, event count, and mean intensity did not reach the $p<0.05$ level. These differences indicate that some elevation relationships are more evident in their linear structure than in their rank-based pattern.

Rare event count showed positive but statistically non-significant relationships with elevation in both correlation approaches. Overall, the results suggest that higher elevation stations tended to exhibit greater cumulative severity, persistence, and, to some extent, higher compound event occurrence and intensity. Nevertheless, elevation should not be interpreted as an independent causal factor because distance to coast, slope, aspect, local exposure, and atmospheric circulation were not controlled in the present analysis.

4 Conclusion

In this study, compound dry hot stress events were examined for 17 meteorological stations in Trabzon province using precipitation, temperature, and relative humidity data from the period 2012–2025. Compound conditions were defined as the simultaneous occurrence of precipitation values below the 25th percentile, temperature values above the 75th percentile, and relative humidity values below the 25th percentile. A total of 149 compound months and 141 compound events were identified during the examined period. Station-based results have shown that the compound stress characteristics are not homogeneous throughout Trabzon. While Köprübaşı Beşköy stands out in terms of occurrence and total severity, Dernekpazarı has drawn attention with the individual event that has the longest duration and the highest severity value. The highest mean intensity was determined for the Tonya Kalınçam station.

As a result of the benchmark comparison with SPI-1, 103 months were jointly identified by both approaches, while 46 months were defined only by the compound framework. This

difference indicates that the compound approach and the SPI-1 method represent different stress structures. The compound framework takes into account the simultaneous effects of high temperature and low relative humidity conditions alongside the precipitation deficit. However, due to the calculation of SPI-1 results over a 14-year observation period, these results have been evaluated not for the purpose of long-term drought climatology but solely as a comparative benchmark.

A total of 17 rare compound events have been identified within the scope of the rare event analysis. Rare events were predominantly observed during the Autumn and Spring periods, with the highest rare event frequency recorded at the Köprübaşı Beşköy station. Elevation analysis showed positive associations between station elevation and several compound stress characteristics. The most consistent relationships were obtained for total severity and persistence ratio, which showed positive associations with $p<0.05$ in both Pearson and Spearman analyses. Frequency, event count, and mean intensity also showed positive linear associations with elevation, whereas rare event count was not statistically significant. These findings indicate that elevation may contribute to the spatial differentiation of compound stress behavior, although it should not be interpreted as an independent causal mechanism.

The obtained results show that the characteristics of a humid climate do not completely eliminate the formation of compound meteorological stress. The joint evaluation of precipitation, temperature, and atmospheric dryness conditions provides complementary information to the classical precipitation-based drought assessment approach. However, the relatively short observation period and the limited sample size available for calendar-month percentile estimation, together with station-based spatial representation and unexamined atmospheric circulation effects, constitute the main limitations of the study. Studies conducted using longer meteorological records and more detailed spatial data can contribute to a more comprehensive evaluation of the long-term and spatial structure of compound stress behavior characteristics.

Acknowledgments

The authors would like to thank the Turkish State Meteorological Service for providing the meteorological data used in this study.

Abstract. Accurate partitioning of green and blue water components in agricultural water footprint assessments is critical for water management decisions. Effective rainfall, as a key determinant of this partitioning, directly influences green water contribution estimates and, consequently, freshwater (blue water) demand. In this study, the virtual water content of wheat production in Türkiye was calculated, and the effects of three widely used effective rainfall methods — CROPWAT, USDA-SCS, and Dependable Rain — on the results were comparatively evaluated. The CROPWAT method, which is generally preferred in literature, was adopted as the reference. The green virtual water content of wheat was estimated at 1,282 m³/t using CROPWAT, while USDA-SCS and Dependable Rain yielded 584 m³/t and 566 m³/t, respectively. Both methods produced estimates approximately 54% and 56% lower than CROPWAT, with the national-scale difference reaching 698–716 m³/t. Spatial analyses revealed that deviations increase markedly in regions with limited precipitation, reaching 60–70% around Şanlıurfa under the USDA-SCS approach. The findings demonstrate that effective rainfall method selection constitutes a significant source of uncertainty in agricultural water footprint calculations. Developing locally calibrated approaches that adequately represent Türkiye's diverse hydro-climatic conditions is therefore a priority for improving the reliability of national-scale water footprint analyses.

Keywords: Uncertainty analysis, Effective rainfall approaches, Green water, Türkiye

1 INTRODUCTION

The water footprint (WF) concept quantifies the direct and indirect volumes of water consumed along the production chain of a commodity, thereby providing a holistic assessment of water use that extends beyond conventional water withdrawal measures. Within this framework, water consumption is examined under three principal components: blue water, which denotes irrigation water supplied from surface and groundwater resources; green water, which originates from precipitation and is stored within the crop root zone; and grey water, which represents the associated pollution load. This distinction is particularly critical for agricultural water management, as it enables the irrigation water requirement to be separated from the contribution of precipitation to crop water consumption. The boundary between the blue and green water components is, to a large extent, defined through the concept of effective rainfall (P_{eff}).

According to the FAO definition, effective rainfall refers to the portion of precipitation that contributes to crop production at the location where it falls, without requiring any additional energy input for pumping or conveyance [2]. In practical terms, the concept represents the fraction of rainfall that is temporarily stored in the soil and thus becomes available within the

crop root zone. P_{eff} is therefore a decisive variable in partitioning the blue and green water components in WF assessments, and its accurate estimation is directly critical to the reliability of the resulting calculations.

Direct measurement of P_{eff} under field conditions is nevertheless highly limited, owing to its considerable cost, time and data requirements. Consequently, empirical and semi-empirical approaches are predominantly preferred in practice [5]. Water balance methods, although theoretically more accurate, are impractical for large-scale analyses because they depend on numerous parameters such as evapotranspiration, infiltration, deep percolation and soil hydraulic properties [5]. This situation has led to the widespread use of a variety of effective rainfall estimation methods; however, the structural differences among these methods may generate substantial deviations in net irrigation water requirements and, accordingly, in green WF estimates. Bokke and Shoro [1] demonstrated that irrigation water requirement results vary significantly depending on the method employed. Similarly, Hess [3], in a study conducted at the scale of the United Kingdom, showed that the choice of effective rainfall model considerably affects green WF calculations. Despite this, the vast majority of large-scale water footprint studies in the existing literature adopt the CROPWAT approach directly, without any comparison of methods [3]. This points to the need for a systematic examination of the uncertainty introduced by effective rainfall model selection.

Motivated by this gap, the present study comparatively analyses the influence of the FAO-CROPWAT, USDA-SCS and Dependable Rain methods on wheat agricultural WF calculations at the district scale across Türkiye. Owing to its widespread use in literature, the CROPWAT method is adopted as the reference approach, and the results obtained from the remaining methods are evaluated within this framework. The principal objective of the study is to quantify the uncertainty that effective rainfall model selection introduces into national-scale agricultural water footprint estimates, and to map the spatial pattern of this uncertainty at the district level.

2 MATERIALS AND METHODS

This study was carried out across Türkiye at the district scale and focuses on the green water component of the agricultural WF of wheat, which is the most widely cultivated crop in the country in terms of harvested area.

The analyses were based on meteorological records covering the period 2020–2024, obtained from the Turkish State Meteorological Service upon official request [9]. Precipitation, relative humidity, solar radiation, wind speed, and minimum and maximum air temperature were compiled for each station and used as input to the calculations. Reference evapotranspiration (ET_0) was computed using the FAO Penman–Monteith equation. Wheat yield data for the same period were obtained from the Turkish Statistical Institute [10]. All calculations were performed at the district level, and the resulting values were aggregated to the provincial and national scales for comparative evaluation.

The green virtual water content was computed following the Water Footprint Assessment Manual [4], based on the relationship between crop water use and crop yield (Equation 1). Here, VWC_{green} (m^3/t) denotes the green virtual water content, CWU_{green} (m^3/ha) the green water use of the crop, and Y (t/ha) the crop yield.

$$VWC_{green} = CWU_{green} / Y \quad (1)$$

Crop water use (CWU) represents the total evapotranspiration occurring over the growing period of the crop, whereas CWU_{green} refers to the precipitation-derived fraction of this total consumption (Equation 2).

$$CWU_{green} = 10 \times \sum_{d=1}^{n} ET_{green} \quad (2)$$

Precipitation-derived evapotranspiration (ET_{green}) is determined through the relationship between total crop water requirement (ET_c) and P_{eff} (Equation 3). Accordingly, when soil moisture is sufficient to meet the water requirement of the crop, ET_{green} is taken as equal to the ET_c value of the corresponding time period. Conversely, under conditions of insufficient soil moisture, ET_{green} is constrained by the amount of water available in the root zone.

$$ET_{green} = MİN\left(ET_c, P_{eff}\right) \quad (3)$$

Effective rainfall denotes the portion of precipitation that is stored in the crop root zone and becomes directly available to the plant without any contribution from irrigation. In this study, P_{eff} was computed using different methods and the results were evaluated comparatively. In the CROPWAT method, P_{eff} is calculated through distinct empirical equations depending on whether total monthly precipitation falls below or above a threshold of 250 mm (Equations 4 and 5) [6].

$$P_{eff} = \frac{P\left(125 - 0.2P\right)}{125} \quad \text{if} \quad P \leq 250 \text{ mm} \quad (4)$$

$$P_{eff} = 125 + 0.1P \qquad \text{if} \quad P > 250 \text{ mm} \quad (5)$$

One of the alternative approaches, the USDA-SCS method, is an empirical model developed on the basis of long-term precipitation records from the United States [7]. In this method, the estimation of effective rainfall depends not only on the amount of precipitation but also on the ET_c parameter representing crop water requirement, and it additionally incorporates a storage factor (SF) determined by the usable soil water depletion depth D (mm) (Equations 6 and 7). This dependency indicates that the method may introduce additional uncertainty into the results when applied to climatic regions other than those for which it was developed.

$$P_{eff} = 25.4 \times SF \times \left[\left(0.70917 \times \frac{P}{25.4} \right)^{0.82416} - 0.11556 \right] \times \left(10^{0.02426 \times ET_c}\right) \quad (6)$$

$$SF = 0.531747 + 0.11620D - 0.000089394D^2 + 0.0000002318D^3 \quad (7)$$

The Dependable Rain method is a further empirical approach based on the classification of monthly precipitation according to specified threshold values. In this method, effective rainfall is calculated using two different equations depending on whether monthly precipitation falls below or above a threshold of 70 mm (Equations 8 and 9).

$$P_{eff} = 0.6P - 10 \quad \text{if} \quad P \leq 70 \text{ mm} \quad (8)$$

$$P_{eff} = 0.8P - 24 \text{ if } P>70 \text{ mm} \quad (9)$$

Within this scope, the effects of the effective rainfall values obtained from the CROPWAT, USDA-SCS and Dependable Rain methods on the green water footprint component were analysed comparatively at the district scale across Türkiye.

3 RESULTS AND DISCUSSION

Figure 1 presents the district-scale distribution of the percentage deviation of the effective rainfall values obtained from the USDA-SCS (a) and Dependable Rain (b) methods relative to the CROPWAT method. The results reveal that both empirical methods systematically produce lower effective rainfall values than CROPWAT throughout Türkiye. This pronounced reduction in effective rainfall estimates is directly reflected in the green water footprint results: the green VWC of wheat, determined as 1,282 m³/t on average across Türkiye using the CROPWAT method, decreased to 584 m³/t and 566 m³/t with the USDA-SCS and Dependable Rain methods, respectively, corresponding to reductions of approximately 54% and 56%. These findings are consistent with literature. Mohan et al. [5] reported that the USDA-SCS method tends to underestimate effective rainfall, while Hess (2010) [3] demonstrated that the CROPWAT method yields results relatively closer to those of water balance approaches. Likewise, Muratoğlu et al. [6], in a comparative study based on field data, showed that the CROPWAT method provides more consistent estimates, whereas the USDA-SCS and Dependable Rain methods systematically underestimate effective rainfall.

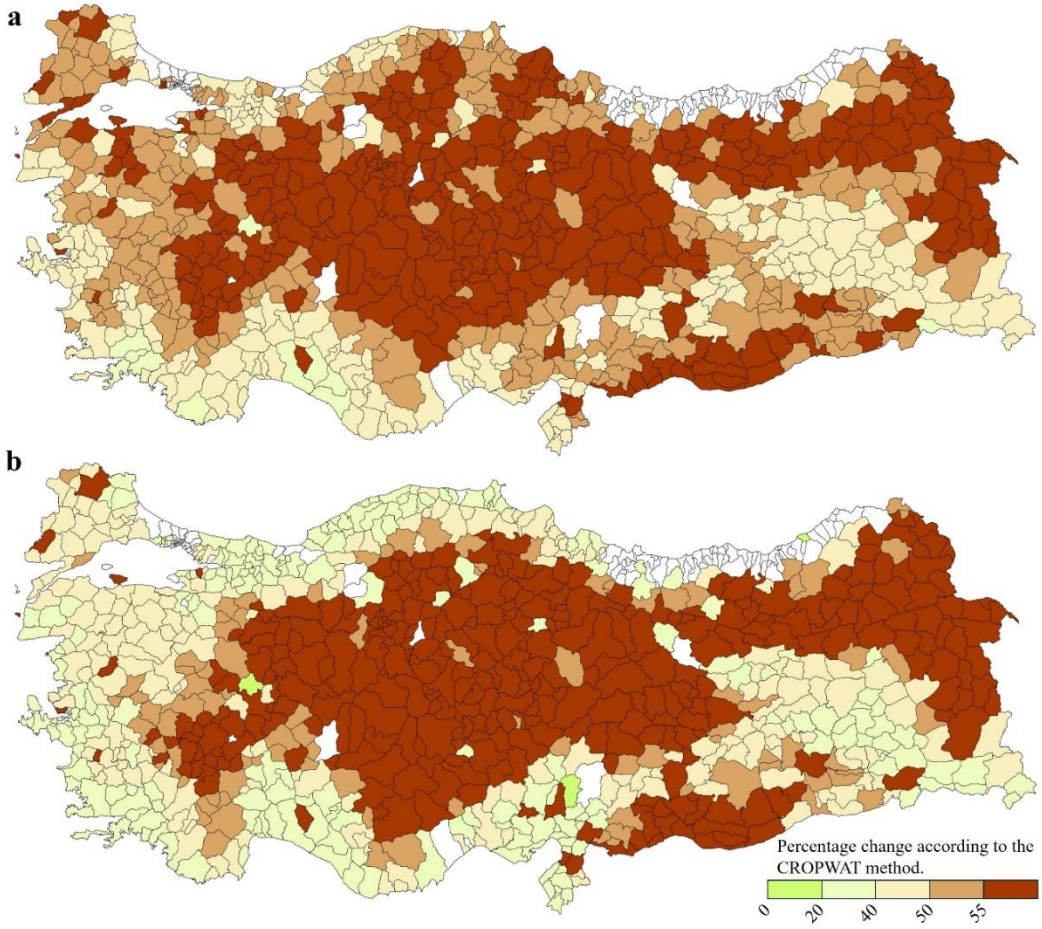

Figure 1. Spatial distribution of the percentage deviations in effective rainfall values obtained from the USDA-SCS (a) and Dependable Rain (b) methods relative to the reference CROPWAT method

An examination of the spatial distribution shows that both alternative methods deviate markedly from the CROPWAT results in Central Anatolia, along the southern border belt and in the north-eastern regions, whereas the deviations remain proportionally more limited in coastal provinces such as Antalya, Muğla and Zonguldak. Where total precipitation is high, as in the coastal areas, the proportional difference between the values produced by the methods diminishes; under the low-precipitation conditions of the interior, however, the influence of the differences between the underlying equations becomes pronounced. In particular, the low-threshold linear relationships employed in the Dependable Rain method suppress effective rainfall dramatically during dry periods, thereby maximising the deviation from CROPWAT. This finding is in agreement with the observations of Saracoglu and Kaynar [8], who emphasised that discrepancies between models may increase in areas characterised by high regional climate variability.

The structural origins of the methods constitute a further important factor explaining the observed deviations. The USDA-SCS method rests on an empirical approach developed using long-term data representative of the climatic conditions of the United States, and it estimates effective rainfall through a function that depends not only on the amount of precipitation but also on crop water requirement (ET_c) (Equations 6–7). This structural characteristic provides the basis for the method to diverge markedly from CROPWAT and to produce inconsistent results, particularly in arid climatic regions with high evaporative demand [7]. The Dependable Rain method, by contrast, has a comparatively simpler parameter structure (Equations 8–9). The fact that all of the methods analysed — including the reference CROPWAT approach — rely on empirical relationships that have not been specifically calibrated for the conditions of Türkiye is the fundamental reason for the pronounced deviations and the methodological uncertainty observed.

At the provincial level, Malatya, Iğdır, Sivas and Şanlıurfa were identified as the provinces exhibiting the largest deviations from CROPWAT for both methods. In these provinces, the deviations between the USDA-SCS and Dependable Rain methods themselves also remain high, indicating that empirical models may diverge substantially from one another under semi-arid geographical conditions. Conversely, it is noteworthy that the two methods display their highest mutual agreement in the province of Ardahan.

Overall, the empirical methods examined can deviate considerably both from one another and from the CROPWAT method taken as the basis for comparison. The sensitivity of effective rainfall — one of the principal inputs of agricultural WF calculations — to method selection points to a significant source of uncertainty and supports the need to develop effective rainfall models calibrated with local data that account for the diverse climatic and topographic conditions of Türkiye.

4 CONCLUSION

This study quantified, at the national scale, the uncertainty that the choice of effective rainfall method introduces into agricultural WF estimates. The USDA-SCS and Dependable Rain methods were found to produce systematically lower effective rainfall values than the reference CROPWAT approach, reducing the green virtual water content of wheat by approximately 54% and 56%, respectively. Rather than being uniformly distributed, these deviations intensified in semi-arid and low-precipitation districts and narrowed along the humid coastal margins, indicating that the choice of method affects not only the magnitude of the estimates but also

their spatial pattern — a consideration of direct relevance where water footprint results are intended to inform basin- or province-level allocation decisions.

The magnitude of these discrepancies is attributable primarily to the fact that none of the methods examined, including CROPWAT, rests on relationships calibrated for the hydro-climatic conditions of Türkiye. Two limitations should be acknowledged in interpreting the results. First, the analysis was confined to a single crop and to the green water component; the propagation of the same uncertainty into blue water and, consequently, into irrigation water requirement estimates remains to be examined. Second, in the absence of measured reference values, the comparison was made relative to CROPWAT rather than against observations, so the reported deviations express inter-method divergence rather than error.

Future work should therefore extend the comparison to the principal irrigated crops and to the blue water component, and should evaluate the examined methods against soil moisture observations or water balance measurements representative of Türkiye's main agro-climatic zones. Such evidence would provide the basis for locally calibrated effective rainfall relationships and, in turn, for more reliable national-scale water footprint assessments.

Abstract. At river confluences, interactions among hydrodynamics, sediment transport, and morpho-dynamics result in changes to bed topography, posing significant risks such as flood, bank erosion, and problems for navigation. Hence, controlling the flow structure and bed morphology in confluence is essential for mitigating or preventing associated risks. This study experimentally investigated the equilibrium bed morphology of a river confluence equipped with a guiding wall designed to prevent the immediate mixing of tributary flows. The experiment was conducted in the large-scale open-channel at the İzmir Kâtip Çelebi University Hydraulics Laboratory, where two symmetrical tributaries merged at a at a 45˚ junction angle into this main channel. Flow was supplied only through the right tributary at a discharge of 15 L/s. The flow depth was adjusted at 5.0 cm over a 21.0 cm sand layer. Bed topography was measured at regular intervals along the cross-section located 5 cm downstream of the guiding wall (x = 105 cm) until equilibrium conditions were reached (t = 167 h). The equilibrium bed morphology was obtained using a Vectrino probe (ADV). According to results, the expected scour at the confluence formed at the tip of the guiding wall. Scour depth increased rapidly during the early stages but gradually slowed as equilibrium was approached. Eroded sediment from the scour hole deposited in the downstream region. With flow supplied only through the right tributary, no significant changes occurred on the left side of the guiding wall or within 30 cm of the left bank, whereas a distinct deposition zone formed along the right bank, extending downstream.

Keywords: Open channel confluence; Sediment transport; Guiding wall; Morphological structure.

1 Introduction

Confluences are locations where two or more open-channels with the equal or different water and sediment discharge rates merge into a single downstream channel, Confluences are rather common features in natural rivers and artificial systems of open-channels [1].

River confluences can display symmetrical or asymmetrical planforms, depending on the angle between the two converging channels and their orientation in relation to the downstream channel (Fig. 1).

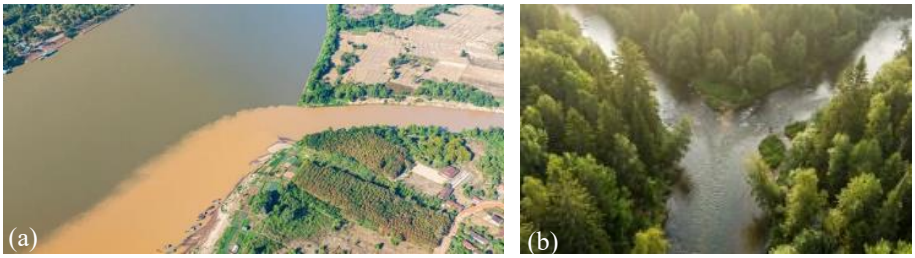

Fig. 1. River confluences: (a) asymmetric; (b) symmetric [2]

At river confluences, hydrodynamic processes and sediment transport mechanisms are strongly interrelated, with each influencing and altering the other. The interaction between flow dynamics within the confluence zone and sediment transport patterns governs the evolution of bed morphology [3-4], while the resulting morphological changes, in turn, affect the local hydrodynamic conditions. Due to these complex and dynamic interactions, river confluences may present significant challenges, including increased risks of flooding, bank erosion, navigation problems, and potential threats to structural safety of bridges or other nearby structures. Given these risks and the widespread occurrence of river confluences, a comprehensive understanding of the flow structure and sediment transport mechanisms in the confluence zone is of significant importance [5].

Therefore, river confluences represent critical environments for both scientific investigations and engineering applications.

In the existent first studies on river confluences, Taylor [6] studied the confluence hydrodynamics of confluent rigid-bed open channels. Advances in measurement techniques and computational technology have substantially improved the understanding of flow structure, sediment transport, and bed evolution at river confluences, leading to a significant increase in experimental and numerical studies since the 1980s. The first comprehensive experimental investigation of mobile-bed river confluences was conducted by Mosley (1976), who examined a small-scale experimental set-up both symmetric and asymmetric confluences under different junction angles, discharge ratios, and sediment supply conditions [7]. The study demonstrated that these parameters strongly influence the development of scour and deposition patterns, showing that increasing sediment supply significantly reduced scour depth in both confluence configurations. Subsequently, Best (1988) investigated sediment transport processes in laboratory and natural river confluences with junction angles ranging from 15° to 105°. The experiments revealed that scour depth increased with increasing junction angle and led to the first conceptual model describing the characteristic bed morphology of mobile-bed river confluences [8].

The conceptual morphological model of natural symmetric and asymmetric mobile-bed river confluences, established on the based on extensive laboratory and field investigations (Fig. 2).

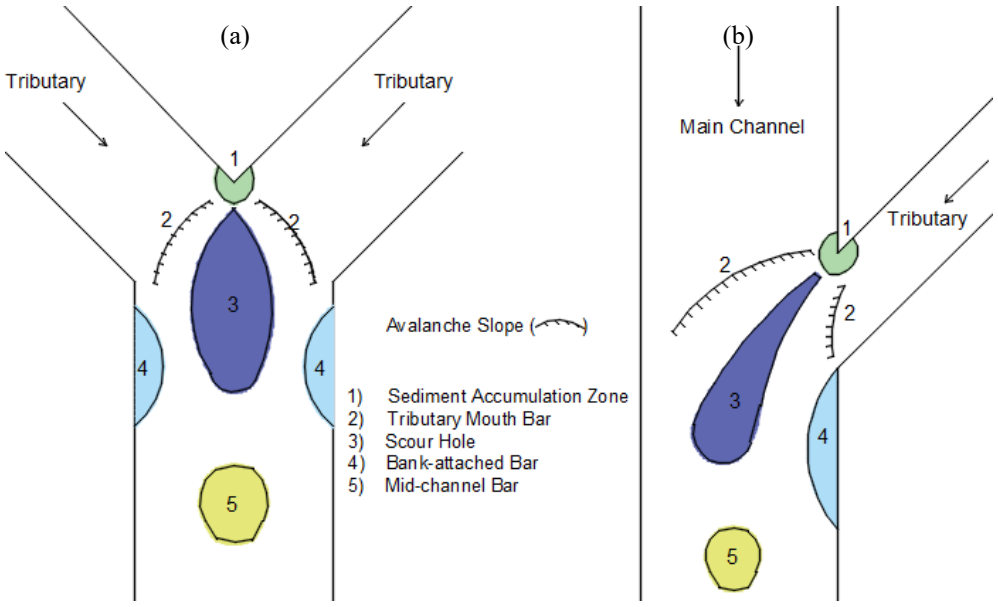

Fig. 2. Bed morphology at open-channel confluences, (a) symmetrical, (b) asymmetrical

The characteristic bed morphology generally consists of all or most of the following features: a sediment accumulation zone (underneath a flow stagnation zone) at the vertex of the junction;

two tributary mouth bars or a main channel bar and a tributary mouth bar (depending on the type of planform); a scour hole (in most cases); one or two bank attached bars (also depending on the type of planform); and a downstream mid channel bar (in some cases) [7,8]. These morphological features are formed as a result of the complex interactions between flow structure and sediment transport processes within river confluences.

Bombar and Cardoso (2020) confirmed that asymmetric mobile-bed confluences are characterized by several distinct morphological features, including scour corridors, tributary mouth bars, and deposition bars [9]. Rhoads and Sukhodolov (2004) demonstrated that sediment eroded from the scour hole is transported and deposited downstream in regions of reduced flow velocity and turbulence intensity [10]. More recently, Öztürk et al. (2022) experimentally investigated the temporal evolution of bed morphology in a symmetric mobile-bed river confluence and reported that both scour holes and deposition zones continued to develop until equilibrium conditions were approached [11].

Numerous experimental and numerical studies have confirmed that scour holes and deposition zones are the dominant morphological features of river confluences. Because excessive scour degrades aquatic habitats, deteriorates water quality, and threatens the stability of hydraulic structures, while excessive sediment deposition reduces channel conveyance capacity and increases flood risk during high-flow events, therefore, controlling the hydro-morpho-dynamic processes occurring at river confluences is of considerable importance for both river engineering applications and sustainable river management. For this purpose, flow-training structures, such as submerged vanes, pile groups, and guiding walls, have been widely employed at river confluences as effective, economical, and low-maintenance measures for modifying the flow pattern and controlling scour and sediment deposition.

The use of river-training structures to control scour and sediment deposition at river confluences has received increasing attention over the past decades. Odgaard and Wang (1991) first demonstrated that submerged vanes could improve navigation by redirecting the flow from the scour region toward downstream deposition zones, thereby reducing scour and enhancing sediment transport [12]. Subsequently, Wuppukondur and Chandra (2015), experimentally investigated the performance of pile groups and submerged vanes in asymmetric river confluences and reported that their geometry and arrangement significantly influenced scour depth, bed morphology, and local scour around the structures [13]. More recently, Ali et al. (2019) numerically evaluated different submerged vane configurations and showed that vane orientation plays a key role in controlling scour and deposition, with vanes installed at 30° providing better performance than those installed at 15° [14].

Despite the extensive research on scour control at river confluences, previous studies have primarily focused on asymmetric confluences. Therefore, there is still limited knowledge regarding the bed morphology of symmetric river confluences incorporating a guiding wall. To address this research gap, the present study experimentally investigates the downstream bed morphology of a large-scale symmetric mobile-bed river confluence, where a guiding wall prevents the converging flows from the two tributaries from merging immediately at the confluence vertex.

2 Experimental Study

The experimental study was conducted in the large-scale open channel located at the Hydraulics Laboratory of İzmir Kâtip Çelebi University.

2.1 Experimental Set-up

The experimental set-up was a large symmetrical confluence which consisted of two rectangular tributary channels merging into an equally rectangular, wider, downstream main channel (see Figure 3 and Figure 4). Both tributaries were 4.9 m long and 1.0 m wide, whereas

the main channel was 6.5 m long and 2.0 m wide, the lateral walls of these channels being 0.9 m high. They were made of smooth concrete, the same as their horizontal bottom. The junction angle between the two tributaries was 90°, and its bisectrix was aligned with the longitudinal axis of the downstream main channel (see Figure 4).

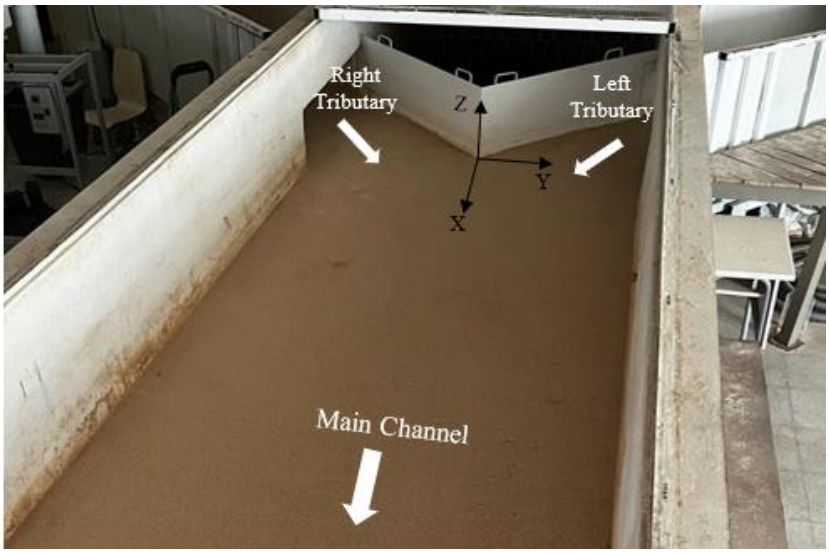

Fig. 3. General view of the experimental set-up

In the area highlighted in yellow in Figure 4, including the main channel and tributary channels, a 20.0 cm thick layer of uniform sand (median diameter, d_{50} = 1.044 mm; geometric standard deviation σ_g=1.16) was added on top of the horizontal concrete bottom. The guiding wall, with dimensions of 100 cm in length, 2 cm in width, and 30 cm in height, was installed in the confluence region to separate the flow and coincided with the longitudinal axis of the main channel. (see Figure 4).

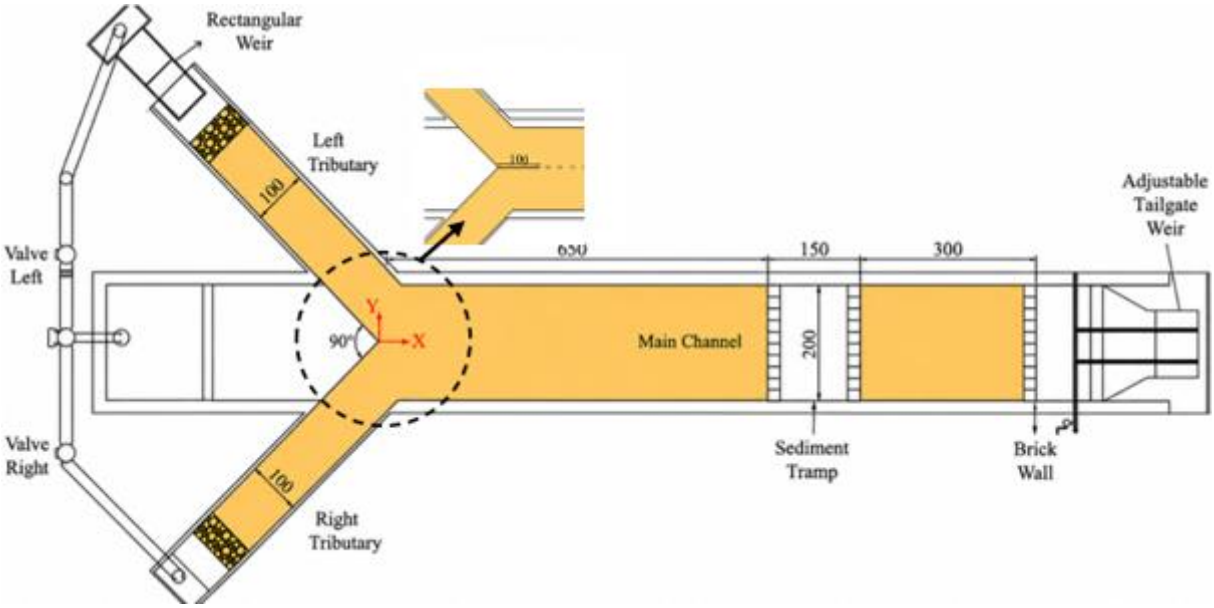

Fig. 4. Plan view of experimental set-up (all units are in cm)

The experimental set-up included a water reservoir placed underneath the laboratory floor. The water was pumped out from there with the help of two centrifugal pumps and circulated in two independent water circuits (one per pump). Each circuit was connected to a different tributary. The circuit of the right tributary was equipped with an electromagnetic flowmeter

used to measure the water discharge (± 0.1 l/s). The discharge in the left tributary was measured using a 0.70 m wide basin weir equipped with a limnimeter. The upstream head over the weir crest (h) was measured as the difference between the water level in the reservoir and the crest elevation, with an accuracy of ±0.1 mm. The discharge coefficient (C_d) of the weir was determined using the empirical equation proposed by Rehbock [15] as given in Eq(1):

$$C_d = 0.602 + 0.83h/P \quad (1)$$

where *P* is the height of weir. The discharge in each circuit was adjusted through one valve per circuit until it reached the predefined value.

The flow depth was controlled by an adjustable tail gate at the downstream end of the experimental setup. It was measured with a limnimeter (± 0.1 mm) and kept constant during the experiment (see Figure 5).

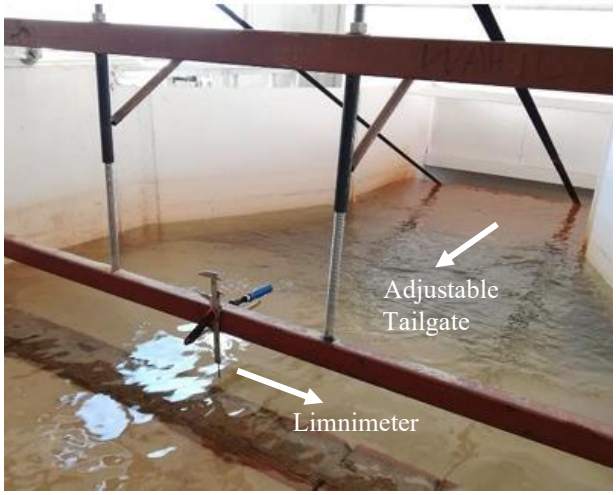

Fig. 5. Adjustable tailgate and limnimeter

The bed morphology was measured using the distance measurement feature of the down-looking Vectrino probe (Figure 6), with a measurement accuracy of 1 mm.

Fig. 6. Downlooking Vectrino probe

2.2 Experimental Procedure

Initially, the 21.0 cm thick sand layer was made perfectly plan with the help of a movable platform. Following the installation of the guiding wall along the longitudinal axis of the main channel, the downstream tailgate was raised and the pump of the right tributary started the pumping a very low discharge rate (2 l/s) to guarantee that the sand bed grains were not entrained. When the flow depth reached 15.0 cm, the discharge was gradually increased to 15.0 l/s by adjusting the valve, ensuring that the sand bed remained undisturbed, while the

discharge in the other tributary was set to zero. Then, the tailgate was gradually lowered until the flow depth reached 5.0 cm above the sand bed, immediately upstream of the downstream water chamber. This instant was considered as the beginning of the experiment (t = 0). Bed topography was measured at specific time intervals along the cross-section located 5 cm downstream of the guiding wall (x = 105 cm), and the measurements continued until no significant morphological changes were observed, indicating equilibrium conditions (t=167 hours). The equilibrium bed morphology was obtained using a Vectrino probe at a grid of points 10 cm apart for x and y directions in the main channel.

3 Experimental Results and Discussion

Bed topography was measured at specific time intervals along the cross-section located 5 cm downstream of the guiding wall (x = 105 cm). Figures 7 and 8 illustrate the time evolution of the scour hole and bed morphology at this cross-section until equilibrium conditions were achieved.

At the beginning of the experiment, a distinct scour hole rapidly developed at the tip of the guiding wall due to the discharge supplied through the right tributary, and it became clearly visible within 50 minutes (Figure 7). The average scour rate was 20.4 mm/h in first 50 min of the experiment, indicating a rapid initial scour development. The incoming flow expanded toward the left side of the main channel after passing the guiding wall.

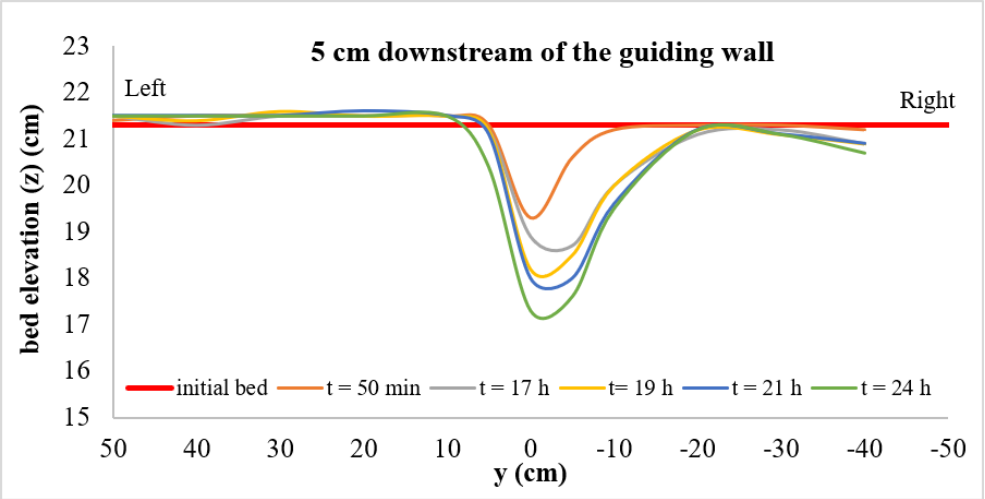

Fig. 7. Early-stage evolution of bed topography during the first 24 h of the experiment

During the initial stage, scour progressed continuously, leading to an increase in both scour depth and scour width. Over the first 24 h, the maximum scour width reached 25.0 cm, while the scour depth increased to 3.7 cm, with an average scour rate of 1.5 mm/h.

The rate of increase in both scour depth and width gradually decreased with time (Figure 8). During the later stages of the experiment, the development of the scour hole became considerably slower, indicating a reduction in the scour rate over time, as also observed by [11]. The bed profiles obtained during the final 55 h showed only a 1.1 cm increase in scour depth.

Over the final 55 h approaching equilibrium conditions, the maximum scour depth increased to 10.9 cm at t = 167 h. The average scour rate between t = 112 h and t = 167 h was only 0.2 mm/h, while no significant variation was observed in the maximum scour width. Although minor variations in the bed profiles continued to occur, these changes remained within an acceptable range for the equilibrium condition and did not significantly modify the overall scour geometry. At the end of the experiment (t = 167 h), the negligible differences between successive bed profiles confirmed that the system had reached a morphological equilibrium condition.

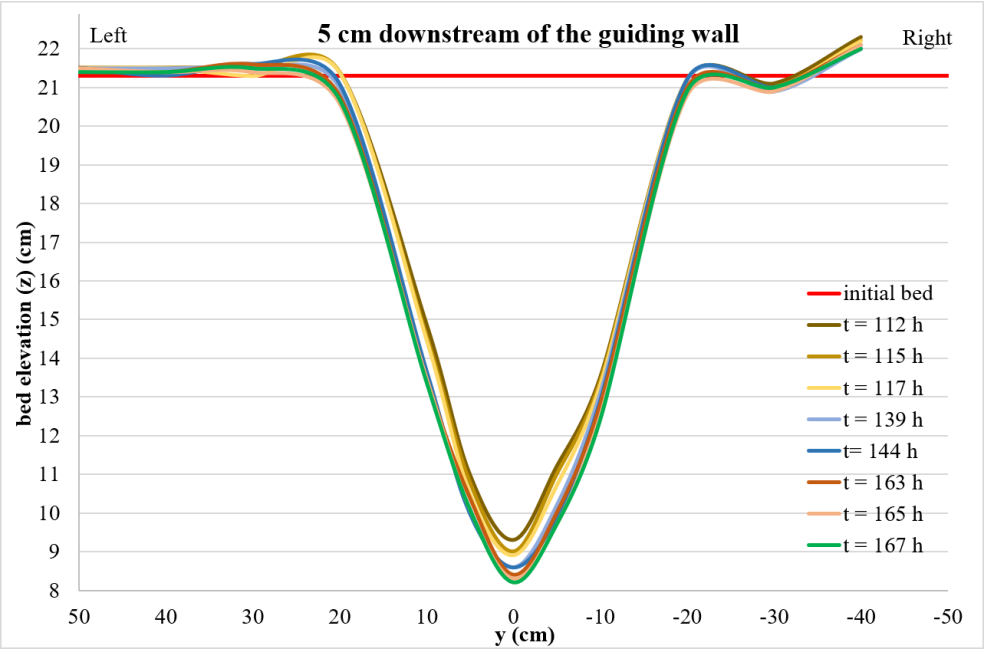

Fig. 8. Evolution of bed topography during the final 55 h approaching equilibrium conditions

The horizontal projection of the confluence bed morphology at equilibrium conditions is given in Figure 9.a, covering the area defined by 0 m ≤ x ≤ 3.5 m and –1 m ≤ y ≤ 1 m. The plan view of the main channel is presented in Figure 9.b.

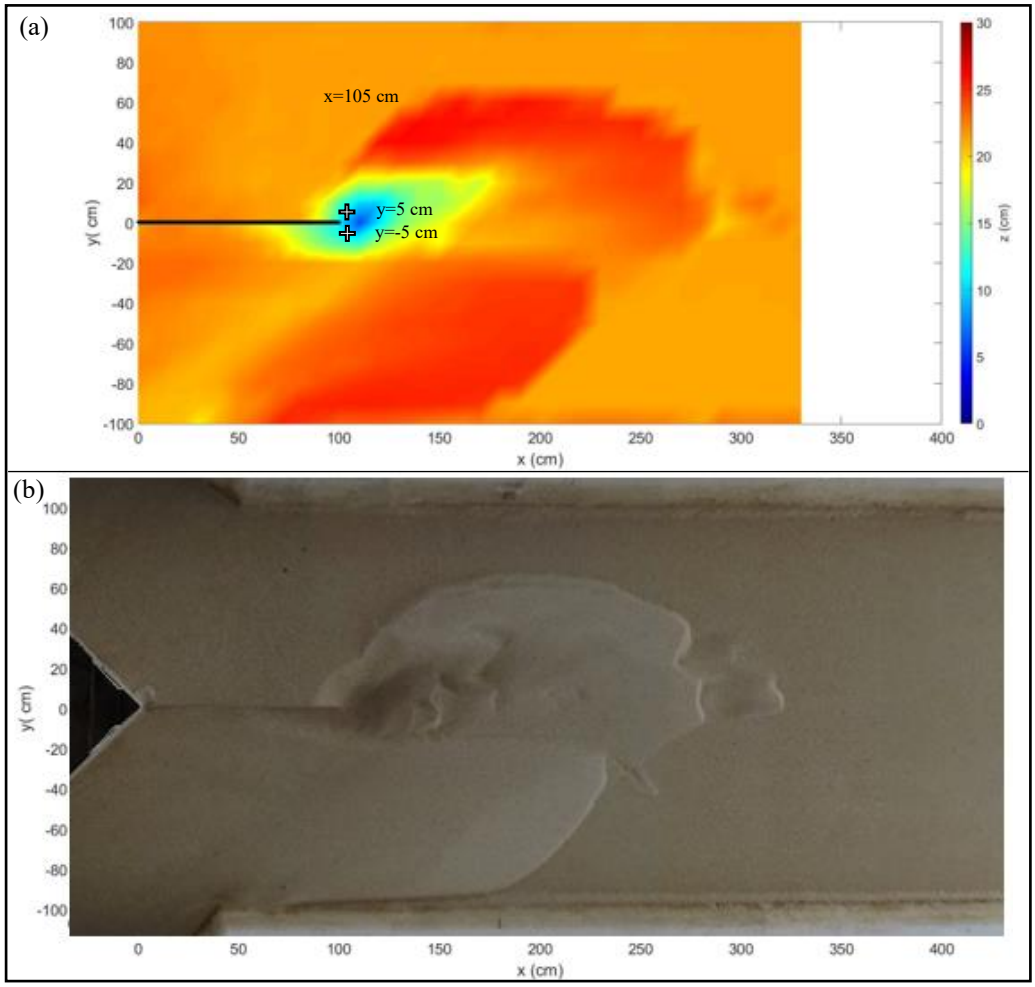

Fig. 9. Bed morphology at equilibrium conditions: (a) bed topography; (b) plan view

The morphological model proposed by [7] and [8] (Figure 2) indicates that a scour hole is formed near the confluence region due to the complex flow interactions. In the present study, the expected scour hole was observed at the tip of the guiding wall instead of the confluence vertex (Figure 9). Eroded sediment from the scour hole was transported downstream and deposited in the downstream region, forming distinct deposition zone. As the discharge was supplied only through the right tributary, no significant bed changes were observed on the left side of the guiding wall or within approximately 30 cm from the left bank. In contrast, a pronounced deposition zone developed along the right bank and extended downstream.

Figure 10 shows the temporal changes in bed elevation at two measurement points located near the tip of the guiding wall. The reduction in bed elevation at the measurement points (x, y) = (105, −5) and (105, 5) reflects the progression of the scour and supports the morphological changes observed in the confluence region. At both locations, the bed elevation remained nearly constant after t = 161 h, suggesting that the scour development had reached a equilibrium condition.

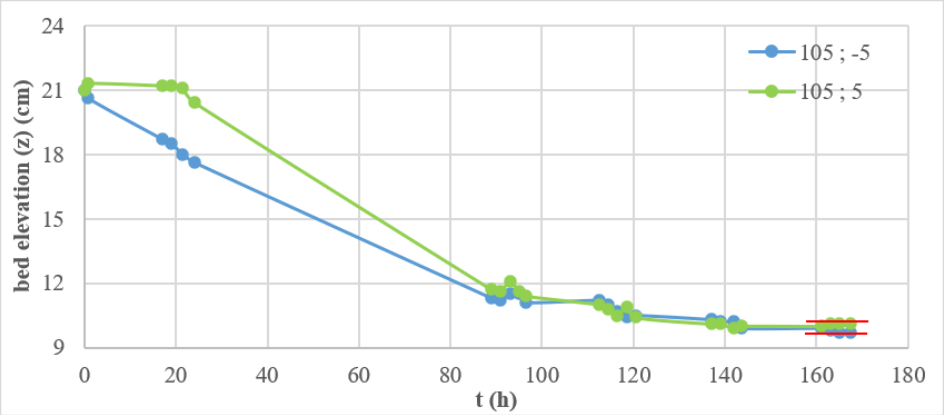

Fig. 10. Temporal changes in bed elevations of the points at x = 105 cm cross-section

4 Conclusions

Controlling the flow structure and bed morphology in river confluences is essential for reducing the potential impacts of associated risks. Therefore, this study aims to investigate the time evaluation and equilibrium bed morphology in a large-scale symmetric mobile-bed river confluence, where the flow and bed morphology are controlled by a guiding wall, in order to address the existing knowledge gap in the literature.

The results showed that the expected scour hole in the confluence region developed at the tip of the guiding wall. The scour depth increased during the early stages of the experiment; however, the rate of scour development gradually decreased as equilibrium conditions were approached. Sediment eroded from the scour hole was transported downstream and deposited in the downstream region. Since the flow was supplied only through the right tributary, no significant bed changes were observed on the left side of the guiding wall or within 30 cm from the left bank. In contrast, a distinct deposition zone developed along the right bank and extended downstream.

Acknowledgments

The authors would like to thank Prof. Dr. António Heleno Cardoso for his valuable contributions to this study who was supported by the TÜBİTAK 2221 Fellowship Program for Visiting Scientists and Scientists on Academic Leave (Sabbatical).

The experiments were conducted using the experimental facility constructed within the scope of the project No. 2016-GAPMÜMF-0020 entitled “Experimental Investigation of Bed Morphological Changes Due to Sediment Load in Symmetric River Confluences.”

This study was supported by the TÜBİTAK 2224-B Domestic Scientific Events Participation Support Program.

ABSTRACT

Pile-supported dolphins are so widely used at marine terminals that design guidance tends to treat them as the default, and gravity-based options receive little attention when the structural type is chosen. This paper asks what sets the gravity-based block-type dolphin apart from other dolphin types, and when those differences matter. It draws on the design basis and construction records of block-type mooring and breasting dolphins recently completed at an LNG terminal and covers five aspects: load path and structural behaviour, construction method and marine plant, tolerance and execution control practice, foundation and scour interaction, and the connection between precast elements. The block-type dolphin resists actions as a rigid stacked mass, without relying on structural deflection. Its installation avoids the noise of percussive piling, and quality-critical production moves to a precast yard. Execution risk is concentrated in bedding flatness and in placement tolerances that build up layer by layer, and a post-installed dowel-core connection serves as a supplementary provision. For berthing at LAT, one-plane screening of the case-study breasting dolphin gave factors of safety of 6.69 against base sliding and 3.72 against overturning. For berthing at HAT, interlayer screening with a joint friction coefficient of 0.60 gave sliding factors between 2.68 at the uppermost shaft joint and 6.98 at the base slabs. These are demand calculations on disclosed inputs, not code verification. No conclusion on bearing adequacy is drawn. A comparative table of selection criteria is provided to support the choice of dolphin type.

Keywords: *block-type dolphin; dolphin selection; pile-supported dolphin; caisson; gravity-based marine structures; LNG terminal*

1. INTRODUCTION

A dolphin is a freestanding marine structure that takes the berthing impact and mooring line loads of a vessel without the support of a continuous quay. For liquefied natural gas (LNG) the standard arrangement is the open-jetty liquid-bulk terminal, where the berth is made up of a central loading platform flanked by breasting dolphins, which absorb berthing energy through their fender systems, and by mooring dolphins, which anchor the vessel's mooring pattern (Reeve et al., 2018; PIANC, 2002). Since the dolphins, and not a quay wall, form the interface with the vessel, choosing their structural system is one of the first decisions in terminal design and among the most consequential.

Piled dolphins are so common that much of the design literature implicitly takes "dolphin" to mean "piled dolphin". In reality the choice is broader than day-to-day practice would suggest. The gravity family (caissons, cellular sheet-pile cells, and stacked precast blockwork) offers solutions that differ at a fundamental level in behaviour, construction logic, and risk profile (Gaythwaite, 2004; OCDI, 2020; García-Espinel et al., 2015). At the same time, vessels continue to grow in displacement and installed propulsion power, which raises berthing energies, mooring loads, and propeller-induced flows at the seabed, so selecting a structural family whose weaknesses coincide with the governing site conditions now carries greater consequences than before (PIANC, 2015). In terms of method, the paper is a retrospective documentary review of a single case, based on one terminal's disclosed design basis and execution records. Document revisions, signed acceptance records, and measurement distributions are not published here, and statements of achieved compliance are taken from the project records without independent verification.

This paper concentrates on those differences. The full construction procedure is the subject of a companion study from the same research and is not repeated here. Instead, the paper sets out what makes the block-type dolphin distinct and tests these points against the design basis and execution records of dolphins recently

completed at an LNG terminal. It is based on the first author's M.Sc. thesis at Istanbul Technical University; commercial identifiers of the case project are withheld for confidentiality.

2. OVERVIEW OF DOLPHIN STRUCTURAL SYSTEMS

Dolphins are normally grouped by how they resist horizontal actions. Flexible systems, which are either groups of steel, concrete, or timber piles tied by a rigid cap or large-diameter monopiles, deflect under load and dissipate part of the berthing energy through pile bending and soil yielding. Their design is governed by pile structural capacity and by lateral pile–soil interaction (Feygin, 2015; Tomlinson & Woodward, 2015). Rigid systems take the same actions with practically no deflection, mobilizing self-weight, base friction, and footprint geometry, and nearly all of the berthing energy is then taken up by the fender instead of being shared with the structure (Gaythwaite, 2004). Figure 1 compares the two load paths under the fender reaction.

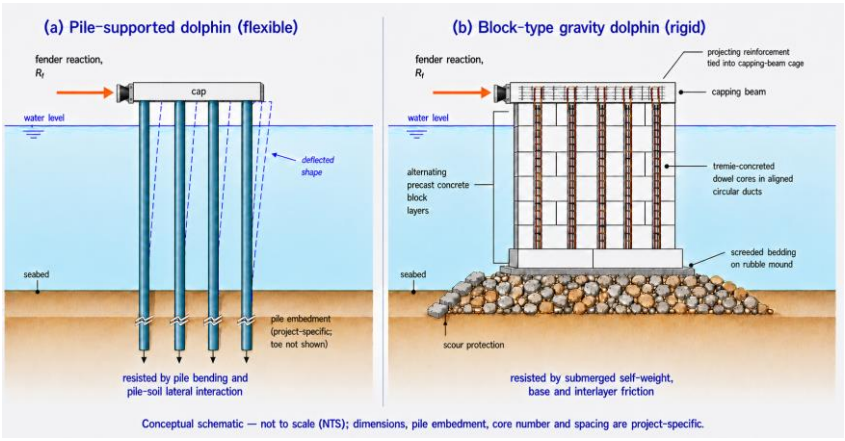

Figure 1. Load paths under the berthing (fender-reaction) action in a pile-supported dolphin and a block-type gravity dolphin. Conceptual schematic, not to scale; dimensions, pile embedment, and the number and spacing of dowel cores are project-specific. Prepared with AI assistance to the authors' specification and technically verified by them; not derived from project documentation or from any project drawing.

Three branches of the rigid family have to be kept apart. A caisson dolphin is a single hollow monolith, cast in a dry dock or casting basin, floated to site, and ballasted down onto a prepared base. A cellular dolphin is a ring of interlocking sheet piles filled with granular material. The block-type dolphin, the subject of this paper, is the modular branch: several large precast units, each of liftable weight, are stacked in layers on a prepared bedding and then connected so that the assembly comes close to acting as one body (OCDI, 2020). The main advantages of the system derive from this modularity, and so do its characteristic risks.

3. DISTINGUISHING FEATURES OF THE BLOCK-TYPE DOLPHIN

3.1. Load path and structural behaviour. A block-type dolphin resists berthing and mooring actions as a rigid body. Sliding is checked at the bedding interface and at each interlayer joint, overturning about the base toe, and bearing under the eccentric base reaction. Because the structure hardly deflects, the fender has to absorb almost all of the energy, so it is usually a compliant, long-stroke unit selected on energy capacity, reaction, hull pressure, and deflection limits, and the governing structural action is the fender reaction, not the berthing energy (PIANC, 2002; British Standards Institution, 2014). In a piled dolphin, the structure itself acts as an energy-absorbing element during the same berthing event. Verification priorities differ as a result. Geotechnical quantities such as friction coefficients, bearing demand, and base contact dominate for the block-type dolphin, and structural ones such as pile section capacity, fatigue, and corrosion allowance for the piled dolphin. Both families need both kinds of check, and what varies is the relative weight. One further feature is specific to blockwork: the interlayer friction available decreases towards the top of the stack, which tends to make the upper joints, and not the base, the critical sliding surfaces. In the case study, interlayer screening for berthing at HAT gave sliding factors from 2.68 at the uppermost shaft joint to 6.98 at the base slabs, against base sliding factors of 6.69 at LAT and 6.33 at HAT.

3.2. Construction method and marine plant. In place of the marine piling spread (piling barge, leader, hydraulic hammer), the block-type dolphin uses a precast yard, a flat-top transport barge, and heavy-lift plant working from a jack-up or spud-stabilized barge. Quality is largely built in onshore under yard conditions,

and offshore work is mostly controlled placement. On the other hand, the offshore operations depend on heavy-lift availability. Without the crane spread, the method cannot proceed. Foundation preparation also becomes a critical control stage. Dredging to formation, placing a 2–20 kg rubble mound, and screeding a 20–40 mm crushed-stone bedding layer to a flatness of ±20 mm over 3 m all take place before any structure is visible. The documented method involves no impact pile driving, which removes the noise source that dominates piled-dolphin construction. However, total underwater noise was not measured for comparison, and how much the difference matters for permitting depends on the site.

3.3. Tolerance and execution control regime. Geometric error in a piled dolphin stays largely with the individual element: a mislocated pile is corrected or accommodated at the cap. In a stacked assembly the errors accumulate, and a non-conforming unit cannot be recovered once another layer has been built over it. The block-type regime therefore rests on survey-verified hold points, running from acceptance of the bedding screed at ±25 mm in level and ±20 mm flatness over 3 m, through base unit placement within ±50 mm in plan and ±25 mm in level, to an assembled face deviation of no more than 50 mm at completion of stacking. It also rests on a strict re-lift rule, under which no unit stays in place with an exceedance carried into the next layer (Project documentation, 2023). Quality control is thus front-loaded and geometric in nature. In piled work it is dominated by driving records and integrity testing.

3.4. Foundation and scour interaction. A gravity dolphin bears directly on the seabed it was built on, whereas a piled dolphin stands on embedment many diameters deep. Scour around the base perimeter of a block-type dolphin can undermine the bedding, change the contact conditions achieved at acceptance, and increase the eccentricity of the base reaction. In a piled structure scour acts differently, reducing lateral soil support and increasing the unsupported pile length (PIANC, 2015). Scour protection is therefore an integral part of the block-type concept and not an add-on. At the case-study dolphins the equilibrium scour depth reported by the project for the native sand, approximately 1.2 m, exceeded the thickness of the bedding works. Protection was differentiated by exposure: a linked-block concrete mattress at least 200 mm thick on the vessel-facing side and, elsewhere, 150–600 kg graded rock at least 1,050 mm thick over geotextile (CIRIA, CUR, & CETMEF, 2007).

3.5. Inter-element connection. Older blockwork relied on friction and shear keys alone. The case-study dolphins add a post-installed dowel-core connection. Vertical ducts of approximately 0.64 to 1.05 m diameter are pre-formed through the layers and aligned during stacking. The ducts are reinforced with duplex stainless steel cages and tremie-concreted after the stack has been surcharged and the project records report that settlement has stabilized, a sequencing rule that keeps incompatible deformations from being locked into the connected system. The dowels are intended to provide a defined shear path across the critical upper joints, tensile continuity into the cast-in-place capping beam, and displacement control between units. They remain a supplementary provision, however. The reported screening takes no credit for them, their capacity calculations are not reproduced, and the in-service degree of composite action was not measured. Even so, the detail sets the modern block-type dolphin apart from loose-stacked blockwork and also from the monolithic caisson, which has no inter-element joints to connect.

4. CASE-STUDY EVIDENCE AND APPLICABILITY RANGE

The two dolphin types at the case-study terminal differ in geometry. Each breasting dolphin has two 0.80 m base slab layers, 8.70 × 11.05 m in plan, and six standard shaft layers 2.50 m high, eight precast layers in all, with the underside of the base slab at −13.80 m CD and a self-weight in air of approximately 40.4 MN. Each mooring dolphin has a single 0.80 m base slab, 9.00 × 11.50 m in plan, and six standard layers 2.30 m high, seven precast layers in all, with the underside at −11.50 m CD and a self-weight of approximately 38.3 MN. The berth is designed for a vessel of approximately 110,000 t displacement approaching at 0.12 m/s, which gives a design berthing energy of approximately 1,050 kN·m and a fender reaction of approximately 2,100 kN; the mooring hook input is 1,500 kN at a line angle of 20°. On these disclosed inputs, one-plane screening gives factors of safety against sliding and overturning of 6.69 and 3.72 for breasting at LAT, 6.33 and 3.52 at HAT, and 8.93 and 4.65 for mooring at HAT. In each of the three reported global base cases the base reaction stays within the middle third. Interlayer screening for berthing at HAT gives sliding factors from 2.68 at the uppermost shaft joint to 6.98 at the base slabs. For reproducibility, the scope of the screening needs to be stated. It is a one-plane rigid-body check. The fender reaction acts at +1.86 m CD, and the 1,500 kN hook load at +5.80 m CD resolves into 1,409.5 kN horizontal and 513.0 kN uplift. Submerged self-weights are 28.1/26.6 MN for the breasting dolphin at LAT/HAT and 25.7 MN for the mooring dolphin at

HAT. The base and joint friction coefficients, 0.50 and 0.60, are assumed values whose source is not reproduced, and no three-dimensional or load-sharing model is implied. Actions are taken from PIANC (2002) and BS 6349-4:2014, the editions referenced in the disclosed case-study inputs (the contractual design-basis register behind these inputs is not reproduced). Current practice is represented by PIANC (2024) and BS 6349-4:2026 (British Standards Institution, 2026). These are illustrative demand calculations and do not constitute code verification. Because neither the allowable bearing pressure nor the geotechnical acceptance basis is reproduced, the computed bearing demands support no conclusion on adequacy (Project documentation, 2023). Table 1 brings the comparative selection criteria together.

Table 1. Selection criteria for pile-supported, caisson, and block-type dolphins. Cellular sheet-pile dolphins (driven construction, with different noise and installation characteristics) are discussed in the text and are not included in the table. Entries are indicative and depend on method, plant, and site conditions (Gaythwaite, 2004; OCDI, 2020; Project documentation, 2023).

Criterion	Pile-supported (flexible)	Caisson (gravity, monolithic)	Block-type (gravity, modular)
Load resistance	Pile bending and pile–soil lateral interaction	Self-weight and base friction of a single monolith	Submerged self-weight, base and interlayer friction; supplementary dowel cores
Deformation behaviour	Flexible; energy partly absorbed by structure deflection	Rigid; berthing energy absorbed by fender	Rigid; berthing energy absorbed by fender
Foundation requirement	Stratum suitable for embedment at depth	Competent stratum at seabed; prepared rubble base	Competent stratum at seabed; rubble mound and screeded bedding
Fabrication / installation	Piles driven in situ (impact or vibratory hammer)	Cast in dry dock or casting basin; floated, towed, ballasted down	Cast at a suitable precast yard (QC, load-out access); barge-hauled; crane-placed in layers
Unit handling	Pile sections; lifts sized to piling plant	Thousands of tonnes (floated, not lifted)	Large precast units (heavy-lift crane)
Underwater noise	Method-dependent; high for impact driving	Low (no driving; floating and ballasting works)	Low (no percussive installation)
Geometric tolerance risk	Per-pile position and rake	Single seating operation	Cumulative, layer-by-layer; survey hold points
Structural joints	Welded / capped connections above water	None below cap (monolithic)	Many interlayer joints; friction plus post-installed dowel cores
Scour vulnerability	Scour reduces lateral soil support; longer free pile length	Moderate–high (bears at seabed)	Moderate–high; protection integral to concept
Typical water depth	Wide range; limited by pile design and plant	Moderate–deep	Shallow–moderate
Repair below water	Project-specific; often difficult offshore	Very difficult	Very difficult

The comparison yields an applicability range and is not meant as a ranking. The block-type concept has its clearest advantage where a competent bearing surface lies at or near the seabed, where underwater noise is restricted, and where heavy-lift plant and precast capacity are already mobilized or can be secured at reasonable cost. Piled dolphins remain the better choice on soft or compressible seabeds where the prepared-bearing assumption breaks down, in water deep enough to push unit weights or placement stability beyond the available plant, and wherever heavy-lift logistics cannot be justified. Where deeper water and an available casting basin favour a floated monolith, caissons become attractive.

5. CONCLUSIONS

The block-type dolphin differs from the rest of the dolphin family in five respects that matter when structural options are being selected. It resists actions as a rigid stacked mass and leaves energy absorption to the fender, so the emphasis of design verification shifts from structural to geotechnical checks; in the reported friction-only screening for berthing at HAT, the lowest interlayer sliding factor was found at the uppermost joint, not at the base. Yard precasting and crane placement take the place of percussive marine piling; the substitution trades underwater noise and driving risk for heavy-lift dependence and demanding foundation preparation.

Execution control is geometric and cumulative and is required from the early stages, by means of survey-verified hold points and a strict re-lift rule. Because the dolphin bears at the seabed, it is sensitive to scour, and protection differentiated by exposure belongs to the structural concept itself. The post-installed dowel-core connection, a supplementary provision, is intended to give a defined load-transfer path into the capping beam; it sets the system apart from loose blockwork and from monolithic caissons without amounting to verified composite continuity. Within its range, the concept is documented as constructible under the disclosed case conditions, and it is an attractive choice where permits restrict underwater noise and logistics favour precasting. The two main research needs that remain open are quantifying the composite contribution of the dowel cores and reproducing the geotechnical acceptance basis needed to turn the reported demands into a verified adequacy statement.

Abstract. Ride-hailing research has predominantly represented driver responses as binary accept-reject decisions, offering limited insight into how unsuccessful assignments accumulate for the same passenger request. This study examines sequential rejection exposure at the request level using one month of operational data from Istanbul. The analysis is restricted to 236,384 passenger requests that ultimately achieved a successful driver-passenger match. Rejection counts are strongly overdispersed (variance-to-mean ratio = 2.40) and concentrated at zero (61.3%). Poisson, negative binomial (NB), zero-inflated Poisson (ZIP), and zero-inflated negative binomial (ZINB) specifications were compared; the ZINB model provided the best overall fit according to log-likelihood, AIC, and BIC while closely reproducing the observed zero proportion. Inference is based on robust standard errors clustered at the eventually accepting driver level. In the count component, each additional minute of pickup time and realized travel-time delay relative to free-flow conditions is associated with 15.4% and 4.6% higher conditional rejection counts, respectively, whereas each additional minute of realized trip time is associated with a 2.7% lower count. Evening-peak requests exhibit the largest temporal increase (11.7%). Because operational and driver variables describe the final successful match, estimates are interpreted as conditional associations with preceding rejection exposure, not causal effects on individual rejecting drivers. The findings demonstrate the value of evaluating ride-hailing matching as a request-level sequential process.

Keywords: Ride-hailing; Driver rejection counts; Zero-inflated model.

1 Introduction

Ride-hailing platforms coordinate passenger demand and available drivers through real-time dispatch mechanisms. In a sequential assignment system, however, a successful match is not guaranteed at the first dispatch: the same passenger request may be offered to several drivers before one eventually accepts it. Each unsuccessful assignment keeps the passenger in the matching process and requires the platform to continue searching for another available driver. The operational performance of ride-hailing therefore depends not only on aggregate acceptance rates, but also on how unsuccessful assignments accumulate before a successful match is established [1, 3].

Existing empirical research has predominantly examined driver response at the individual offer level and represented it as a binary accept-reject decision [9-13]. This perspective is appropriate for studying a driver's response to a particular offer, but it does not describe the complete trajectory experienced by a passenger request after an initial rejection. From the request

perspective, the number of preceding rejections is a distinct measure of sequential matching performance because repeated unsuccessful assignments can prolong matching, increase uncertainty, and contribute to cancellation or platform switching [4-6]. This issue is especially relevant in congested and supply-constrained metropolitan markets such as Istanbul.

This study examines the number of preceding driver rejections experienced by passenger requests that ultimately achieve a successful driver-passenger match. The analysis focuses on pickup time, realized trip time, realized travel-time delay relative to a GIS-based free-flow benchmark, temporal request conditions, and characteristics of the eventually accepting driver. Poisson, NB, ZIP, and ZINB specifications are compared, after which the preferred ZINB model is used to characterize variation in sequential rejection exposure. The contribution is a request-level representation of repeated rejection that complements offer-level acceptance research. Because the explanatory variables describe the final successful match rather than the preceding unsuccessful offers, all estimates are interpreted as conditional associations and not as causal effects on individual rejecting drivers.

2 Literature Review

Ride-hailing operations depend on real-time coordination between passenger requests and available drivers. Research on platform operations has consequently examined matching intervals and radii [1], vehicle routing [2], pricing under driver-acceptance uncertainty [3], and adaptive matching mechanisms [7]. These studies show that dispatch performance depends on both the design of the matching system and the willingness of drivers to accept assigned requests.

Driver-side studies commonly formulate the response to an incoming offer as a binary accept-reject outcome [9-13]. This literature demonstrates that acceptance behaviour varies with pickup burdens, trip attributes, expected returns, temporal conditions, and driver heterogeneity. The offer-level formulation is essential for explaining individual decisions, but it does not measure how many unsuccessful assignments the same passenger request accumulates before eventual acceptance.

Repeated rejections also have passenger-facing and platform-level consequences. Continued reassignment can extend the time needed to establish a match and increase uncertainty in service delivery. Unfavourable waiting conditions may contribute to service discontinuation, cancellation, or the use of competing alternatives [4-5], while inefficient matching can reduce effective driver utilization and overall platform performance [6]. Accordingly, the accumulated rejection count provides information that is not contained in a single binary response or an aggregate acceptance rate.

Despite these related research streams, comparatively limited attention has been devoted to sequential rejection exposure as a request-level outcome. The present study addresses this gap by defining the rejection count as the number of unsuccessful driver assignments preceding eventual acceptance and examining how it varies with the operational and temporal characteristics surrounding the final successful match. This framing connects individual dispatch outcomes to the broader matching trajectory while maintaining a clear distinction between request-level associations and the behaviour of the individual drivers responsible for earlier rejections.

3 Data and Variables

This study uses one month of anonymized operational data provided by a ride-hailing platform operating in Istanbul. The raw data include request and acceptance timestamps, driver and passenger locations, realized pickup and trip durations, temporal indicators, and driver characteristics. Requests that remained unmatched or were cancelled before successful acceptance were excluded because the analytical outcome requires an observed endpoint at

eventual acceptance. Records with missing values, inconsistent timestamps, invalid spatial information, or implausible operational values were also removed. The final sample comprises 236,384 successfully matching passenger requests associated with 9,901 active drivers. The results are therefore conditional on eventual successful matching and should not be generalized to unmatched or cancelled requests. Figure 1 summarizes the sequential process considered in the analysis.

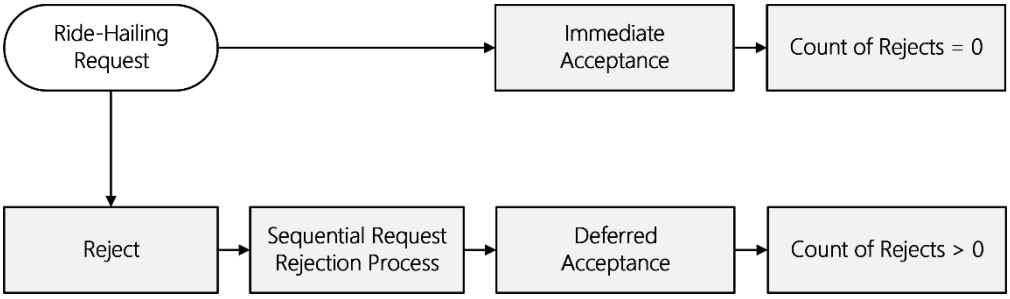

Fig. 1. Conceptual framework of the sequential request rejection process.

The dependent variable, count of rejects, is the number of unsuccessful driver assignments experienced by a passenger request before it is ultimately accepted. A value of zero indicates acceptance at the first dispatch, whereas a positive value indicates one or more preceding rejections before a subsequent driver accepts the request. The measure therefore represents accumulated rejection exposure at the passenger-request level rather than repeated rejection behaviour by a single driver. In the analytical sample, the mean rejection count is 0.90 and the variance is 2.16, yielding a variance-to-mean ratio of 2.40. A total of 144,945 requests (61.3%) has zero preceding rejections, and the distribution is strongly right-skewed (skewness = 1.95), as illustrated in Fig. 2.

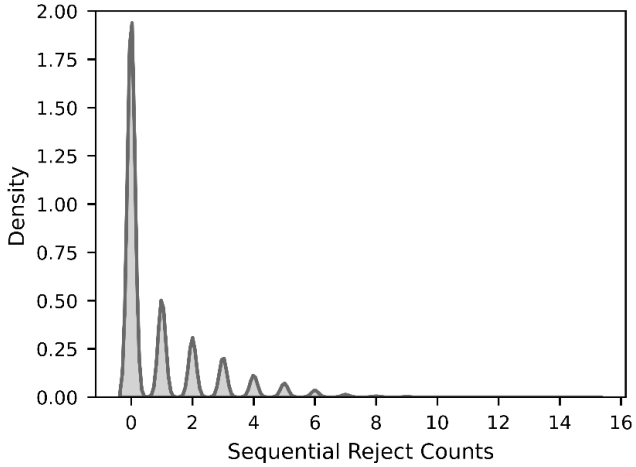

Fig. 2. KDE distributions of dependent variable.

The count component includes pickup time, realized trip time, realized travel-time delay, request day, request-hour category, and driver shift. Driver age and platform experience are included in the zero-inflation component. Pickup time is the elapsed duration between final request acceptance and the arrival of the eventually accepting driver at the passenger's pickup location. Trip time is the realized in-vehicle duration of the final completed trip. Request day distinguishes weekdays from weekends; request hour distinguishes morning peak (7 am-9 am), evening peak (5 pm-7 pm), and non-peak periods; and driver shift distinguishes 2 am-2 pm, 2

pm-2 am, and full-day operation. Driver experience denotes cumulative tenure on the platform rather than general professional driving experience.

GIS-based free-flow benchmarks were constructed by dividing Istanbul into 10,758 regular 500 m x 500 m zones. Trip origins and destinations were assigned to grid cells, and centroid-to-centroid shortest paths were calculated in QGIS using the most recent road-network dataset supplied by Istanbul Metropolitan Municipality. Segment-level free-flow speed values provided with the network were used to derive interzonal free-flow travel times. Intrazonal trips were excluded because centroid-to-centroid network measures are not informative within a single cell; these trips represented only a small share of the original data. Delay is defined as $max(0, T_i^{obs} - T_i^{ff})$, where T_i^{obs} is realized in-vehicle trip time and T_i^{ff} is the corresponding free-flow benchmark. Because delay and trip time are observed after completion of the final successful trip, they characterize the eventual match and are not direct observations of what preceding drivers perceived when evaluating the request.

Driver-specific variables refer to the driver who ultimately accepted the request. Their inclusion in the zero-inflation component captures statistical associations with the additional probability mass at zero and does not identify an 'always-accepting' driver group. Descriptive statistics for the explanatory variables are presented in Tables 1 and 2.

Table 1. Descriptive statistics of independent variables.

Variables	Unit	Min	Mean	Max
Pickup time	min	0.4	2.7	9.0
Trip time	min	3.3	20.6	115.0
Delay	min	0.0	7.6	66.5
Driver age	year	21	43	68
Driver experience	year	0.0	4.0	11

Pickup time ranges from 0.4 to 9.0 min, with a mean of 2.7 min. Realized trip time averages 20.6 min and ranges from 3.3 to 115.0 min. Delay ranges from 0 to 66.5 min, with a mean of 7.6 min. Driver age ranges from 21 to 68 years (mean = 43), while platform experience ranges from 0 to 11 years.

Table 2. Distribution of categorical independent variables.

Variables	Categories	Percentage
Driver shift	2 am – 2 pm	43.6
	2 pm – 2 am	51.4
	Full day	5.0
Request day	Weekday	81.0
	Weekend	19.0
Request hour	Morning peak hours	19.4
	Evening peak hours	15.8
	Non-peak hours	64.8

Regarding driver shift patterns, slightly more than half of the observations correspond to drivers operating between 2 pm and 2 am (51.4%), while 43.6% of drivers work between 2 am and 2 pm. A smaller share of drivers, accounting for 5.0% of the sample, follows a full 24-hour shift schedule. In terms of weekly distribution, most requests occur on weekdays (81.0%), whereas weekend requests represent 19.0% of the sample. The temporal distribution by time of day shows that most requests are observed during off-peak periods, accounting for 64.8% of all requests, followed by morning peak hours from 7 am to 9 am with 19.4% and evening peak hours from 5 pm to 7 pm with 15.8%.

4 Methodology

The rejection count is a non-negative outcome with substantial overdispersion and a pronounced concentration at zero. Because these features alone do not establish the preferred count specification, Poisson, NB, ZIP, and ZINB models were estimated to use the same analytical sample and count-component covariates. The ZIP and ZINB models also used the same zero-inflation covariates. Models were compared using log-likelihood, AIC, BIC, and the predicted zero proportion. The ZINB specification provided the best overall fit and was retained for inference.

The ZINB model represents the observed rejection-count distribution through two statistical components. The zero-inflation component contributes additional probability mass to zero-rejection observations, whereas the negative binomial component models count variation and can also generate zeros. Positive rejection counts arise from the negative binomial component. The zero-inflation component is therefore a statistical representation of excess zeros, not evidence of a behaviourally distinct population of drivers or requests [8].

The probability associated with the zero-inflation component is specified as Equation (1).

$$\pi_i = \frac{\exp(\mathrm{z}_i'\gamma)}{1+\exp(\mathrm{z}_i'\gamma)} \tag{1}$$

where π_i is the zero-inflation probability for request i, z_i is the vector of covariates in the zero-inflation component, and γ is the corresponding parameter vector. The conditional meaning of the negative binomial count component is specified in Eq. (2).

$$\mu_i = \exp(\mathrm{x}_i'\beta) \tag{2}$$

Here, μ_i denotes the expected number of preceding rejections conditional on the count-generating process, x_i is the vector of explanatory variables in the count component, and β is the corresponding parameter vector. Exponentiating β yields an incidence rate ratio (IRR): values above one indicates a positive association with the conditional rejection count, whereas values below one indicates a negative association, holding the remaining variables constant.

The unconditionally expected number of preceding rejections for request i is given by Eq. (3).

$$E(y_i \mid \mathrm{x}_i, \mathrm{z}_i) = (1-\pi_i)\mu_i \tag{3}$$

Accordingly, the overall expected rejection count depends jointly on the additional zero probability and the conditional mean of the negative binomial component. Driver-specific and realized operational variables describe the eventually accepting driver and final successful match; model estimates are therefore interpreted as request-level conditional associations with preceding rejection exposure rather than direct effects on the individual decisions of preceding drivers.

5 Results and Discussion

The Poisson model substantially underpredicted the observed zero proportion (43.6% versus 61.3%) and produced the weakest information criteria. The NB model improved both dispersional fit and zero prediction (60.0%), while the ZIP model predicted 60.9% zeros. The ZINB model achieved the highest log-likelihood (-295,238.0) and the lowest AIC (590,502.0) and BIC (590,636.9), while predicting 60.8% zeros. These diagnostics support the ZINB specification as the preferred overall representation of the rejection-count distribution. Table 3

presents its estimates; statistical inference uses robust standard errors clustered by the eventually accepting driver.

* base category; SE: driver-clustered robust standard error.

Within the negative binomial count component, pickup time has the largest operational association (β = 0.1434; IRR = 1.1542): one additional minute is associated with a 15.4% higher conditional rejection count. Each additional minute of realized delay is associated with a 4.6% increase (β = 0.0449; IRR = 1.0460), whereas each additional minute of realized trip time is associated with a 2.7% decrease (β = -0.0270; IRR = 0.9734). Weekday requests exhibit a 6.2% higher conditional count than weekend requests. Relative to non-peak periods, morning- and evening-peak requests exhibit increases of 6.2% and 11.7%, respectively. The 2 am-2 pm shift does not differ significantly from the full-day reference category, whereas requests eventually accepted by drivers operating the 2 pm-2 am shift are associated with a 9.8% higher conditional count. These patterns show that preceding rejection exposure varies systematically with the operational and temporal conditions surrounding eventual successful matches.

In the zero-inflation component, driver age (β = 0.0039, p = 0.010) and platform experience (β = 0.0309, p < 0.001) are positively associated with the additional probability mass assigned to zero rejection. Because these variables describe the eventually accepting driver, the coefficients do not show that older or more experienced drivers generally reject fewer requests, nor do they identify a persistent 'always-accepting' group. They indicate only that requests eventually matched with older or more experienced drivers receive a greater probability contribution from the model's statistical excess-zero component. The estimated overdispersion parameter (0.4715) further confirms substantial extra-Poisson variation. Operationally, the findings identify pickup-related conditions and evening operating periods as useful targets for dispatch

monitoring, but the request-level data do not reveal the attributes or decision processes of the drivers responsible for earlier rejections.

6 Conclusion

This study reframes repeated driver rejection as a request-level sequential process rather than a collection of isolated binary decisions. Among 236,384 passenger requests that ultimately achieved a successful match, rejection exposure is strongly overdispersed and concentrated at zero, and the ZINB model provides the best fit among the evaluated count specifications. Pickup time is the most pronounced operational correlate, while realized delay and evening-peak conditions are also associated with greater preceding rejection exposure. Longer realized trip times exhibit the opposite pattern.

From a platform perspective, rejection counts provide information beyond aggregate acceptance rates by showing how many unsuccessful assignments a request experiences before eventual acceptance. Improving driver-request proximity, monitoring periods of elevated rejection exposure, and adapting dispatch procedures to pickup-related burdens may help reduce repeated assignment attempts and improve the utilization of available driver supply. These implications should be treated as operational directions for further testing rather than causal effects established by the present observational model.

The findings are subject to important limitations. The data covers one month, one platform, and only requests that ultimately achieved successful matching; unmatched and cancelled requests may contain more severe rejection sequences. Driver age, experience, pickup time, trip time, and delay describe the eventually accepting driver and final completed trip, while the characteristics of preceding rejecting drivers are unavailable. Trip time and delay are also ex-post measures. Future research should combine complete offer-level histories with ex-ante request attributes, unmatched outcomes, richer local supply-demand indicators, and longer multi-platform observation periods.

Abstract. Urban Air Mobility (UAM) has emerged as a significant focus in transportation research, propelled by advancements in electric vertical take-off and landing (eVTOL) aircraft and increasing mobility challenges in metropolitan regions. UAM presents opportunities to reduce urban congestion, enhance emergency medical services, enable air taxi operations, facilitate small-scale logistics, and promote sustainable transport systems. This study analyzes UAM from technical, operational, environmental, social, and regulatory perspectives. The concepts of UAM and Advanced Air Mobility (AAM) are defined, and major eVTOL configurations—including Multicopter, Lift+Cruise, Tiltrotor, and Vectored Thrust—are compared based on speed, range, capacity, energy consumption, and operational suitability. Representative aircraft models such as AirCar, Joby Aviation S4, Eve Air Mobility, and Leonardo AW609 are reviewed to illustrate recent technological developments. The analysis further addresses vertiport infrastructure, site selection, charging requirements, battery safety, airspace integration, environmental impacts, public acceptance, and regulatory preparedness. Special consideration is given to Türkiye, where UAM advancement depends on technological maturity and coordinated progress in infrastructure, airspace management, safety regulation, legal frameworks, cybersecurity, and societal acceptance. The findings suggest that UAM could enhance future urban transportation, but recommend initiating implementation through controlled pilot projects and localized test studies prior to large-scale deployment

Keywords: Urban Air Mobility; eVTOL Aircraft; Vertiport Infrastructure.

1 Introduction

The rapid expansion of cities combined with the steady migration of people into metropolitan areas has been putting growing pressure on urban transportation systems for years. Road networks, in particular, are struggling with a familiar range of persistent issues — heavy traffic congestion, much longer commuting times, rising pollution, safety concerns, and limited access for emergency services and other time-critical needs. These problems are especially pronounced in large cities, where building additional roads or expanding existing ones is rarely feasible due to severe land shortages, extremely high costs, and the practical difficulties created by already dense urban environments.

It is against this challenging background that Urban Air Mobility (UAM) has started to attract serious consideration. While the basic idea of moving people and goods through urban airspace has been around for decades, recent progress in battery systems, electric propulsion, digital control technologies, autonomous systems, and eVTOL aircraft has revived strong interest in the concept. Recent research suggests that enthusiasm for both UAM and the broader Advanced Air Mobility (AAM) field is increasing quickly, largely because eVTOL

aircraft are seen as potentially safer, much quieter, and more economically viable alternatives to conventional helicopter services [1], [2]. UAM is primarily associated with short-distance services within urban and metropolitan areas. Potential applications include urban air taxi operations, airport transfers, emergency medical services, disaster response, tourism, and small-scale cargo or logistics operations. UAM represents not only the introduction of new aircraft technology but also the development of a comprehensive mobility ecosystem that requires integrating vehicles, vertiports, energy systems, airspace management, digital platforms, regulatory frameworks, and user assistance. It calls for the creation of a complete mobility ecosystem that brings together vehicles, vertiports, energy systems, airspace management, digital platforms, regulatory structures, and user support services. Given that eVTOL aircraft are still under development, they are best seen — at least in the short and medium term — as supplementary solutions that can enhance and expand current transportation options rather than fully substitute them [1].

Although Urban Air Mobility offers important opportunities, its implementation also brings a number of infrastructure, operational, environmental, and social challenges. Among these, vertiport planning is particularly important. Vertiports must provide safe areas for take-off and landing, while also supporting passenger processing, charging, maintenance, emergency response, and integration with existing ground transport systems. In addition, operating safely at low altitudes will demand strong communication, navigation, and surveillance capabilities, reliable procedures for traffic separation, well-prepared emergency protocols, and close coordination with today's conventional aviation activities.

Environmental concerns — especially noise pollution and overall life-cycle emissions — as well as social issues such as perceived safety, privacy, affordability, and building public trust, will play a major role in whether UAM gains broad acceptance. Therefore, the rollout of UAM should be treated as a full system-level planning challenge, not just a matter of developing new aircraft technology.

Regulation will play a decisive role in the practical implementation of UAM. UAM brings several new elements into play: different types of aircraft, new ways of using urban airspace at low altitudes, much higher frequency of operations, and safety risks that current aviation rules are not fully equipped to handle. In Türkiye, the present regulatory system is based largely on the Turkish Civil Aviation Law and the rules set by the Directorate General of Civil Aviation (SHGM). However, according to various studies, the country still lacks specific regulations tailored to UAM, detailed rules on safety and environmental protection, and clear instructions on how to integrate low-altitude flights with the existing airspace [3].

In the Turkish context, UAM should be evaluated not only as an aviation-related innovation, but also as a multidisciplinary socio-technical transition. Its implementation requires the coordinated development of vehicle technologies, vertiport infrastructure, energy systems, airspace management, cybersecurity governance, legal responsibility mechanisms, and public acceptance strategies. The use of autonomous or semi-autonomous aerial vehicles in dense urban environments also raises important questions regarding liability, property rights, privacy, software governance, and the distribution of responsibility among operators, manufacturers, infrastructure providers, municipalities, and public authorities [4]. Based on this perspective, the present study provides an integrated assessment of UAM from technical, operational, environmental, social, and regulatory perspectives, with particular attention to its possible future implementation in Türkiye.

2 Conceptual and Methodological Framework

Urban Air Mobility constitutes a novel low-altitude transport system intended for the movement of passengers and freight within metropolitan boundaries. Unlike conventional aviation, which depends on airport infrastructure and extended routes, this model prioritizes

short, high-frequency operations tailored to the demands of densely populated urban settings. AAM represents a broader concept encompassing regional, rural, intercity, and remote-area air transport applications. Accordingly, UAM can be considered an urban subcategory of AAM, with a particular emphasis on congestion mitigation, improved accessibility, reduced travel times, and integration with existing public transport networks [2], [3].

The technological foundation of UAM is closely linked to eVTOL aircraft. These platforms differ from traditional helicopters by utilizing electric propulsion, distributed rotor configurations, lower anticipated noise levels, and the potential for reduced operating and maintenance costs. Performance characteristics vary based on configuration, mission profile, energy system, payload, range, and certification requirements. The literature typically categorizes eVTOL platforms as Multicopter, Lift+Cruise, Tiltrotor, and Vectored Thrust designs. Each configuration presents distinct trade-offs; therefore, aircraft selection should account for speed, range, capacity, energy consumption, safety, noise, infrastructure compatibility, and economic feasibility [5-7].

A structured review-based methodology was employed in this study. Academic literature, regulatory documents, technical reports, and selected aircraft data were analyzed to evaluate UAM across four analytical dimensions. The first dimension is technical and vehicle-related, encompassing eVTOL design, range, speed, capacity, energy consumption, and safety. The second dimension addresses infrastructure and operations, including vertiport planning, charging infrastructure, maintenance, multimodal integration, and low-altitude airspace management. The third dimension considers environmental and social factors, such as emissions, noise, visual impact, privacy, perceived safety, and public acceptance. The fourth dimension focuses on regulatory and Türkiye-specific issues, including legal gaps, Directorate General of Civil Aviation-related concerns, certification requirements, cybersecurity governance, and pilot implementation priorities.

The review incorporates a multidisciplinary perspective, emphasizing that UAM should not be viewed solely as a vehicle-centered aviation innovation. Successful deployment necessitates the involvement of aircraft manufacturers, infrastructure providers, software developers, energy operators, public authorities, municipalities, emergency services, and end users. This approach is particularly pertinent for Türkiye, where UAM-related discussions must address not only technical feasibility but also legal responsibility, product liability, criminal liability, data governance, public acceptance, and institutional readiness [4].

3 eVTOL Configurations and Representative Aircraft Models

The technical feasibility of UAM is intrinsically linked to the development and operational performance of eVTOL aircraft. Unlike conventional fixed-wing aircraft, eVTOLs operate without the need for long runways and enable flexible access to dense urban environments via vertiports or other dedicated landing facilities. eVTOL aircraft encompass multiple technological configurations, each offering specific advantages and limitations in terms of range, speed, payload, energy efficiency, noise, safety, operational reliability, and certification complexity.

Multicopter platforms utilize multiple rotors for vertical take-off, hovering, and flight control. These platforms are mechanically simpler than other eVTOL configurations and are effective during take-off, landing, and low-speed operations. Their simplicity and maneuverability render them suitable for short-distance urban missions, cargo transport, emergency response, and demonstration services. However, the absence of wings limits cruise efficiency, thereby restricting range and endurance and increasing reliance on battery performance and vehicle mass. Research on multirotor aerial vehicles highlights energy storage configuration, propulsion chain sizing, and flight endurance as critical design constraints for this class of aircraft [6], [8].

Lift+Cruise aircraft employ distinct propulsion systems for vertical lift and forward flight. Lift rotors facilitate take-off and landing, while fixed wings and cruise propellers enable efficient horizontal flight. This configuration enhances range and endurance relative to multicopters and is frequently regarded as a balanced solution for urban air taxi services and airport connection routes. However, integrating separate propulsion systems can increase structural weight and design complexity, and the small propellers used for vertical lift may generate additional noise due to elevated blade tip speeds [6], [9].

Tiltrotor and Vectored Thrust configurations deliver higher performance but entail greater complexity. Tiltrotor aircraft feature rotors or propulsion units that rotate during the transition from vertical lift to forward flight, while Vectored Thrust systems utilize propulsion units capable of changing direction to provide both lift and forward thrust. These configurations offer improved cruise efficiency and are suitable for extended UAM or regional air mobility missions. However, they necessitate advanced transition control, redundancy, maintenance protocols, and rigorous certification processes. Recent literature indicates that tiltrotor concepts provide speed and flexibility, multicopters offer simplicity but limited range, and Lift+Cruise designs represent a compromise between endurance and operational flexibility [6], [9].

The variety of eVTOL configurations demonstrates the absence of a dominant aircraft design within the UAM market. Garrow et al. highlight that manufacturers have developed markedly different concepts regarding seating capacity, speed, range, and business models [1]. This lack of convergence is attributable to the novelty of electric propulsion technologies and ongoing uncertainty about commercially viable mission profiles. Some designs prioritize short urban trips, while others are intended for airport shuttles, regional routes, cargo operations, or premium air taxi services. Consequently, UAM planning should align vehicle type with mission profile rather than presuming a universal aircraft solution for all operations.

Representative aircraft models exemplify these technological pathways. AirCar, developed in Türkiye, serves as a short-distance urban aerial mobility concept. The technical data reviewed in this study describe AirCar as a two-passenger vehicle equipped with eight electric motors, a maximum speed of approximately 120 km/h, a range of 50–80 km, and rapid charging capability that achieves 80% charge in 15 minutes. These features render it suitable for short urban operations where turnaround time is critical. However, like other early eVTOL concepts, its scalability depends on certification, operational safety, vertiport availability, charging infrastructure, and public acceptance.

Joby Aviation's S4 exemplifies a more advanced tiltrotor or vectored-thrust design. It accommodates one pilot and four passengers, with a reported cruise speed of approximately 322 km/h, a range of 131–161 km depending on reserve assumptions, and a maximum payload of approximately 450 kg. The aircraft employs six tilting rotors and is frequently cited as one of the more mature eVTOL models for passenger air taxi operations. Its high speed and range render it suitable for short urban trips, metropolitan airport connections, and selected regional missions [6].

Eve Air Mobility, developed by Embraer, exemplifies the Lift+Cruise configuration. This design separates vertical lift and horizontal propulsion and is intended for urban air taxi operations that require a balance of range, capacity, safety, and system simplicity. According to the reviewed material, Eve achieves a cruise speed of approximately 200 km/h, a range of 100 km, and accommodates one pilot plus four passengers, with potential for increased capacity in autonomous operation. Leonardo AW609, a tiltrotor aircraft, differs from fully electric eVTOL models and is positioned between conventional aviation and future advanced air mobility concepts. Although not a direct competitor for urban short-distance eVTOL operations, it serves as a benchmark for tiltrotor performance, certification experience, and the transition from helicopter-like vertical operations to fixed-wing cruise efficiency.

“In summary, eVTOL configurations present distinct trade-offs. Multicopters offer simplicity and are suitable for short missions; Lift+Cruise platforms provide balanced performance; and Tiltrotor or Vectored Thrust systems deliver higher speed and range but entail greater complexity. Table 1 summarizes the operational implications of main eVTOL configurations. For Türkiye, initial UAM deployment will necessitate careful alignment between aircraft type and intended use case. Short urban demonstration routes, airport transfers, emergency medical services, and limited logistics operations may each require specific vehicle configurations, infrastructure designs, operating procedures, and regulatory frameworks.

Table 1. Operational implications of main eVTOL configurations.

Configuration	Operational strengths	Main limitations	Potential early use cases
Multicopter	Mechanical simplicity, hovering capability, maneuverability, flexible take-off and landing.	Limited range and endurance because vertical flight is energy-intensive; sensitive to battery mass.	Short demonstration routes, small cargo, emergency support, controlled urban missions.
Lift+Cruise	More efficient cruise flight through wings; balanced range and operational simplicity.	Separate lift and cruise systems may increase structural weight, complexity, and noise around vertiports.	Airport shuttles, urban air taxi services, hospital connections, medium-distance routes.
Tiltrotor / Vectored Thrust	Higher cruise speed and range; better suitability for metropolitan and regional connections.	Transition control, redundancy, maintenance, and certification are more complex.	Premium air taxi, airport access, regional links, time-critical passenger missions.
Rotorcraft / tiltrotor benchmark	Existing vertical-lift experience, higher payload and range in selected models.	Noise, operating cost, fuel or hybrid architecture, and urban acceptance constraints.	Benchmarking, emergency services, medical transfer, advanced vertical-lift operations.

4 Infrastructure, Airspace, Environmental and Regulatory Requirements

The effective implementation of UAM requires not only mature aircraft but also dedicated ground infrastructure and the safe integration of operations with existing transport and aviation systems. Vertiports represent a critical component of the UAM ecosystem. These facilities extend beyond basic landing and take-off functions to encompass touchdown and lift-off zones, final approach and take-off areas, passenger processing, charging or battery-swap systems, maintenance, emergency response equipment, digital communication infrastructure, and connections to ground transport. Consequently, vertiport planning must be addressed as an integrated challenge involving aviation, urban planning, energy, and transport systems.

Recent literature highlights several key research themes in vertiport development, including location and network planning, capacity and throughput, safety, cost, weather sensitivity, noise, security, and regulatory requirements. Schweiger and Preis demonstrate that the term vertiport has become increasingly prevalent in UAM research, indicating a consensus on the necessity for specialized ground infrastructure [10]. Di Mascio et al. further contend that vertiport design and regulation cannot be directly adapted from conventional airports or heliports, as eVTOL operations involve distinct aircraft characteristics, energy systems, passenger flows, operational frequencies, fire-safety requirements, and urban impacts [11].

The Vertiport location is a critical planning decision. An effective vertiport network must be situated near major demand centers to offer travel-time benefits while also satisfying safety, land-use, structural, environmental, and accessibility requirements. Potential sites

include airport terminals, existing heliports, rooftops of large buildings, parking structures, transport hubs, commercial centers, hospitals, and logistics facilities. The appropriateness of each site depends on factors such as population density, public transport accessibility, road connectivity, structural capacity, emergency access, obstacle clearance, proximity to noise-sensitive areas, and grid connectivity. Therefore, vertiport site selection should employ a multi-criteria framework rather than relying solely on available space.

Energy infrastructure is a fundamental component of vertiport development. As eVTOL vehicles rely on high-capacity batteries or alternative energy systems, vertiports must facilitate rapid charging, battery swapping, energy storage, and grid connectivity. High-frequency operations can result in significant peak electricity demand, particularly in dense urban environments. Accordingly, vertiport design should account for electrical grid capacity, charging schedules, local storage, renewable energy integration, and operational turnaround times. In Türkiye, recent studies indicate that scaling UAM operations will require fast-charging or battery-swap facilities and integration with the energy grid or local storage systems [4].

Safety and emergency management are essential considerations in vertiport planning. eVTOL aircraft utilize energy sources such as lithium-ion batteries or, in some cases, hydrogen systems, which differ from conventional aviation fuels and introduce new requirements for fire safety, maintenance, emergency response, and local safety protocols. Additionally, factors such as downwash and outwash effects, rotor proximity, passenger movement, cybersecurity risks, and automated system failures must be addressed in vertiport design and operation. Updated guidelines on zoning, environmental noise, power infrastructure, and fire safety are necessary before large-scale deployment [4], [11].

Airspace integration constitutes a significant implementation challenge. UAM operations are expected to take place in low-altitude urban airspace, where eVTOL aircraft may interact with helicopters, drones, general aviation, restricted zones, tall structures, and emergency flight operations. Effective UAM deployment requires coordination between traditional Air Traffic Management and Unmanned Aircraft System Traffic Management. Essential requirements include establishing low-altitude corridors, implementing dynamic geofencing, deploying collision-avoidance systems, enabling real-time traffic deconfliction, providing communication and navigation infrastructure, establishing emergency landing procedures, and implementing digital monitoring tools. International initiatives such as Europe's U-Space framework and Japan's AAM roadmap underscore the need for specialized airspace zones and traffic management systems to ensure safe integration [3].

Environmental and social considerations are equally critical in UAM planning. While eVTOL aircraft are anticipated to generate lower local emissions compared to fossil-fuel aircraft during operation, their overall environmental performance is influenced by factors such as the electricity generation mix, battery production, charging infrastructure, vehicle occupancy, operational efficiency, and life-cycle impacts. UAM should not be presumed to be a zero-impact mobility solution. Its sustainability must be assessed based on energy sources, operational patterns, substitution of ground trips, and the environmental costs associated with infrastructure.

Noise remains a significant environmental and social concern. Although eVTOL aircraft are often characterized as quieter than helicopters, frequent low-altitude flights over densely populated urban areas may still cause annoyance, particularly near vertiports, residential neighborhoods, hospitals, schools, and historic districts. UAM planning must therefore incorporate noise-aware route design, strategic selection of vertiport locations, operational time restrictions, and community-sensitive flight procedures. Simulation-based and noise-aware planning methodologies can facilitate more acceptable operations by accounting for fleet size, flight frequency, trajectory design, and community noise constraints [4].

Public acceptance is a fundamental prerequisite, as both users and non-users will be impacted by UAM operations. Factors such as perceived safety, cost, travel time savings, comfort, trust in automation, privacy, and willingness to pay are likely to influence acceptance. Mermertaş and Karakan demonstrate that attitudes toward UAM vary according to socio-economic characteristics, and that willingness to use and pay for UAM services should be assessed prior to implementation [12]. This consideration is particularly relevant for Türkiye, where initial deployments should be accompanied by public engagement and transparent communication regarding safety, cost, and social benefits.

Regulatory readiness is intrinsically connected to safety and public trust. UAM introduces dense low-altitude operations, autonomous or semi-autonomous flight, high-frequency take-off and landing cycles, vertiport-based passenger processing, and digital traffic management. While existing aviation regulations provide a general framework, they do not yet encompass detailed UAM-specific standards for aircraft certification, pilot or operator qualifications, environmental protection, low-altitude corridor management, data privacy, and cybersecurity. Consequently, UAM regulation should address not only aircraft certification but also the broader context of a software-intensive, multi-actor mobility ecosystem [3], [4].

5 Environmental, Social, and Regulatory Considerations

UAM implementation in Türkiye should proceed through a gradual, controlled transition rather than an immediate large-scale deployment. Türkiye possesses favorable conditions, including congested metropolitan areas, expanding domestic technological capacity, established aviation expertise, and diverse potential use cases such as airport access, emergency medical services, disaster response, tourism, and limited logistics. These opportunities must be assessed in conjunction with infrastructure, airspace, regulatory, legal, environmental, and social constraints [3], [4].

The initial priority is to identify realistic pilot use cases. Early deployment should avoid focusing on widespread commercial air taxi services. Instead, limited and high-value applications, including airport-city center connections, medical transport between hospitals, rapid access to disaster zones, and small-scale cargo delivery, should be tested through controlled demonstration corridors. These pilot projects would enable operators and regulators to collect operational data, assess safety risks, test charging infrastructure, evaluate noise impacts, and measure public perception prior to broader deployment.

Major metropolitan areas such as Istanbul, Ankara, and İzmir present strong demand potential but also significant planning challenges. Dense urban structures, restricted airspace, high-rise buildings, limited land availability, and noise-sensitive zones necessitate careful vertiport planning. Potential sites include airport areas, existing heliports, rooftops of structurally suitable buildings, transport hubs, hospitals, and logistics centers. Each location should be evaluated based on safety zones, emergency access, structural capacity, multimodal integration, energy supply, environmental effects, and social acceptance. Recent assessments of Türkiye indicate that vertiports in dense cities require structural reinforcement, noise mitigation, emergency service access, environmental compliance, and integration with metro stations, airports, and bus depots [4].

The second priority is airspace integration. Türkiye currently lacks a dedicated low-altitude corridor system and specific provisions for high-frequency eVTOL operations. SHGM, municipalities, air traffic authorities, emergency institutions, and private operators should collaboratively develop operating zones, low-altitude corridors, geofencing rules, collision-avoidance procedures, real-time traffic management protocols, and emergency response procedures. The absence of UAM-specific operating categories may create uncertainty in certification, liability, and enforcement; therefore, airspace planning must be coordinated with regulatory and legal preparation.

The third priority is establishing a phased regulatory framework. International experience demonstrates that countries preparing for UAM require specific airworthiness standards, pilot and operator certification, vertiport design regulations, public acceptance strategies, and low-altitude traffic management systems. In Türkiye, targeted reforms are necessary for eVTOL certification, operational safety, environmental regulation, cybersecurity, data governance, and urban airspace management. Regulatory sandboxes, controlled test zones, and simulation-based safety assessments can facilitate this transition.

UAM in Türkiye should be conceptualized as a socio-technical mobility transition. Beyond aircraft and infrastructure, deployment will require robust cybersecurity governance, software update management, product liability regulations, data privacy protection, and clear allocation of responsibilities among manufacturers, operators, software developers, infrastructure providers, public authorities, and municipalities. This is essential because autonomous and semi-autonomous aerial vehicles will introduce new questions regarding fault, negligence, foreseeable risk, property rights, neighborhood law, and criminal liability [4]. Türkiye's UAM strategy should commence with controlled pilot projects supported by environmental monitoring, public engagement, safety assessment, and institutional coordination. Suggested pilot implementation priorities for Türkiye is summarized at Table 2.

Table 2. Suggested pilot implementation priorities for Türkiye.

Priority area	Recommended action	Expected contribution
Pilot corridors	Test airport-city, hospital-hospital, disaster logistics, and limited cargo missions before commercial air taxi deployment.	Produces operational data and demonstrates public value in controlled settings.
Vertiports and energy	Evaluate rooftops, heliports, airport areas, hospitals, and transport hubs with charging, storage, and emergency-access requirements.	Links aircraft capability with infrastructure feasibility and multimodal access.
Low-altitude airspace	Define corridors, geofencing, deconfliction, emergency landing rules, and coordination between ATM and UTM functions.	Reduces safety, certification, and enforcement uncertainty.
Governance and acceptance	Use regulatory sandboxes, cybersecurity rules, data-governance procedures, noise monitoring, and public engagement.	Builds institutional readiness, accountability, and social trust.

6 Discussion: Cross-cutting Research Needs

The review suggests that future research on UAM should transition from technology-focused feasibility analyses to integrated planning and governance frameworks. Demand remains a critical uncertainty. UAM will generate significant benefits only if it attracts users from trips with substantial travel-time savings and if access, waiting, boarding, and transfer times do not negate these advantages. Consequently, demand studies should account for total door-to-door travel time, willingness to pay, service reliability, user heterogeneity, and the competitive or complementary roles of metro, rail, bus, taxi, and ride-hailing systems. In Türkiye, such analyses are especially important, as high congestion does not necessarily translate into sufficient willingness to use or pay for aerial mobility services.

A second research priority involves simulation and network design. UAM system performance is determined by the interplay among vertiport locations, fleet size, charging durations, passenger demand, dispatching protocols, airspace limitations, and weather conditions. Simulation tools enable the evaluation of these factors prior to infrastructure investment. For instance, event-based operational simulations and digital-twin methodologies

can assess passenger delays, aircraft utilization, energy consumption, queuing at vertiports, emergency capacity, and noise exposure. These approaches would enable Turkish cities to compare alternative pilot corridors and determine whether proposed vertiport networks can function safely and efficiently under realistic conditions.

Future UAM research in Türkiye should emphasize institutional coordination among aviation authorities, municipalities, transport operators, energy providers, emergency services, technology companies, and legal institutions. Developing a coordinated roadmap is essential to delineate responsibilities for certification, vertiport approval, corridor designation, cyber incident response, environmental monitoring, and public communication.

7 Conclusion

UAM has emerged as a promising mobility concept, driven by eVTOL aircraft, electric propulsion, autonomous systems, digital aviation technologies, and increasing challenges of urban transport. This study demonstrates that UAM could enhance future urban transportation through applications including airport access, emergency medical transport, disaster response, tourism, selected logistics operations, and limited air taxi services. However, UAM should not be evaluated solely as an aircraft technology. It represents a complex mobility ecosystem that requires coordinated development of vehicles, vertiports, energy systems, low-altitude airspace management, safety procedures, regulatory frameworks, and public acceptance.

Different eVTOL configurations offer distinct operational advantages. Therefore, aircraft selection should be aligned with the intended use case, infrastructure capacity, safety standards, and regulatory readiness.

In Türkiye, UAM presents both opportunities and challenges. Metropolitan areas such as Istanbul, Ankara, and İzmir may generate demand for airport access, emergency response, and selected logistics applications, while domestic initiatives suggest emerging technological capacity. However, scalable implementation requires certified vertiport infrastructure, charging and energy systems, dedicated low-altitude corridors, eVTOL-specific standards, operational safety rules, and clearer airspace integration procedures. Existing aviation regulations provide a foundation for conventional aviation but are inadequate for addressing UAM-specific operational, environmental, legal, and cybersecurity concerns.

Therefore, Türkiye should implement a phased approach that includes controlled pilot projects, regulatory sandboxes, public engagement, environmental and noise monitoring, and simulation-based safety assessments. This strategy would enable the testing of technical feasibility while simultaneously developing the institutional, legal, and social readiness necessary for safe, sustainable, and publicly acceptable UAM operations.

Abstract. Understanding user preferences is a key challenge in transportation planning. Although data mining and big data approaches have advanced considerably, stated-preference surveys remain an effective method for analyzing travel behavior, particularly for future-oriented scenarios and policy alternatives. This study conducted an online Stated Preferences survey to examine the mode-choice behavior of e-scooter users under varying travel-time and cost conditions. Participants evaluated 24 hypothetical scenarios and selected one of four modes: private car, taxi, public transportation, or e-scooter.

The collected data were analyzed using traditional discrete-choice models and four machine-learning methods. Model performance was assessed through accuracy, precision, recall, and F1-score. The results showed that machine-learning methods outperformed traditional choice models, especially in capturing nonlinear relationships and complex interactions among variables.

In the second stage, a synthetic population of 5,000 users was generated from the survey data. Mode choices across the 24 scenarios were estimated using the two best-performing machine-learning methods, Random Forest and Decision Tree, together with the traditional choice model. This enabled comparison not only in terms of classification performance but also in terms of behavioral distributions within the synthetic population.

The findings revealed that models with similar predictive performance can produce different mode-choice distributions in specific scenarios. Therefore, high accuracy alone does not ensure behavioral consistency. The study contributes to the literature by highlighting the importance of considering both prediction accuracy and behavioral plausibility in preference modeling and synthetic population generation.

Keywords: Micromobility; E-scooter users; Machine learning; Behavioral modeling.

1 Introduction

User preferences are a central concern in transportation planning, especially with the introduction of emerging mobility services into established urban transport systems. In densely populated metropolitan areas, rising congestion, limited road capacity, environmental challenges, and evolving mobility needs have promoted the adoption of flexible, short-distance transport alternatives. Shared e-scooters have emerged as a significant element of urban

micromobility because they facilitate first and last kilometer connectivity, complement public transportation, and offer a practical solution for short urban journeys.

The role of e-scooters within urban mobility systems is highly context-dependent. Their adoption is shaped by factors such as travel time, cost, safety perceptions, infrastructure availability, traffic conditions, parking opportunities, trip purpose, and user characteristics. Prior research indicates that e-scooter users differ by socio-demographic attributes, including age, gender, income, education level, and ownership status [1–4]. The transport modes replaced by e-scooter trips also vary by context. Some studies report that e-scooters primarily substitute for walking and public transportation, while others find that they may replace private car, taxi, or ride-hailing trips, depending on local infrastructure, parking, and travel patterns [1, 3–5].

Discrete-choice models have long been employed to analyze mode-choice behavior in transportation planning. Grounded in the principle of utility maximization, these models have been applied to urban and intercity travel, route selection, airport access, freight transport, and emerging mobility services [6–8]. Binary Logit, Multinomial Logit, Nested Logit, and Mixed Logit models establish interpretable relationships between travel attributes and user choices, with Mixed Logit models further accommodating preference heterogeneity [9, 10]. However, the application of these models to e-scooter mode choice remains limited. Existing research has explored e-scooter and e-bike preferences, integration with public transportation, infrastructure selection, and sensitivity to travel time and cost [4, 11–14].

Recent developments in data mining and machine learning have expanded opportunities for modeling travel behavior. Machine-learning techniques can capture nonlinear relationships and complex variable interactions that conventional utility-based models may not fully represent. In the context of e-scooters, prior studies demonstrate that machine-learning approaches are effective for identifying demographic differences, access-related effects, and behavioral patterns in short-distance micromobility choices [15]. Nevertheless, higher predictive accuracy does not guarantee that a model yields behaviorally consistent or policy-relevant outcomes, particularly when applied to scenario-based analyses.

This concern is especially relevant for synthetic population applications. Within the broader transportation modeling literature, synthetic populations and agent-based models have been utilized to represent travel demand, parking demand, shared mobility, and network-level impacts [16–19]. However, the integration of e-scooter mode-choice modeling with synthetic population analysis is still limited. This gap is methodological in nature: models may exhibit comparable classification performance yet produce divergent aggregate mode-choice distributions when applied to larger hypothetical populations.

The present study addresses this methodological gap by comparing traditional discrete-choice models and machine-learning methods for e-scooter mode-choice behavior. An online stated-preference survey was administered in Istanbul to assess user choices under varying travel-time and cost conditions. Participants evaluated 24 hypothetical scenarios designed for a 4 km corridor between Bostancı and Selamiçeşme on Bağdat Avenue, selecting one of four transport modes: private car, taxi, public transportation, or e-scooter. The resulting data were analyzed using both conventional choice modeling and machine-learning techniques, with model performance assessed through accuracy, precision, recall, and F1-score.

In the subsequent stage, a synthetic population of 5,000 users was generated based on the survey data. Mode choices across the 24 scenarios were estimated using the two best-performing machine-learning models, Random Forest (RF) and Decision Tree (DT), alongside the traditional discrete-choice model. This approach enabled a comparison of modeling techniques not only in terms of predictive performance but also regarding the behavioral distributions produced under identical scenario conditions. The study contributes to the literature by demonstrating that prediction accuracy alone is insufficient for model evaluation

and that behavioral plausibility must also be considered in synthetic population-based mode-choice analysis.

2 Survey Design and Data Collection

An online stated-preference (SP) survey was developed to examine mode-choice behavior associated with e-scooter use in Istanbul. The survey sought to determine how users respond to varying combinations of travel time and travel cost when selecting among private car, taxi, public transportation, and e-scooter options. Initially, 512 responses were collected. Given that the study focused exclusively on Istanbul, responses from participants residing outside the city were excluded from the analysis. Following this filtering process, the final sample comprised 461 valid respondents. This sample size was deemed sufficient, as it exceeds the minimum recommended sample size of 384 for heterogeneous populations larger than 500.000 individuals [20].

The questionnaire comprised three main sections. The first section gathered socio-demographic information, including gender, age, education level, income level, driving license ownership, private car ownership, household size, number of cars in the household, and employment status. These variables were incorporated to capture individual heterogeneity in mode-choice behavior and to assess the influence of user characteristics on e-scooter preferences.

The second section addressed respondents' current travel habits and attitudes toward e-scooters. Participants provided information regarding their most frequently used transport mode, primary trip purpose, availability of bicycle lanes within 250 meters of their residence, preferred infrastructure for e-scooter use, willingness to use e-scooters on sidewalks or roads, perceived safety of e-scooters, parking preferences, compliance with traffic regulations, and the main factors influencing their decision to choose or avoid e-scooters. These questions were designed to describe the behavioral and perceptual context underlying the stated-preference choices.

The third section of the survey presented hypothetical mode-choice scenarios. These scenarios were constructed for a 4 km urban trip along Bağdat Avenue, between Bostancı and Selamiçeşme, a dense urban corridor in Istanbul. In each scenario, participants were offered four alternatives: private car, taxi, public transportation, and e-scooter. Each alternative was characterized by two primary attributes: travel time and travel cost. Respondents were instructed to select the mode they would prefer under the specified conditions.

Travel time levels were established based on three traffic conditions: free-flow, unstable, and congested. For private car and taxi, travel times were set at 9, 20, and 30 minutes, respectively. Public transportation travel times were 15, 29, and 45 minutes. As the e-scooter speed was assumed to remain constant regardless of traffic conditions, its travel time was fixed at 16 minutes for the 4 km trip, corresponding to the legal speed limit of 15 km/h.

Travel cost was represented by two levels for each mode, reflecting the base cost and an increased cost level. The increased cost was calculated using the 2023 inflation rate of 65%. For the 4 km trip, the resulting cost levels were 65 TL and 105 TL for private car, 15 TL and 25 TL for public transportation, 75 TL and 125 TL for taxi, and 75 TL and 125 TL for e-scooter. The e-scooter base cost was determined by averaging the prices of three shared e-scooter operators and rounding to 75 TL for clarity in the survey.

A full factorial design would have resulted in 48 scenarios based on the combinations of travel cost levels and traffic conditions. Presenting this number of scenarios to each respondent could have increased response burden and compromised data quality. To address this, a fractional factorial design was implemented to reduce the number of scenarios while maintaining the integrity of the experimental structure. Consequently, the final questionnaire included 24 scenarios. Each of the 461 respondents evaluated 24 scenarios, resulting in a dataset

of 11,064 respondent-scenario observations for subsequent modeling. The properties of the scenarios are given at Table 1.

Table 1. The properties of the scenarios.

		Private Car		Taxi		E-scooter		Public transport

3 Modeling Methodology

A sequential modeling framework was implemented, comprising three primary stages: traditional discrete-choice modeling, machine-learning-based prediction, and synthetic population-based comparison. In the initial stage, discrete-choice models were constructed to estimate respondents' mode choices among private car, taxi, public transportation, and e-scooter alternatives. Discrete-choice models were selected as the starting point because they constitute the conventional framework for mode-choice analysis and offer interpretable utility-based relationships between travel attributes and user choices.

The explanatory variables comprised travel time, travel cost, and selected user-specific characteristics obtained from the survey. Travel time and travel cost were treated as alternative-specific variables, while socio-demographic and attitudinal variables captured preference heterogeneity. Categorical variables were converted into dummy variables prior to model

estimation. Each respondent evaluated 24 stated-preference scenarios, resulting in a modeling dataset with repeated respondent-scenario observations.

The initial discrete-choice models yielded valuable behavioral insights; however, their predictive performance was limited. Both the pooled model and the model for respondents without private car ownership achieved an accuracy of approximately 54%, whereas the model for private car owners attained only 40%. This relatively low performance was primarily due to the dominance of public transportation choices in the dataset and the models' tendency to classify some private car and e-scooter choices as public transportation.

Given the limited predictive performance of the discrete-choice models, supervised machine-learning methods were subsequently evaluated. Four models were developed: an Artificial Neural Network (ANN), a DT, a RF, and a gradient boosting-based classification model (GB). These models were trained using the same survey-based dataset and targeted the selected transportation mode. In contrast to discrete-choice models, machine-learning methods do not require a predefined utility specification and can capture nonlinear relationships, threshold effects, and complex interactions among explanatory variables.

Model performance was assessed using confusion matrices and standard classification metrics, including accuracy, precision, recall, and F1-score. Due to dataset imbalance, both macro and weighted metrics were reported. This distinction was necessary because public transportation and private car constituted the majority classes, while taxi and e-scooter had lower support values. Specifically, the dataset contained 5.186 public transportation observations, 3.663 private car observations, 1.599 e-scooter observations, and 640 taxi observations.

Table 2. Summary of machine-learning model performance.

	Macro				**Weighted**			
	Accuracy	**Precision**	**Recall**	**F1**	**Accuracy**	**Precision**	**Recall**	**F1**
ANN	0,844	0,571	0,509	0,505	0,872	0,717	0,704	0,690
Decision Tree	**0,924**	**0,835**	**0,815**	**0,829**	**0,897**	**0,828**	**0,890**	**0,854**
Random Forest	0,859	0,664	0,553	0,575	0,827	0,701	0,723	0,701
Gradient Boosting	0,833	0,706	0,725	0,698	0,863	0,663	0,524	0,553

The results shown in Table 2 demonstrate that the machine-learning models consistently outperformed the traditional discrete-choice models. Among the evaluated approaches, the Decision Tree model exhibited the strongest overall performance, achieving the highest macro accuracy, macro F1-score, weighted accuracy, and weighted F1-score. The Random Forest model was retained for the synthetic population stage as a benchmark for ensemble-based machine learning. Consequently, Decision Tree and Random Forest were selected as the two machine-learning models for comparison with the discrete-choice model in the subsequent synthetic population analysis.

4 Synthetic Population Generation

Following model development, a synthetic population was constructed to assess the impact of model selection on scenario-based mode-choice outcomes. This stage aimed to extend the analysis beyond observation-level performance metrics by determining whether different models yield consistent aggregate distributions when applied to a larger hypothetical population. A synthetic population of 5.000 users was generated by maintaining the proportional distribution of key characteristics identified in the stated preference (SP) survey, such as socio-demographic variables, travel-related attributes, and e-scooter-related attitudes. Each synthetic user was evaluated across the same 24 scenarios described in Table 1, resulting in 120.000 user-scenario observations. Mode choices were predicted using three models: the

traditional discrete-choice model, Decision Tree, and Random Forest. The discrete-choice model served as an interpretable benchmark, while Decision Tree and Random Forest were selected for their superior machine-learning performance. For each scenario, predicted choices were aggregated to determine the percentage distribution of users selecting private car, taxi, public transportation, or e-scooter. This approach facilitated comparison of the population-level implications of model selection. Although accuracy, precision, recall, and F1-score assess predictive performance, these metrics do not necessarily reflect whether a model produces plausible aggregate mode-choice patterns. Consequently, the synthetic population analysis provided an additional evaluation step to assess behavioral consistency under scenario-based conditions.

5 Results and Discussion

The results were evaluated in two complementary stages. First, the predictive performance of the modeling approaches was assessed using classification metrics. Second, the models were applied to the synthetic population to compare their scenario-based mode-choice distributions. This second stage is significant because models with distinct prediction mechanisms can produce different aggregate behavioral outcomes, even when trained on the same stated-preference dataset.

As shown in Table 2, machine-learning models generally outperformed traditional discrete-choice models in predictive performance. The Decision Tree model demonstrated the strongest overall performance, achieving the highest macro and weighted F1-scores. The Random Forest model also yielded competitive results and was retained as an ensemble-based machine-learning benchmark. In contrast, discrete-choice models exhibited lower predictive accuracy, with the pooled model achieving approximately 54% accuracy. While the discrete-choice model remains valuable as an interpretable benchmark, its limited predictive performance indicates that it may not fully capture nonlinear relationships and interaction effects present in the survey data.

Table 3 presents the mode-choice shares predicted by the Decision Tree, Random Forest, and discrete-choice models for the synthetic population across the 24 stated-preference scenarios. The table enables a direct comparison of how the three modeling approaches respond to changes in travel time and travel cost.

The results indicate substantial differences among the three models. The Decision Tree model produced the most balanced mode-choice distributions across the four alternatives. On average, it predicted 16,2% e-scooter use, 4,8% taxi use, 42,9% public transportation use, and 36,1% private car use across the 24 scenarios. This finding demonstrates that the model distributed choices across alternatives more flexibly and generated non-zero shares for all modes in every scenario. The e-scooter share predicted by the Decision Tree model increased systematically under congested traffic conditions, rising from an average of 3,2% in free-flow conditions to 12,4% in unstable traffic and 33,1% in congested traffic.

The Random Forest model also demonstrated sensitivity to traffic conditions, but it produced more conservative e-scooter shares in free-flow and unstable traffic scenarios. The average e-scooter share was 0,9% in free-flow traffic and 2,3% in unstable traffic, increasing sharply to 30,1% under congested conditions. This pattern suggests that the Random Forest model associated e-scooter preference primarily with situations where e-scooters offered a clear travel-time advantage over motorized modes and public transportation. Regarding overall distribution, Random Forest assigned the highest average share to public transportation, followed by private car, e-scooter, and taxi.

The discrete-choice model produced a more rigid distributional pattern. Across the 24 scenarios, it assigned no taxi share in any scenario and predicted e-scooter use only in four scenarios: Scenarios 6, 12, 18, and 24. These scenarios all represent congested traffic conditions

and feature the lower e-scooter fare of 75 TL. In these cases, e-scooter travel time remains 16 minutes, while private car and taxi travel times increase to 30 minutes and public transportation travel time increases to 45 minutes. Thus, the discrete-choice model predicted e-scooter use only when e-scooters provided both a significant travel-time advantage and a relatively low cost.

Table 3. Scenario-based mode-choice shares predicted by the Decision Tree, Random Forest, and discrete-choice models for the synthetic population.

Scenario	Decision Tree				Random Forest				Multinomial Logit			
	E-scooter	Taxi	Public Transport	Private Car	E-scooter	Taxi	Public Transport	Private Car	E-scooter	Taxi	Public Transport	Private Car

16	2,83	2,47	49,93	44,77	0,84	1,32	47,05	50,79	0,00	0,00	74,52	25,48
17	17,55	1,18	36,48	44,79	1,75	0,76	39,44	58,05	0,00	0,00	70,12	29,88
18	33,41	4,19	33,55	28,84	35,09	0,60	41,31	23,00	33,92	0,00	19,36	46,72
19	1,43	1,70	38,84	58,03	0,67	1,49	39,26	58,58	0,00	0,00	74,52	25,48
20	4,43	0,24	37,28	58,05	1,19	0,89	36,82	61,10	0,00	0,00	70,12	29,88
21	30,17	7,35	35,16	27,32	16,03	0,98	52,45	30,54	0,00	0,00	37,52	62,48
22	5,16	1,70	40,34	52,80	0,87	1,58	48,22	49,33	0,00	0,00	80,16	19,84
23	9,34	0,24	38,78	51,64	1,93	0,82	40,86	56,39	0,00	0,00	71,22	28,78
24	32,29	4,86	35,08	27,77	31,88	1,48	49,33	17,31	33,92	0,00	25,60	40,48

These findings indicate that the discrete-choice model produced a threshold-like behavioral response. In congested scenarios with an e-scooter fare of 125 TL, the model assigned no e-scooter share, despite the travel-time advantage. Similarly, in free-flow and moderate traffic scenarios, the model did not predict e-scooter use because the time advantage was either absent or limited. The variation among the four e-scooter-positive scenarios also demonstrates the effect of private car cost. In Scenarios 6 and 12, where private car cost was 105 TL, the predicted

e-scooter share was 43,02%. In Scenarios 18 and 24, where private car cost decreased to 65 TL, the e-scooter share declined to 33,92%. This suggests that lower private car cost reduces the relative attractiveness of e-scooters, even under congested traffic conditions.

Another notable finding relates to public transportation. The discrete-choice model assigned a high average share to public transportation, approximately 68,9%, particularly under free-flow and unstable traffic conditions where e-scooter use was not predicted. In contrast, the Decision Tree and Random Forest models generated more varied distributions and permitted e-scooter shares to increase incrementally as travel conditions deteriorated.

The comparison further demonstrates that high predictive performance does not necessarily result in identical population-level behavioral outputs. Both the Decision Tree and Random Forest models outperformed the discrete-choice model in classification performance, yet they produced different scenario-based distributions. The Decision Tree model generated higher e-scooter shares across a broader range of scenarios, including some free-flow and unstable traffic cases. In contrast, the Random Forest model was more restrictive, concentrating e-scooter demand primarily in congested scenarios. This difference indicates that even machine-learning models with strong predictive performance may yield distinct behavioral interpretations when applied to a synthetic population.

The results demonstrate that model selection significantly affects scenario-based transportation analysis. The discrete-choice model provided a more interpretable but less flexible representation of e-scooter preferences, while the Decision Tree and Random Forest models produced more responsive aggregate distributions. These findings indicate that, for synthetic population applications and policy-oriented scenario analysis, behavioral plausibility and aggregate distributional effects should be evaluated alongside accuracy and F1-score.

From a policy perspective, the results indicate that e-scooters become competitive primarily when urban traffic conditions deteriorate and their cost remains sufficiently low. Congested scenarios with low e-scooter fares produced the highest e-scooter shares across all models. This finding suggests that e-scooters may serve as an effective alternative for short urban trips under congested conditions, but their competitiveness is highly sensitive to pricing. If e-scooter fares approach or exceed taxi-like cost levels, their modal share may remain limited, even when they offer travel-time advantages. Consequently, pricing strategies, infrastructure provision, and integration with public transportation should be considered collectively when evaluating the future role of e-scooters in urban mobility systems.

6 Conclusion

This study compares traditional discrete-choice models and machine-learning methods for predicting e-scooter-related mode choice using stated preference (SP) survey data from Istanbul. The analysis further examines whether these models yield consistent behavioral distributions when applied to a synthetic population of 5.000 users across 24 scenarios. Results indicate that while discrete-choice models offer valuable behavioral interpretation, their predictive performance is limited. In contrast, machine-learning methods, particularly Decision Tree and Random Forest, demonstrate stronger classification performance and more effectively capture nonlinear relationships in the survey data. However, analysis of the synthetic population reveals that predictive performance alone is insufficient for comprehensive model evaluation. Despite being trained on the same dataset, the models generate different aggregate mode-choice distributions under identical scenario conditions. The discrete-choice model produces a more rigid pattern, predicting e-scooter use primarily in congested scenarios with low e-scooter fares. Conversely, the Decision Tree and Random Forest models yield more flexible distributions and capture gradual shifts in e-scooter preference across varying travel-time and cost conditions. These findings underscore the importance of considering behavioral plausibility and aggregate consistency alongside accuracy, precision, recall, and F1-score. From a policy perspective, the

results indicate that e-scooters become more competitive as congestion increases and fares remain relatively low. Consequently, pricing strategies, infrastructure provision, and integration with public transportation should be jointly evaluated when planning e-scooter systems. Overall, this study advances synthetic population-based mode-choice modeling by demonstrating that model selection can directly influence scenario-based interpretations of micromobility demand.

Abstract. Traffic performance in urban areas can be influenced by the proximity of closely spaced roundabouts and the distance between them. This study investigates the influence of geometric and traffic characteristics on approach-level delays in two closely spaced unsignalized roundabouts. A dataset comprising queue length, delay, and geometric characteristics such as entry width, circulating width, roundabout radius, and the distance between intersections for all turning movements across eight approaches (A-H) was analyzed. Preliminary analysis indicated a nonlinear, quadratic relationship between a combined performance index and degree of saturation, varying by approach. To capture this variability, piecewise regression models were applied approach-by-approach, allowing different functional forms. This method enables good estimation of delay and identification of threshold values where performance deteriorates. Results show that the proposed spillback index-based approach, combined with piecewise modeling, provides a predictive capability across varying flow conditions and approach geometries. The approach-specific models highlight the sensitivity of delay to spillback index. This framework can support traffic engineers in optimizing roundabout spacing and predicting performance under mixed demand scenarios

Keywords:. roundabouts; traffic engineering; delay prediction; piecewise regression

1 Introduction

Closely spaced roundabouts are commonly found in urban networks, where limited space and high traffic demand require careful design and operation [1]. The intermediate distance between adjacent roundabouts can influence traffic behavior, affecting queue formation, delay, and overall performance at each approach [2]. Understanding these effects is essential for accurate delay prediction and effective traffic management.

Previous studies have examined roundabout performance using empirical models, simulation, and analytical approaches [3,4]. Standard guidelines, such as the Highway Capacity Manual (HCM) [5] and tools as SIDRA Intersection, provide methods to estimate approach delays and capacity [6]. However, most existing models focus on isolated roundabouts and do not explicitly address interactions in closely spaced configurations.

This study aims to investigate approach-level delay characteristics in two closely spaced unsignalized roundabouts. A combined performance index was developed to represent geometric and traffic conditions, and its relationship with the flow-to-capacity ratio, degree of saturation was analyzed. Quadratic and piecewise regression models were applied to capture nonlinearities and saturation effects, providing a framework for predicting delays under varying

traffic conditions. The approach-specific analysis highlights how proximity between roundabouts affects performance and identifies thresholds where congestion sharply increases.

2. Data and Study Area

This study focuses on two closely spaced unsignalized roundabouts located in an urban network. Each roundabout has four approaches (A-D for the first, E-H for the second), with turning movements including right, through, and left. Traffic data were analyzed using SIDRA Intersection (version 6.1), which provides detailed operational measures for intersection analysis [3]. Simulation outputs for each scenario were compiled into a structured dataset. The intermediate spacing (L), ranging from 50 m to 250 m, was varied to assess its impact on key performance indicators such as queue length (QL_x) and delay. Shorter spacings can lead to stronger interactions and potential queue spillback, while larger spacings allow more independent operation. The dataset includes approach-level performance measures for all scenarios representing varying traffic demand and operating conditions.

Traffic and geometric parameters were varied within realistic ranges to represent diverse operating conditions. Circulating flow (Q_c) ranged from 200 to 1200 veh/h, while the central island radius (R_i) varied between 10 and 50 m. The number of circulating lanes (n_c) and entry lanes (n_e) ranged from 1 to 3 and 1 to 2, respectively. Circulating width (W_c) and entry width (W_e) were set between 5–12 m and 5–8 m. For each approach, 100 scenarios were performed.

The queue length variable (QL_x) represents the queue formed within the intermediate link between the two roundabouts. It corresponds to the downstream queue at Roundabout 1 (QL_C) for approach C and the upstream queue at Roundabout 2 (QL_E) for approach E. This definition captures the interaction effects of closely spaced roundabouts on intermediate link queue formation.

In addition, a performance index was computed for each approach combining the queue length and spacing between the roundabouts. This index is named spillback index (SI) used as an explanatory variable to model delay (d), capturing both demand intensity and approach capacity, which can be seen in Equation (1).

$$SI = \frac{QL_X}{L} \tag{1}$$

Scenario variations enable the assessment of how traffic demand and geometric features affect queue formation and delay in the intermediate link. The eight approaches were grouped based on their spatial relation to the link: Group 1 (D-F) direct entries, Group 2 (C-E) downstream to upstream approaches, Group 3 (B-H) side entries, and Group 4 (A-G) outer approaches. This classification captures localized interactions between the two roundabouts, which is illustrated in Fig. 1.

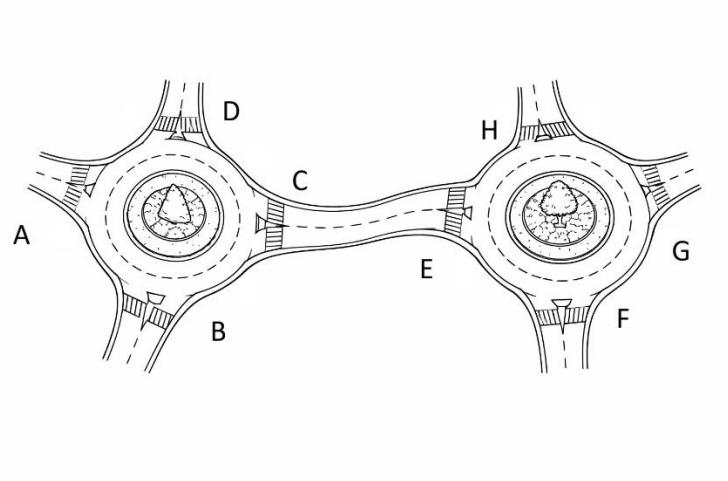

Fig. 1 Closely spaced roundabout system.

3. Methodology

3.1 Spillback index – degree of saturation relationship

Initial analysis revealed a quadratic relationship between the spillback index and X for each approach. This relationship differs across approaches, reflecting local geometry and traffic characteristics. The general form is given in Equation (2).

$$\mathrm{X} = \alpha \cdot (SI)^2 + \beta \cdot (SI) + \gamma \tag{2}$$

where coefficients (α, β, γ) are approach specific.

3.2 Piecewise regression

To capture nonlinearities for high saturation levels (> 1), a piecewise regression was applied. Piecewise regression divides the system of a predictor variable into intervals using breakpoints [7]. For each interval, a separate linear regression model is fitted [8]. The model can be expressed for delay prediction in Equation (3) as:X

$$d = \begin{cases} \beta_2^{(1)} X^2 + \beta_1^{(1)} X + \beta_0^{(1)} & X \le Threshold \\ \beta_0^{(2)} e^{\left[\beta_1^{(2)} X + \beta_2^{(2)} Q_c + \beta_3^{(2)} W_c + \beta_4^{(2)} n_c + \beta_5^{(2)} SI\right]} & X > Threshold \end{cases} \tag{3}$$

This approach allows separate modeling of moderate and oversaturated conditions, improving predictive accuracy. The first model of the model is fitted with 2nd order polynomial, and the second model is represented by log-linear (exponential) model. $\beta_0^{(1)}$ represents the intercept of the first model and β_n^m represents the coefficients. The number of models is m and the number of is shown by n.

4. Results and Discussion

4.1 Spillback Index-degree of saturation relationship

As shown in Fig. 2, the relationship between the spillback index (SI) and the degree of saturation (X) is nonlinear. A 2nd-degree polynomial regression was fitted to the data for all approaches. The regression equation and R^2 value indicate a good fit, capturing the general trend of increasing saturation with higher SI values. This fitted relationship is used for approach-specific prediction of delays in the closely spaced roundabouts studied.

SI values correlate strongly with degree of saturation and indirectly with delays, confirming their ability as a predictive variable. Approach-specific variations reveal that approaches closer to the adjacent roundabout are more sensitive to changes in X. Results indicate that intermediate spacing between roundabouts significantly influences delay, particularly for oversaturated approaches. The regression coefficients can be seen in Table 1.

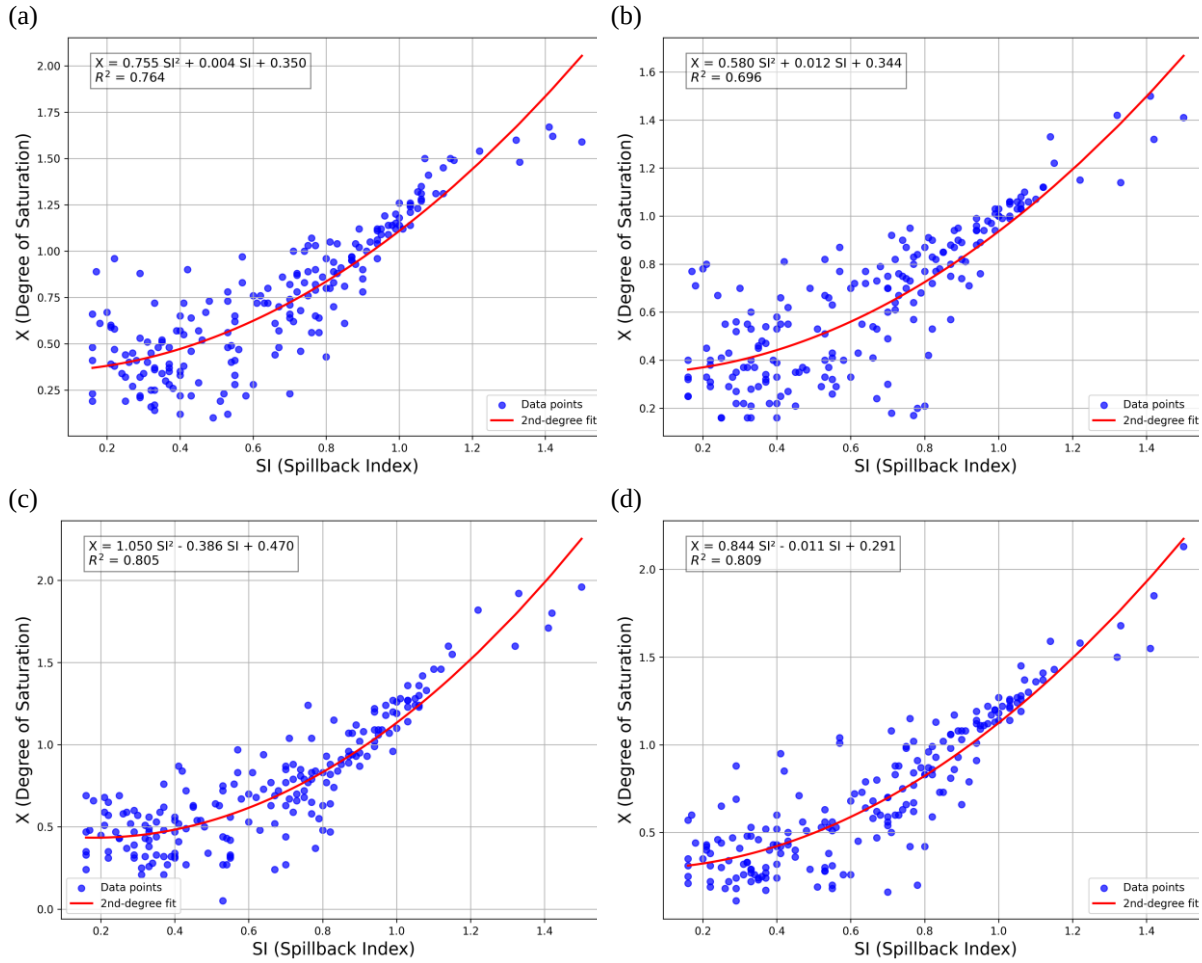

Fig. 2. Relationship between spillback index and degree of saturation for the analysed approaches (a) Group 1 (approaches D-F); (b) Group 2 (approaches C-E); (c) Group 3 (approaches B-H); (d) Group 4 (approaches A-G).

Table 1 Regression coefficients

Approach	α	β	γ	R^2
D-F	0.755	0.004	0.350	0.764
C-E	0.580	0.012	0.344	0.696
B-H	1.050	-0.386	0.470	0.805
A-G	0.844	-0.011	0.291	0.809

4.2 Piecewise regression model

A piecewise regression framework was adopted to capture different traffic regimes. While = 1 represents the theoretical capacity threshold, an optimal breakpoint was also determined through a data-driven approach by minimizing the prediction error across candidate thresholds, which can be seen in Fig. 3. The resulting threshold value indicates a transition between under

and over-saturated conditions. Optimal threshold was determined using a grid search approach by testing multiple candidate values and selecting the one minimizing the total prediction error [9].XX

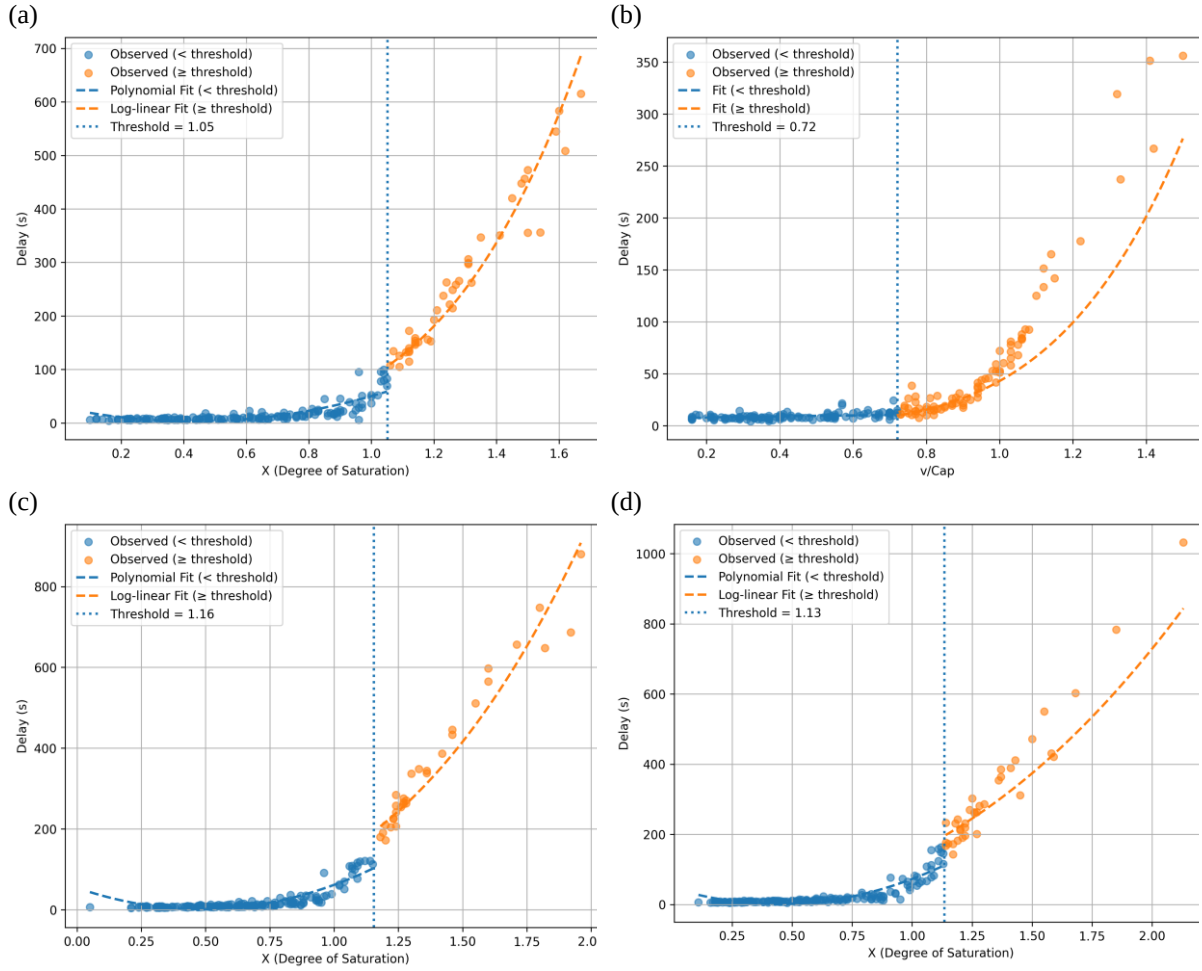

Fig. 3. Piecewise regression fit for (a) Group 1 (approaches D-F); (b) Group 2 (approaches C-E); (c) Group 3 (approaches B-H); (d) Group 4 (approaches A-G).

The approach-specific piecewise regression framework allows for accurate delay prediction across both moderate and high traffic conditions. The model performance significantly improves beyond the identified threshold for B-H approach ($X \approx 1.155$), indicating a transition to a more deterministic delay regime, which can be seen in Fig. 3c. The explanatory power of the oversaturated regime suggests that additional factors, such as geometric interactions and driver behavior, play a more prominent role, in contrast to undersaturated conditions. For the C-E approach (Group 2), the polynomial model could not adequately capture the relationship (low R^2), the log-linear model provides a better fit, which is seen in Fig. 3b.

The coefficients and the corresponding threshold values for each approach were given in Table 2. The C–E approach exhibits a notably low X threshold (0.721), indicating a short-distance segment with generally different congestion levels when compared the effect of other approaches. This segment was difficult to fit using the same model (polynomial), as the characteristic remains different over the range of observed traffic flows. In Model 1, only X was used as the independent variable, captures the main effect of saturation on delay and aligns well with the polynomial assumption, providing a predictable baseline. In Model 2, additional traffic and site variables (Q_{eng}, W_c, n_c, SI) were included to improve predictive accuracy by

accounting for secondary effects. For the C-E approach, the polynomial model could not adequately capture the relationship for model 1, resulting in a low R^2; this was better explained using a log-linear model.

Table 2 Regression coefficients and the threshold values

Approach	Model 1 – Polynomial				Threshold value	Model 2 – Exponential						
	$\beta_2^{(1)}$	$\beta_1^{(1)}$	$\beta_0^{(1)}$	R^2		$\beta_0^{(2)}$	$\beta_1^{(2)}$	$\beta_2^{(2)}$	$\beta_3^{(2)}$	$\beta_4^{(2)}$	$\beta_5^{(2)}$	R^2
D-F	145.144	-125.008	30.045	0.673	1.05	3.246	4.033	0.106	0.371	-0.428	-0.294	0.960
C-E	25.104	-13.140	9.454	0.289	0.721	2.483	4.586	0.531	-1.218	0.765	0.359	0.975
B-H	225.842	-218.320	53.955	0.810	1.16	3.765	2.921	0.076	0.402	-0.562	0.04	0.967
A-G	232.376	-206.798	47.139	0.815	1.13	3.200	2.322	-0.094	1.511	-1.295	0.922	0.957

C-E	0.284	0.207	0.329	0.111	-0.120	0.235	0.586

5. Conclusion

This study investigated the relationship between approach-specific, index-based piecewise regression models and delay in closely spaced roundabouts. Optimal thresholds were determined via grid search for each approach, revealing variations linked to segment length and congestion level. The quadratic relationship between SI and X, combined with piecewise fitting for high saturation, provides a practical insight for traffic engineers in operational analysis.

Totally eight approach and four approach groups (D-F, C-E, B-H, and A-G) were analyzed. D-F, B-H, and A-G approaches exhibited higher threshold values (1.05 – 1.16), reflecting sections where congestion significantly affects delay. In contrast, the C-E approach had a notably low threshold point (0.721), consistent with a short-distance segment, which also made fitting more challenging. Furthermore, while polynomial models captured the general trend for most approaches, the C-E approach was better represented by a log-linear model due to the limited fit of the polynomial regression. These findings highlight the importance of approach-specific modeling and threshold selection in accurately predicting delay at closely spaced roundabouts. Future studies may explore multi-roundabout networks and dynamic traffic assignment integration. Future work may extend the approach to larger networks or simulation-based scenarios, also some machine learning models can be adapted to the system to increase the prediction accuracy.

Abstract. This study investigates the effects of autonomous driving strategies on uninterrupted traffic flow, with particular emphasis on heavy vehicle–passenger car interactions. The analysis is based on empirical traffic data collected from multilane urban road sections in İzmir, Türkiye. Observed vehicle speeds and time headways were evaluated together with nine autonomous driving strategies defined in the Research on the Impacts of Connected and Autonomous Vehicles (CAVs) on Traffic Flow report prepared by Atkins Ltd. for the UK Department for Transport, ranging from highly cautious to aggressive driving behavior. The results show that aggressive autonomous driving strategies combined with high CAV penetration rates could theoretically increase lane capacity beyond 4,000 veh/h. In contrast, cautious strategies may reduce capacity where human drivers already maintain short headways. Empirical observations also revealed that drivers frequently follow heavy vehicles at critically short effective reaction times, despite apparently acceptable temporal headways, creating potentially unsafe conditions. Simulation results indicate that cautious autonomous driving substantially increases following headways behind trucks, particularly at CAV penetration rates of 50–70%. Overall, the findings demonstrate that adaptive autonomous driving strategies can improve both traffic safety and flow stability. The study highlights the importance of incorporating heavy vehicle interactions and strategy-dependent autonomous driving behavior into future traffic flow models to balance capacity and safety in mixed traffic environments.

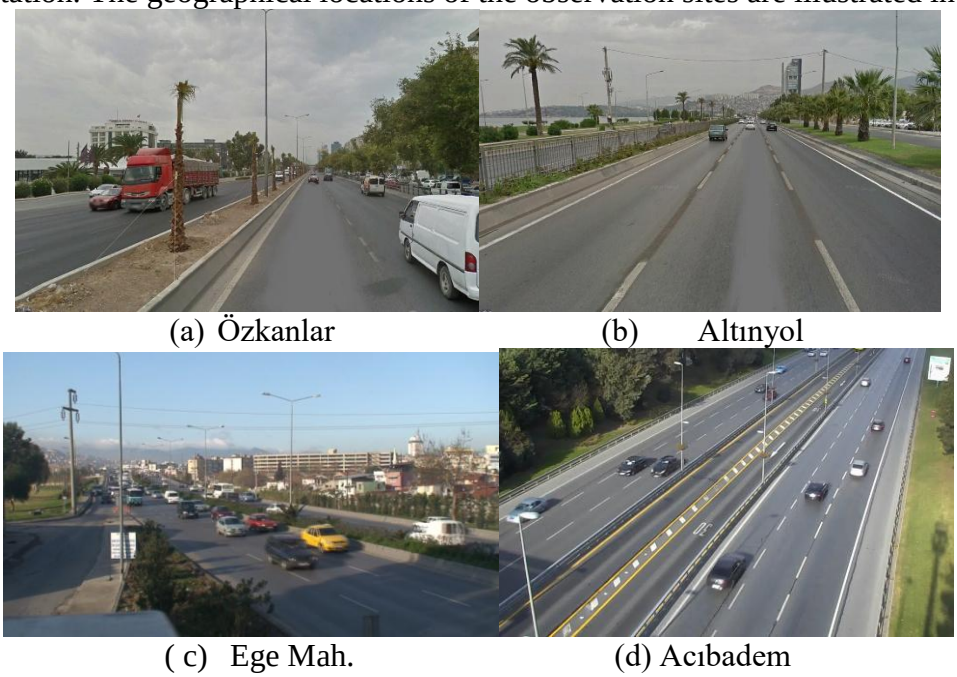
1 Introduction

Traffic congestion and road traffic crashes remain among the most significant transportation challenges worldwide, resulting in considerable economic losses, increased travel times, excessive fuel consumption, and severe social consequences. Roadway capacity is commonly defined as the maximum number of vehicles that can pass a specific roadway section within a given period under prevailing traffic and roadway conditions. Among the numerous factors affecting roadway capacity, vehicle time headway plays a fundamental role because it directly reflects the spacing maintained between successive vehicles. Since time headways are largely governed by drivers' perception-reaction times and individual driving behavior, they exhibit substantial variability among drivers

Human factors continue to be recognized as the dominant contributor to road traffic crashes. Both national statistics reported by the Turkish Statistical Institute (TÜİK) and international studies such as the HAVEit project indicate that driver-related factors account for the majority of traffic accidents [1,2]. Consequently, considerable research efforts have focused on reducing the influence of human driving behavior through the development of advanced driver assistance systems and autonomous driving technologies. These developments have accelerated research on connected and autonomous vehicles (CAVs), which are expected to fundamentally reshape future traffic operations.

Among different roadway facilities, uninterrupted traffic environments—including multilane freeways and freeway-like urban arterials—provide one of the most suitable settings for evaluating the operational impacts of connected and autonomous vehicles. In these facilities, vehicles generally travel at relatively stable speeds with short-to-moderate headways, allowing researchers to isolate the effects of car-following behavior from interruptions caused by traffic signals or stop-controlled intersections. Cooperative Adaptive Cruise Control (CACC) and connected vehicle technologies have therefore attracted considerable attention because they enable shorter following distances, coordinated acceleration and deceleration, and platoon formation. These capabilities have been shown to improve roadway capacity while simultaneously reducing fuel consumption and aerodynamic drag [3–6].

Roadway capacity improvements reported in the literature are largely influenced by the penetration rate of connected and autonomous vehicles, platoon size, traffic composition, particularly the proportion of heavy vehicles, and the geometric characteristics of merge and diverge areas [3–7]. Simulation-based studies have demonstrated that, under homogeneous CACC traffic conditions consisting entirely of passenger-car or truck platoons, increasing CAV penetration rate can raise lane capacity from approximately 2,046 veh/h/lane to more than 6,400 veh/h/lane [5,6]. On the other hand, several studies have shown that under high heavy-vehicle platooning rates, dedicated truck lanes or selective lane management strategies may provide greater operational benefits than allowing platoons to operate across all lanes, thereby preserving both capacity and traffic stability [7]. These findings suggest that the maximum operational benefits of autonomous driving technologies can only be achieved under relatively homogeneous traffic conditions. However, such conditions are unlikely to exist in the foreseeable future. Passenger cars and heavy vehicles will continue to coexist with conventional human-driven vehicles for many years, resulting in mixed traffic environments. Consequently, understanding the interaction between autonomous vehicles and conventional heavy vehicles has become one of the key research challenges in future traffic engineering.



At the end of 2024, approximately 6.2 million medium- and heavy-duty commercial vehicles were in operation across European Union member states. Although the fleet continues to expand, its average age has also increased steadily, indicating that a substantial proportion of heavy vehicles will remain in operation for many years before being replaced by autonomous or highly automated alternatives [8]. A similar situation exists in Türkiye. According to statistics published by the Turkish Statistical Institute (TÜİK), approximately 1.03 million medium and heavy commercial vehicles were registered nationwide in 2024, and nearly 55% of these vehicles were older than 15 years [9]. These statistics clearly indicate that autonomous vehicles are expected to share the road with conventionally driven heavy vehicles equipped with existing technologies for an extended period. Therefore, investigating their operational interaction under mixed traffic conditions is of considerable practical importance.

The primary objective of this study is to investigate the interactions between autonomous vehicles and human-driven heavy vehicles under uninterrupted traffic flow conditions from the perspective of vehicle-following behavior. First, empirical observations collected from three multilane urban arterials in İzmir and one arterial roadway in İstanbul were used to model lane-specific time-headway distributions. Subsequently, autonomous vehicle driving strategies were

incorporated into these empirical headway distributions to estimate lane capacities under different autonomous vehicle penetration rates. Finally, mixed traffic scenarios involving passenger cars, autonomous vehicles, and human-driven heavy vehicles were analyzed to evaluate how autonomous driving strategies influence heavy vehicle interactions, traffic safety, and roadway capacity. The findings are expected to contribute to the development of more realistic mixed traffic flow models capable of representing future transportation systems in which autonomous and conventional vehicles operate simultaneously.

2 Study Sites and Headway Data Collection Procedure

To investigate traffic flow characteristics under uninterrupted traffic conditions, field observations were conducted at four major multilane urban arterial road sections. Three observation sites were located in İzmir, namely Altınyol, Özkanlar (Ankara Street), and Ege District (Mürselpaşa Boulevard), while the fourth site was located in Acıbadem, İstanbul, near the metro station. The geographical locations of the observation sites are illustrated in Fig. 1.

(a) Özkanlar (b) Altınyol

(c) Ege Mah. (d) Acıbadem

Fig. 1. Observation sites used for traffic data collection.

Traffic data were extracted from video recordings obtained under uninterrupted flow conditions. For each observation period, vehicle type, traffic volume, vehicle speed, and individual headways were determined through detailed video analysis. These parameters constituted the primary database used throughout the subsequent analyses. A total of 102 traffic data sets were initially obtained from the right, middle, and left lanes of the four observation sites. Observation periods were established as 15-minute intervals for the İzmir locations and 10-minute intervals for the Acıbadem site in İstanbul. Prior to statistical analysis, all data sets were subjected to a series of quality-control procedures to ensure their suitability for traffic flow modelling.

Trend analysis indicated that only one data set, corresponding to the right lane at the Acıbadem site, exhibited a statistically significant trend. Furthermore, 20 data sets showed evidence of serial dependence, while 17 data sets failed the randomness test. Consequently, these observations were excluded from further analyses, leaving 76 independent data sets suitable for modelling. The final database consisted of 22 right-lane, 27 middle-lane, and 27 left-lane observations.

The analyses demonstrated that vehicle time headways observed in uninterrupted traffic flow can be satisfactorily represented by using the Cowan M3 headway distribution. Originally proposed by Cowan [10], this model has subsequently been applied by several researchers to describe vehicle-following behavior under uninterrupted traffic conditions, including Bunker [11], Akçelik [12, 13] and Ceyhan Yiğiter and Tanyel [14]. The Cowan M3 distribution, also referred to as the deterministic queue model, assumes that a proportion of vehicles travel as followers, maintaining a minimum headway, Δ, behind their respective leading vehicles. The probability density function and cumulative distribution function of the Cowan M3 model are given by Eqs. (1) and (2), respectively.

$$f(t) = \alpha\lambda e^{-\lambda(t-\Delta)} \quad (1)$$

$$F(t) = 1 - \alpha e^{-\lambda(t-\Delta)} \quad (2)$$

where $\boldsymbol{\alpha}$ denotes the proportion of free vehicles, $\boldsymbol{\Delta}$ represents the minimum headway within the traffic stream, and $\boldsymbol{\lambda}$ is the exponential scale parameter. Here a couple of important features of Cowan M3 distribution should be mentioned to have a better understanding of the outcomes of further analysis.

First, it is necessary to discuss the concept of the proportion of free vehicles (α). This parameter is a value that represents the number of vehicles in a traffic flow that do not affect each other in terms of speed and following distance; it can also represent their behavior under different traffic flow conditions. Figure 2 shows the variation of proportion of free vehicles for different lanes, obtained from observations, depending on the traffic flow. Another noteworthy feature of Eqs. (1)–(4) is the repeated appearance of the product Δq. This parameter is directly associated with the minimum time headway, which Akçelik (2003) suggested should correspond to the headway at roadway capacity. Accordingly, Δ can be interpreted as the minimum headway associated with lane capacity as $Q_{cap} = 3600/\Delta$. Consequently, the product Δq represents the degree of saturation of the traffic stream which as an important parameter in traffic flow analysis.

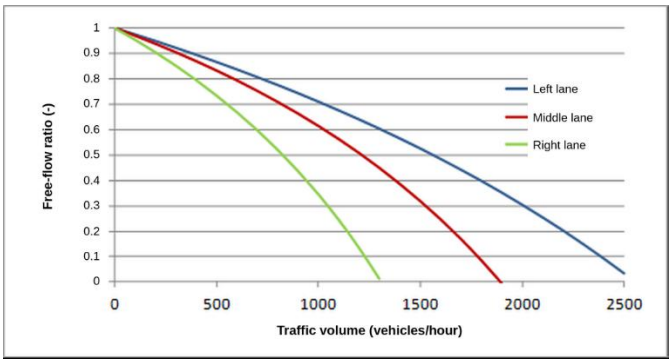


Fig. 2. Variation of the proportion of free vehicles with traffic volume for different lane types.

3. Effects of Autonomous Vehicle Driving Strategies on Traffic Flow Characteristics

Numerous studies have investigated the car-following behavior of autonomous vehicles using microscopic traffic simulation models and theoretical car-following algorithms. The prevailing assumption in the literature is that autonomous vehicles are capable of maintaining considerably shorter and more stable following headways than human-driven vehicles owing to their advanced sensing, communication, and control capabilities. Consequently, higher roadway capacities and improved operational performance are generally expected under increasing autonomous vehicle penetration rates. Martin-Gasulla et al. [15] reported that autonomous vehicles operating under vehicle-to-vehicle (V2V) communication can safely maintain

extremely short following distances when both the leading and following vehicles are autonomous. However, when the leading vehicle is a conventional human-driven vehicle, autonomous vehicle manufacturers may intentionally adopt more conservative following behavior to ensure adequate safety margins. Consequently, the expected capacity improvements may not be fully achieved in mixed traffic environments containing both autonomous and conventional vehicles. This observation suggests that the operational performance of autonomous vehicles depends not only on their penetration rate but also on the driving strategy adopted by their control systems. Friedrich [16] expressed traffic density under uninterrupted traffic conditions as:

$$k = \frac{1}{vT_H + L} \tag{3}$$

where *k* is traffic density (veh/m/lane), *v* is vehicle speed (m/s), *L* is the effective vehicle length consisting of the leading vehicle length plus the clearance between successive vehicles, and T_H is the headway. In autonomous driving applications, the headway may be interpreted as the effective reaction time required by either a human driver or an autonomous driving system.

Although communication among autonomous vehicles may theoretically reduce reaction times to values approaching zero, the strategies adopted while following conventional human-driven vehicles remain uncertain. These strategies primarily determine the desired spacing between the front bumper of the following autonomous vehicle and the rear bumper of the leading vehicle, together with the effective reaction time maintained during vehicle-following operations. Among the available studies, the methodology proposed by Atkins Ltd. [17] provides one of the most comprehensive approaches for representing these behavioural differences. Accordingly, nine autonomous driving strategies were considered in the present study. Strategy TYP1 represents the most cautious behaviour, whereas TYP9 corresponds to the most confident (aggressive) driving strategy. In the study, the recommended safe following distance is expressed as:

$$d_{safe} = CCO + CC1 * v \tag{4}$$

where d_{safe} is the desired following distance (m), *CC0* denotes the minimum standstill distance between the rear bumper of the leading vehicle and the front bumper of the following vehicle (m), *CC*1 represents the desired headway (s), and v is the travelling speed (m/s). The parameter values recommended by Atkins Ltd. [17] are summarized in Table 1.

Table 1. Recommended parameter values for autonomous vehicle driving strategies (adapted from Atkins, 2016).

Autonomous Vehicle Driving Strategy	TYP1	TYP2	TYP3	TYP4	TYP5	TYP6	TYP7	TYP8	TYP9
CC0 (m)	2,5	2,5	2,0	2,0	1,5	1,0	1,0	0,5	0,5
CC1 (sec)	2,1	1,8	1,5	1,2	0,9	0,8	0,7	0,6	0,5

Autonomous Vehicle Driving Strategy	TYP1	TYP2	TYP3	TYP4	TYP5	TYP6	TYP7	TYP8	TYP9
CC0 (m)	2,5	2,5	2,0	2,0	1,5	1,0	1,0	0,5	0,5
CC1 (sec)	2,1	1,8	1,5	1,2	0,9	0,8	0,7	0,6	0,5

Using these parameter values, modified headway distributions were generated for autonomous vehicle penetration rates ranging from 10% to 100%. The headway associated with each observation was calculated using the following equation where t_i is the resulting headway,

t_{CVi} and t_{AVi} denote the headways associated with conventional and autonomous vehicles respectively, while P_{CV} and P_{AV} represent the proportions of conventional and autonomous vehicles within the traffic stream.

$$t_i = \%P_{CV} * t_{CVi} + \%P_{AV} * t_{AVi} \quad (5)$$

Figure 3 presents the probability density functions obtained for the left lane at the Ege District observation site under 50% and 70% autonomous vehicle penetration rates. The distributions clearly demonstrate that increasing autonomous vehicle penetration shifts the headway distribution toward shorter values, particularly for aggressive driving strategies. Consequently, average time headways decrease, leading to substantial increases in theoretical lane capacity. The resulting capacity estimates indicate that, under highly confident autonomous driving strategies (TYP8–TYP9), lane capacities may exceed 4,000 veh/h/lane. Figure 4 illustrates the variation in lane capacity as a function of autonomous vehicle penetration rate for the different driving strategies considered in this study.

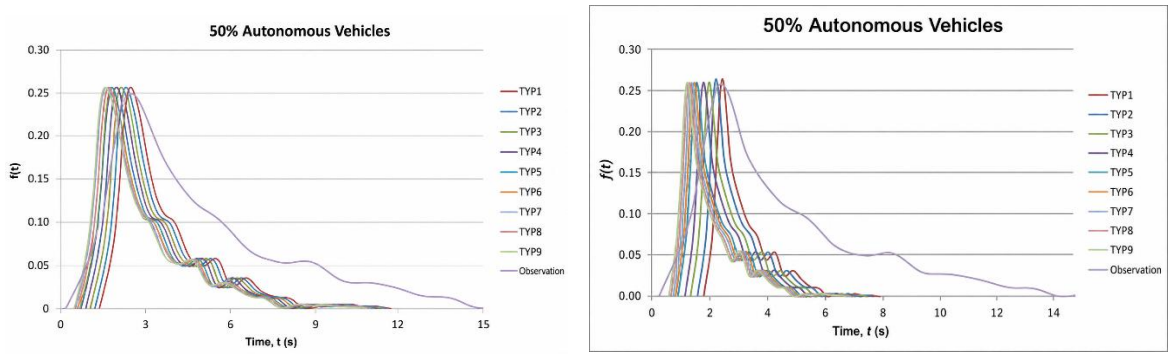

Fig. 3. Probability density functions of vehicle time headways for 50% and 70% autonomous vehicle penetration rate

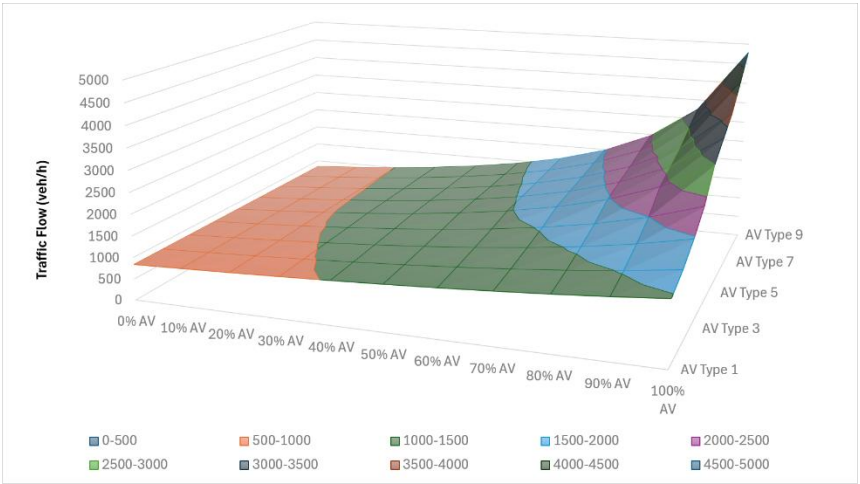

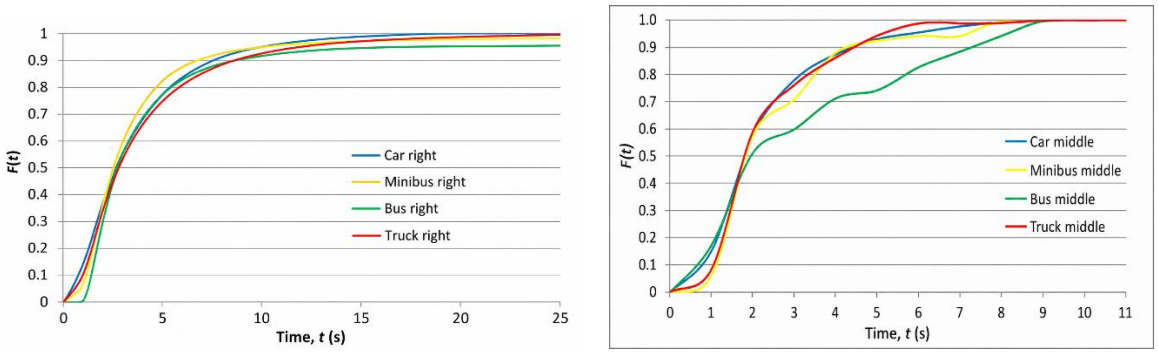

Fig. 4. Variation of lane capacity with autonomous vehicle penetration rate under different autonomous driving strategies.

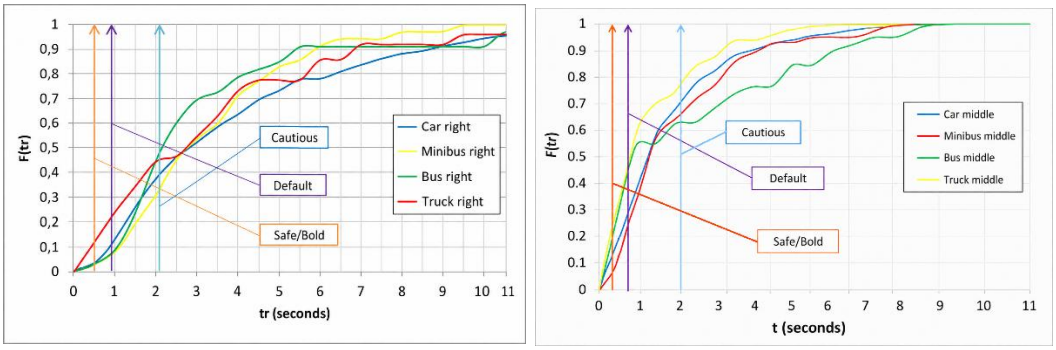
Results indicate that autonomous driving strategy is at least as influential as autonomous vehicle penetration rate in determining future traffic performance. While aggressive strategies maximize roadway capacity by minimizing following headways, conservative strategies preserve larger safety margins and therefore provide more limited capacity improvements. Consequently, future autonomous driving systems may benefit from adaptive driving strategies

that dynamically adjust their car-following behavior according to prevailing traffic conditions, roadway characteristics, and surrounding vehicle composition.

4. Passenger Car–Heavy Vehicle Interaction under Mixed Traffic Conditions

The introduction of autonomous vehicles into existing traffic streams will inevitably lead to interactions with conventionally driven heavy vehicles. Since heavy vehicles are expected to remain in service for many years, understanding the current behavior of human drivers when following these vehicles provides an essential basis for evaluating future mixed traffic conditions involving autonomous vehicles. To investigate these interactions, traffic observations obtained from the right and middle lanes of the Ege District observation site were analyzed, as this location exhibited the highest proportion of heavy vehicles among all study sites. Heavy vehicle composition at this location consisted of approximately 6% minibuses, 4% buses, and 11% trucks in the right lane, while the corresponding values for the middle lane were 7%, 4%, and 13%, respectively. Initially, the observed time headways maintained by passenger cars while following different vehicle classes were analyzed. Separate cumulative distribution functions were developed for passenger cars following passenger cars, minibuses, buses, and trucks. The resulting distributions are presented in Fig. 5.



(a) Right Lane (b) Middle Lane

Fig. 5. Cumulative distributions of passenger-car time headways while following different vehicle classes in the right and middle lanes.

The distributions indicate that passenger-car drivers travelling in the right lane generally maintain similar headways regardless of the vehicle type being followed. In contrast, drivers in the middle lane tend to maintain relatively longer headways when following buses. From a traffic safety perspective, however, one would normally expect substantially larger following distances behind all heavy vehicles due to their greater dimensions, reduced acceleration capabilities, and restricted forward visibility. This apparent contradiction arises because headway alone does not adequately represent the actual spacing maintained behind heavy vehicles. Since trucks and buses are considerably longer than passenger cars, identical headways may correspond to significantly shorter effective clearances between the rear bumper of the leading vehicle and the front bumper of the following vehicle. Consequently, evaluations based solely on temporal headways may underestimate the safety risks associated with heavy vehicle following.

A more representative measure of driver behavior is therefore the effective reaction time, which reflects the time interval drivers perceive as sufficient for maintaining safe vehicle-following conditions. Effective reaction times were calculated using Eq. (4), while explicitly accounting for the physical dimensions of the leading vehicle. Following the methodology proposed by Long (2002), effective vehicle lengths were assumed to be 9.6 m for minibuses, 15.8 m for buses, and 18.0 m for trucks. These values include both the vehicle length and the average clearance maintained between successive vehicles. The resulting cumulative

distributions of effective reaction times are presented in Fig. 6. To facilitate comparison with autonomous driving behavior, the recommended CC1 values corresponding to the cautious (TYP1), default (TYP5), and confident (TYP9) autonomous driving strategies were also superimposed on the reaction-time distributions.

(a) Right Lane (b) Middle Lane

Fig. 6. Cumulative distributions of effective reaction times of different types of vehicles

The results reveal a striking behavioral pattern. Passenger-car drivers consistently exhibit the shortest effective reaction times when following trucks, despite the considerably larger dimensions and reduced maneuverability of these vehicles. This behavior suggests that many drivers intentionally travel close behind trucks in anticipation of overtaking opportunities rather than maintaining recommended safety margins. Although the observed headways behind trucks appear comparable to those maintained behind passenger cars, the corresponding effective reaction times are substantially shorter because of the additional vehicle length occupied by trucks. Consequently, the available stopping distance behind heavy vehicles is considerably smaller than temporal headway measurements alone would suggest. These findings indicate that current driving behavior may involve safety margins that are substantially below desirable levels.

To evaluate the potential influence of autonomous vehicles on these interactions, a simulation was performed assuming that autonomous vehicles adopt the most cautious driving strategy (TYP1) when following trucks. Figure 7 illustrates the resulting reaction-time distributions for autonomous vehicle penetration rates of 10%, 50%, and 70%.

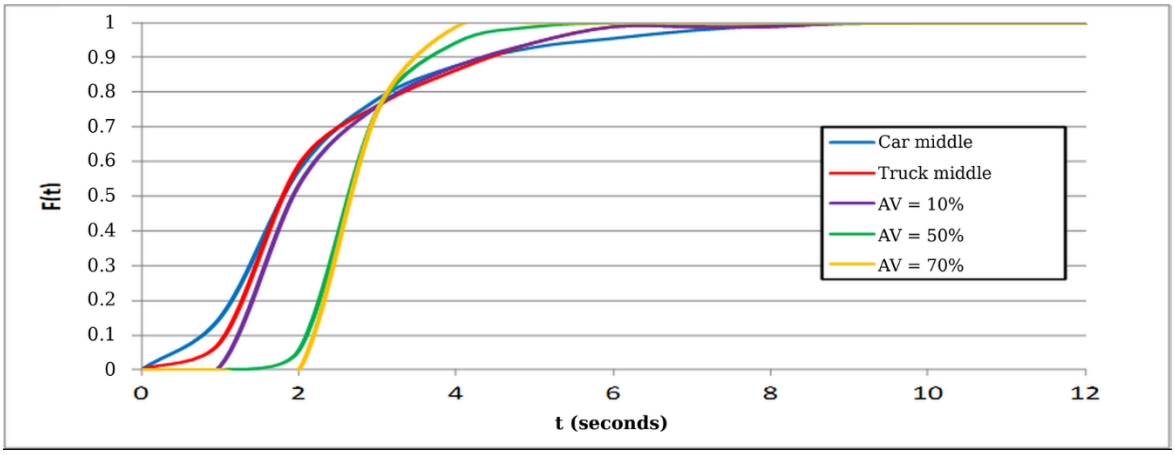


Fig. 6. Effect of autonomous vehicle penetration on passenger car–truck following behavior.

The simulation results indicate that a 10% autonomous vehicle penetration rate produces only marginal changes in the overall headway distribution. However, when the penetration rate reaches 50% and 70%, the distributions shift noticeably toward reaction times between 2 and 3

seconds. This change substantially reduces the proportion of extremely short following headways currently observed behind trucks.

From an operational perspective, this behavioral shift offers two important advantages. First, maintaining longer reaction times significantly improves traffic safety by reducing unsafe close-following conditions and providing greater opportunities for collision avoidance. Second, the reduction in excessively long headways simultaneously mitigates the adverse capacity effects traditionally associated with heavy vehicles. Consequently, autonomous vehicles adopting adaptive and safety-oriented car-following strategies may improve both operational efficiency and traffic safety in future mixed traffic environments.

Overall, the findings demonstrate that the interaction between autonomous vehicles and heavy vehicles cannot be adequately represented using conventional passenger-car-following models alone. Heavy vehicle characteristics must be explicitly incorporated into future traffic flow models to obtain realistic estimates of roadway capacity, traffic stability, and safety performance under mixed traffic conditions.

5. Conclusions

This study investigated the influence of autonomous vehicle driving strategies on uninterrupted traffic flow, with particular emphasis on the interaction between autonomous vehicles and human-driven heavy vehicles under mixed traffic conditions. Unlike many previous studies that primarily focused on capacity improvements resulting from reduced vehicle headways, the present research explicitly considered heavy vehicle–passenger car interactions using empirical traffic observations collected from multilane urban arterials in Türkiye.

The results demonstrate that autonomous vehicle driving strategy is a critical factor influencing both roadway capacity and traffic safety. Under aggressive driving strategies and high autonomous vehicle penetration rates, the theoretical lane capacity may exceed 4,000 veh/h/lane under uninterrupted traffic conditions. Conversely, conservative driving strategies maintain larger following headways, resulting in more modest capacity improvements while providing substantially greater safety margins.

The empirical analyses revealed that human drivers frequently maintain critically short effective reaction times when following trucks, despite apparently acceptable headways. This behavior is largely attributed to drivers' tendency to remain close behind heavy vehicles while preparing for overtaking maneuvers. Consequently, the actual safety margins behind trucks are considerably smaller than those suggested by temporal headway measurements alone.

Results further demonstrated that autonomous vehicles adopting cautious car-following strategies substantially increase following headways behind heavy vehicles, particularly when the autonomous vehicle penetration rate reaches 50–70%. This behavioral adaptation significantly reduces unsafe close-following conditions while simultaneously mitigating the operational impacts traditionally associated with heavy vehicles. Therefore, autonomous vehicles have the potential not only to improve roadway capacity but also to promote safer, more homogeneous, and more stable traffic flow.

Abstract. In this manuscript, the relationship between several gradation parameters (C_u, C_c, etc.) and ballast layer porosity was investigated through discrete element method (DEM) packing simulations and single- and multiple-linear regression. A total of 108 different gradation variations, all falling into the British A, B, C, and D gradation limits, were used in the simulations. Each gradation case was replicated three times, resulting in a total of 324 simulations. Porosity values were recorded at the end of the simulations. The C_u, C_c, and their components, D_{60}, D_{30}, and D_{10}, were used as predictors in linear regression for the recorded values. The results showed that higher Cu values (finer gradations) were associated with lower porosity values. However, the coefficient of determination (R^2) values were quite low, representing weak relationships. To remedy the situation, C_c was added as a predictor besides C_u, and multiple regression was conducted. No improvements, however, were observed. Consequently, the main components of C_u and C_c (D_{60}, D_{30}, and D_{10}) were investigated as predictors. The results showed that compared to D_{60} and D_{30}, D_{10} had significantly stronger predictor performance, indicating that D_{10} is substantially stronger predictor for ballast porosity compared to traditional parameters, C_u and C_c.

Keywords: Ballast Porosity, Ballast Gradation, DEM Packing

1 Introduction

Railway ballast is designed to have a high porosity (values near 40%) to provide rainwater drainage. Without adequate porosity, as in the case of ballast fouling, water accumulates within the granular structure, resulting in reduced shear strength [1]. Therefore, it is paramount to control the porosity of the ballast layer from initial design to its end of life to prevent failures that might arise from low shear strength. Particle size distribution or gradation is the most important factor that affects the ballast layer's porosity.

There are several ballast specifications, such as the American Railway Engineering and Maintenance of Way Association (AREMA) and British, that provide upper and lower limits for percentage by mass passing through specific sieve ranges [2]. These are all designed to create uniform particle distributions to obtain high ballast layer porosity. The upper and lower limits of these specifications, however, contain wide ranges that could lead to significant differences in layer porosity as reported for AREMA No. 24 gradation [3].

ASTM D2487 (the Unified Soil Classification System) [4] uses two important classification parameters, the coefficient of uniformity (C_u) and the coefficient of curvature (C_c), to determine whether a gradation is uniformly (poorly) or broadly (well) graded. C_u, which is calculated by the ratio of particle sizes at which 60% and 10% of particles are smaller by mass (also expressed as D_{60}/D_{10}), is particularly important. A few studies reported a relationship between C_u and porosity. Tutumluer et al. [5] and Bian et al. [6], for example, reported that more uniformly graded aggregates (lower Cu) contained more air voids. Similarly, Rosa et al. [7] reported

decreasing void ratios, therefore also decreasing porosity, with higher C_u. These studies were all conducted using the discrete element method (DEM), introduced by Cundall et al [8].

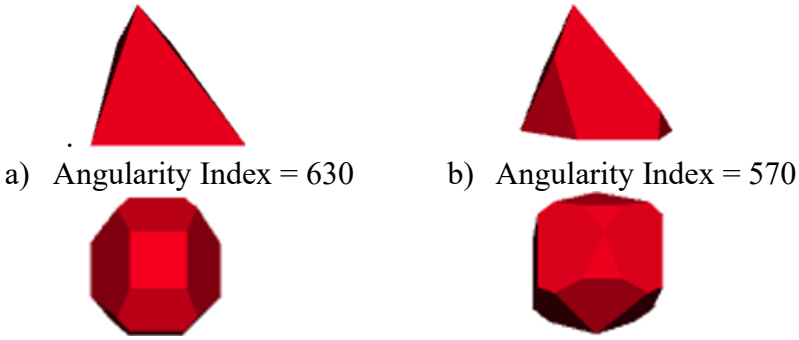
British gradation is widely used and also adopted by Turkish Railways (TCDD) for constructing a new ballast layer [9]. The DEM studies discussed earlier demonstrated that ballast gradation has a significant effect on porosity. However, the predictive performance of gradation parameters (C_u and C_c) was not studied across British ballast specifications. In this study, this gap is addressed by conducting DEM packing simulations covering 108 different gradations and evaluating the predictive performance of several parameters using linear regression.

2 Methodology

2.1 British Gradation Variations

The gradations studied were derived from the British ballast specifications (Gradations A, B, C, and D) with particle sizes ranging from 22.4 mm to 80 mm. Details of the specification limits, i.e., the upper and lower gradation bands, can be found in Guo et al. [2]. **Table 1** presents the gradations (108 in total) used in this study. Each cell under the % passing columns in the table represents the different variations used. Since the British B and C specifications overlap, they were merged into a single gradation category. Throughout the rest of the text, this combined gradation is represented as BC. C_u and C_c parameters of the generated gradations ranged from 1.16 to 1.98 and 0.77 to 1.37, respectively. The influence of the variations in these parameters on packing porosity was analyzed and is discussed in the following sections. It should be noted that the data on the British A specification were also used in a previous study to investigate the effects of percent passing across certain sieve ranges on coordination number and porosity [10]. However, that study did not incorporate the relationship between C_u or C_c and the porosity values but focused primarily on coordination number. Therefore, British A specification was added in this study to specifically investigate the relationship between C_u, C_c, and porosity.

Table 1. Gradation Variations Used based on British Specifications



Sieve Size (mm)	A (% Passing)	B and C (% Passing)	D (% Passing)
80		100	100
63	100	95, 100	93, 100
50	70, 85, 99	55, 70, 85	45, 62.5, 70
40	30, 41.5, 53, 65	25, 50, 75	15, 27.5, 40
31.5	1, 13, 25	1, 13, 25	0, 7
22.4	0	0	0
Total Variations	**36**	**36**	**36**

2.2 Particle Shapes and Contact Model Parameters

The packing simulations in this study were conducted using the GranOO open-source DEM software workbench [11, 12]. The workbench comprises a collection of C++ libraries that enable users to tailor simulations for their specific requirements. GranOO supports various particle geometries, including polyhedra, used in this study to represent individual ballast particles.

Fig. 1 presents the polyhedral particle geometries utilized in this study. These particle geometries were previously generated by Huang et al. [13, 14] through scans of real ballast aggregates using the University of Illinois Aggregate Image Analyzer [15-18]. The properties of these particles were provided using object file format in Huang [13] and adopted in this study to represent ballast particles. All particles had a flat and elongation (F&E) ratio of 1. The

angularity index values provided in the Figure quantify the sharpness of the particle corners and edges. Details regarding this index can be found in [17, 18].

a) Angularity Index = 630 b) Angularity Index = 570

c) Angularity Index = 448 d) Angularity Index = 390

Fig. 1. Particle Shapes Used in Simulations (Shapes Regenerated from Huang [13])

GranOO incorporates several models to calculate the forces between the contacting particles. In this study, the Hertz-Mindlin [19] contact model was used. The equivalent Young's modulus and Coulomb's modulus were set to 25 and 10 GPa, respectively, with a restitution coefficient of 0.3. The friction coefficient was varied between 0 and 0.3. In addition, the particle density was assigned to 2650 kg/m^3 to represent a typical aggregate.

2.3 Packing Simulation Steps

Before starting the simulations, the particle shapes, sizes, and initial positions were determined using a Python script [20] and exported to a CSV file. A 40 cm x 40 cm rectangular domain was created in GranOO, and the particles were generated using the CSV file. A compaction plate (40 cm x 40 cm x 5 cm) was created and placed on top of the particles. The time step, gravity, and friction coefficient were initially set to 10^{-6} seconds, 10 g, and 0. The simulation was then conducted using the following steps, as also detailed in [20].

- Drop particles onto the domain with 10 g gravity (Step duration: Varies depending on the number of particles).
- Once the packed particles have stabilized, i.e., not moving excessively, drop the gravity to 5 g (Step duration: 0.1 second).
- Drop the gravity to 1g. Set the friction coefficient to 0.3 (Step duration: 0.1 second).
- Apply an 8 kN vertical force to the compaction plate (Step duration: 0.05 second).

Once these steps were completed, the sample porosity was calculated and recorded. Since the initial particle arrangement can affect the results of a DEM simulation, three different CSV files were generated for each variation case. Therefore, each gradation case had three distinct replicates.

3 Results and Discussions

In this section, the results of single- and multiple-linear regression are presented. The cases studied are listed as follows.

- Linear regression of sample porosity (%) using C_u as predictor.
- Multiple linear regression of sample porosity (%) using C_u and C_c as predictors.
- Linear regression of sample porosity (%) using D_{60}, D_{30}, and D10 (individually) as predictor.
- Linear regression of sample porosity (%) using D_{10} as predictor.

An 80%-20% training-test set split was done before regression. In addition to the train-test split, a 5-fold cross-validation was also conducted on the training set to investigate consistency of the results within the data.

3.1 The relationship between porosity and C_u

Fig. 2 presents the linear regression trends for C_u vs sample porosity for British A, BC, D, and all gradations combined. At first glance, gradations with higher C_u values presented with lower porosity, i.e., denser packing. The test R^2 values, however, were generally quite low, indicating a lack of linear relationship between C_u and porosity. Compared to the other groups, British A presented with relatively higher train (0.635) and test (0.595) R^2 values. However, upon investigating the 5-fold cross-validation results presented in

Table 2, it is evident that test R^2 values were quite low, with high standard deviations across validation folds, for all combinations, including British A. These findings suggest that although a visual trend can be observed between porosity and C_u, it is weak and not reliable. Given that C_c is another important parameter utilized in ASTM D2487, both C_u and C_c were used as predictors for porosity, and the results are presented in the following section.

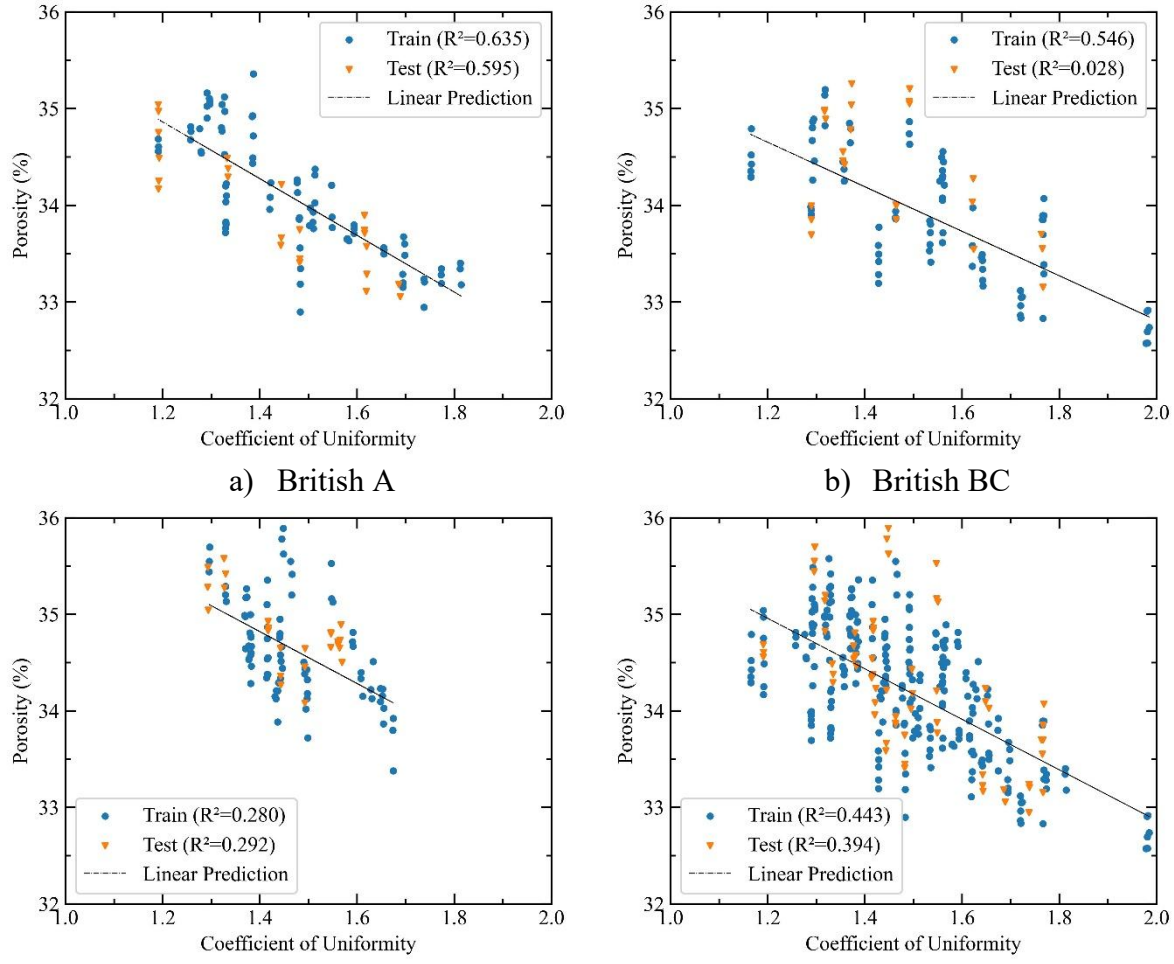


Fig. 2. Coefficient of Uniformity vs Porosity Linear Regression

Table 2. 5-Fold Cross Validation Test R^2 for C_u vs Porosity (%)

Gradation	Test R^2 ± Stdev
British A	.365 ± .369
British B and C	.315 ± .280
British D	.138 ± .319
British A, B, C, and D	.336 ± .284

3.2 The relationship between porosity and C_u combined with C_c

Table 3 presents multiple regression results of C_u and C_c as predictors for porosity. The table also includes the results for the 5-fold cross-validation. As shown in the table, inserting C_c as a predictor besides C_u did not improve the results. Therefore, instead of Cu and Cc, their components, D_{60}, D_{30}, and D_{10}, were individually studied to search for a better trend.

Table 3. Multiple Regression Results Porosity vs C_u and C_c combined

Gradation	Train R^2	Test R^2	CV Test R^2 ± Stdev
British A	.636	.610	.359 ± .357
British B and C	.547	.030	.288 ± .284
British D	.385	.329	.107 ± .315
British A, B, C, and D	.447	.397	.326 ± .274

3.3 The relationship between porosity and D_{60}, D_{30}, and D_{10}

In this section, the individual components of the C_u and C_c equations, D_{60}, D_{30}, and D_{10}, were individually tested as predictors for porosity, and the results are presented in **Table 4**. Note that for brevity, the table includes results for British A, BC, and D combined. As shown in the table, among the 3 components, D_{10} showed significantly higher R^2 values (both in the train-test split and 5-fold CV). Therefore, D_{10} was selected as a promising predictor, and its relationship with porosity was further investigated in the next section.

Table 4. Linear Regression Results Porosity vs D60, D30, and D10

Gradation	Train R^2	Test R^2	CV Test R^2 ± Stdev
D_{60} vs Porosity	.047	.112	.0 ± .086
D_{30} vs Porosity	.407	.426	.321 ± .213
D_{10} vs Porosity	.806	.850	.777 ± .075

3.4 The relationship between porosity and D_{10}

Fig. 3 and **Table 5** present linear regression results with D_{10} vs porosity for British A, BC, D, and all combined. As seen, the higher D10 values, which indicate a coarser gradation, result in higher porosities. What is more, both the train-test split and 5-fold cross-validation R^2 results demonstrated strong predictive performance for porosity across all gradation datasets.

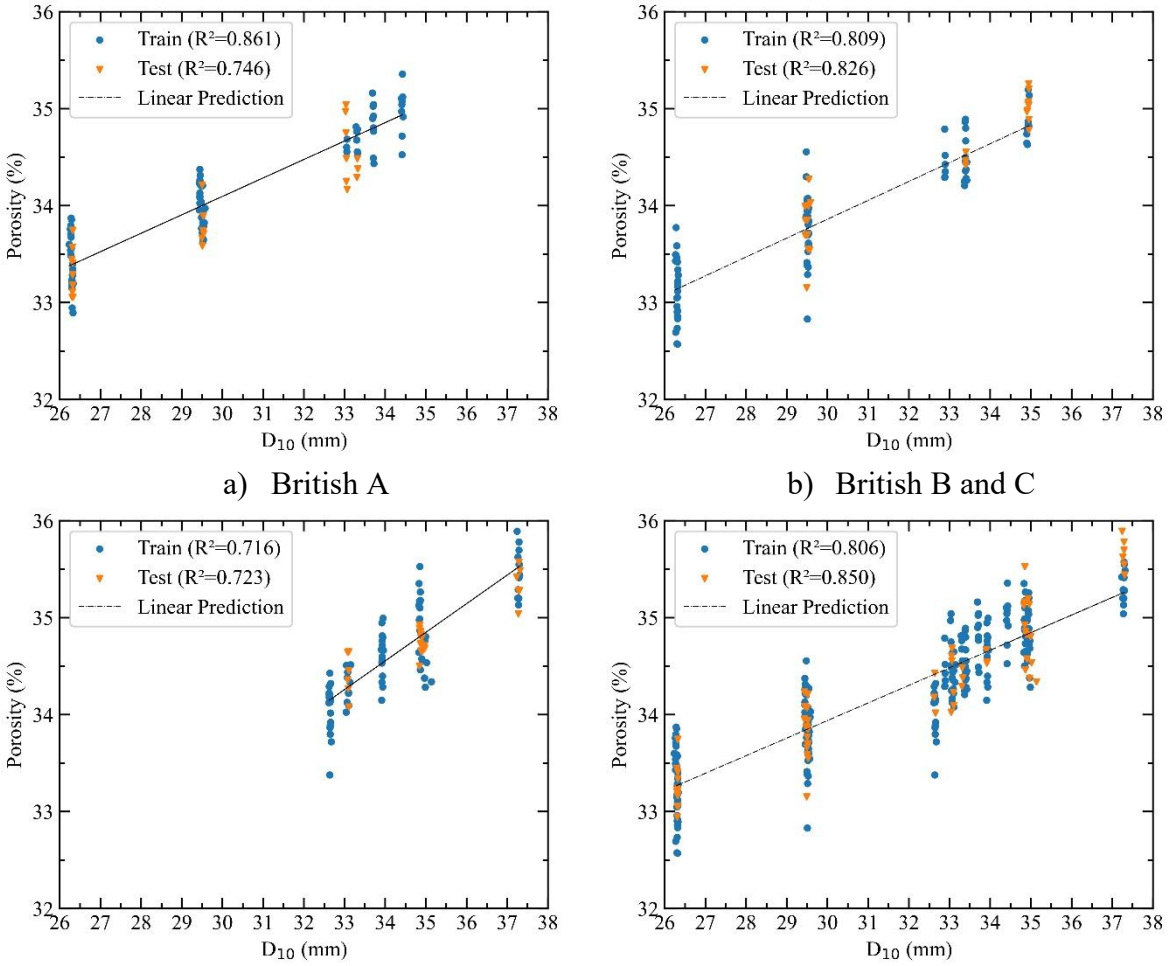

Fig. 3. D_{10} vs Porosity Linear Regression

Table 5. 5-Fold Cross Validation Test R^2 for D_{10} vs Porosity (%)

Gradation	Test R^2 ± Stdev
British A	.799 ± .098
British B and C	.711 ± .140
British D	.631 ± .182
British A, B, C, and D	.777 ± .075

4 Conclusions

In this study, the effect of changes within British ballast gradations (A, B, C, and D) on porosity was investigated using DEM packing simulations with polyhedral shapes and linear regression. A total of 108 unique gradation variations were created within the specification limits, and three replicate DEM packing simulations were conducted for each case. Sample porosities were recorded at the end of the simulations, and linear regressions were conducted between porosities and several predictive parameters, including C_u, C_c, and their components D_{60}, D_{30}, and D_{10}. The findings are summarized as follows.

- While a visual relationship between C_u and porosity was observed, when the R^2 values and five-fold cross-validation results were investigated, it was seen that the relationship was weak and certainly not linear.
- Inserting C_c as an additional predictor besides C_u did not improve the results.

- When D_{60}, D_{30}, and D_{10} were tested as porosity predictors, D_{10} displayed significantly higher performance.
- Increasing D_{10} values, i.e., coarser gradations, resulted in higher porosities with strong linear relationships.

In conclusion, D10 may serve as a design indicator for estimating ballast packing porosity during gradation selection within the British ballast specification.

Abstract. Public transportation (PT) is key to breaking the vicious cycle of private vehicles, a critical challenge in developing countries. The increase in population raises the number of cars, and this trend continues. PT plays a crucial role in reducing car use, traffic congestion, and environmental pollution. PT Fare is vital to the system's ability to encourage passenger's use. It affects mobility, the quality of life, and the sustainability of the system. This study aims to find tailor-made fare system for Istanbul using the BWM (Best–Worst Method) for PT fare for the first time. Moreover, it is the first study for fare structures and criteria for Istanbul, Europe's second-largest city. The most used fare structures and criteria in the literature and practice were weighted by experts using BWM surveys for the Istanbul Metro. The results show that distance-based fare (DBF) (43.7%) is the best fare structure, while flat fare (FF) (12.2%) is the weakest. For the criteria weightings, benefit received (24.4%) and social equity (22.7%) are seen as superior. Finally, the impact of the criterion on the fare structure was demonstrated, and its importance for experts in evaluating PT was highlighted.

Keywords: public transport; fare structure; fare structure criteria; Best–Worst Method.

1 Introduction

In urban areas where the population increases, the importance of transportation planning and decisions also increases. Since these plans and decisions affect not only passengers and operators but also the entire city, they need to be considered from many perspectives [1]. The plans can change where cities will grow, where they will generate profit, which areas will develop, and which areas will lose attractiveness. So, plans and projects in the field of transportation should be long-term and based on a wide range of sources and accurate data.

In modern city's, despite high levels of travel demand, the classic transportation approach, dependent on cars, creates a vicious cycle. This vicious cycle is shown in Figure 1. As a result of increase in demand, congestion begins on the newly built road intended as a solution, and the vicious cycle starts again [1].

In Traffic in Towns, the author argues that this vicious cycle should be broken in cities. Buchanan emphasizes that the car is an expensive mode, therefore, different systems should be developed in cities with populations over 100,000 [1]. One of the main recommendations to break the vicious cycle is on rail systems. Vivier et al. reported that passengers, on average, consume one-quarter as much energy per passenger-kilometer as private cars. Still, increasing congestion on roads and highways in many cities has led to greater investment in car-oriented infrastructure, while relatively few cities have prioritized investments in PT.

H. Mohring emphasizes that this vicious cycle will not occur with an increase in demand for PT and rail systems. An increase in demand creates a positive externality. It is known in the literature as the Mohring effect. The Mohring effect is the observation that if the frequency of a transit service (e.g., trains per hour) increases with demand, then a rise in demand reduces passengers' waiting times at stations [2].

Mohring argued that rail transit can shift passengers' travel behavior by inducing a modal shift, thereby generating a traffic diversion effect. From the user's perspective, this virtuous cycle is explained below (Figure 1) [2].

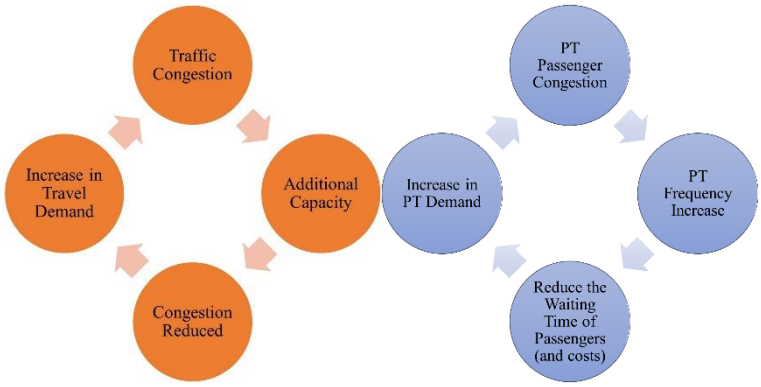

Fig. 1. The vicious cycle of the car-oriented approach (a) and the virtuous cycle of the PT approach (b).

To find a best solution for the Istanbul, need to understand the reason for fare reconstruction. Farebox recovery ratio (FRR) of Metro Istanbul, defined as the share of operating costs covered by passenger revenues, is reported in the Strategic Plan as 68.41% for 2021, 78.23% for 2022, and 75.92% for 2023, with a target of 77.50% set for 2024 [3]. The operating deficit, defined as the proportion of operating costs not covered by fare revenues, was 31.59% in 2021, 21.77% in 2022, 24.08% in 2023, and projected at 22.50% in 2024 [3].

High FRRs are observed in Hong Kong (~107%), Singapore (~101%), and Taipei (~88%), while European systems range from ~30% to ~94%, and North American metros achieve 30–40%. The London Underground exceeds 129%. Istanbul's ratio is moderate, higher than many North American and some European systems, but below top-performing Asian and UK metros [3]. Also, understanding the distribution of trip lengths provides further insight into passenger behavior and system usage patterns. According to 2025 Istanbul Metro data, long-distance trips—journeys of six or more stations—account for 31.7% of all trips. In short-distance trips, the most frequent journey length is three stations, whereas for long-distance trips, seven stations are the most common [3].

2 Conceptual Review

Fares are the core of PT, playing a vital role in ridership patterns and the financial sustainability of transit agencies [4]. When decision-makers target more sustainable city based on PT, an optimal fare strategy can create more intense cities, reduce carbon emissions and maintenance costs [5].

2.1 Fare Structure

Fare structure is pivotal to PT policies, as it significantly affects passengers' socio-economic outcomes, land-use patterns, and the sustainability of systems [5]. Differentiated fare structures are an efficient tool for demand management.

The most used fare structures in theory and practice are given below:

1. Flat fare (FF) does not vary based on any factor. Passengers pay the same fare.

2. Distance-based fare (DBF) determined by the distance or the number of stations crossed.
3. Time-based fare (TBF) determined by when the trip is made.
4. Zone-based fare (ZBF) determined by where the trip is made, and no. zones crossed.

Table 1. Table captions should be placed above the tables.

Fare Structure Type	Advantages	Disadvantages
Flat Fare	Easiest to understand. Simplest and cheapest to implement and administer.	It places an unfair burden on those making short trips. A fare increase will cause the greatest loss of riders. It places an unfair burden on those making short trips.
Distance-Based Fare	It should make the biggest revenue. Considered equitable; longer trip	Difficult to use. Hard to implement and oversee.
Time-Based Fare	Should increase ridership. Allows management of fleet usage through shift to off-peak.	Possibility of fraudulent behavior. Could necessitate new equipment.
Zone-Based Fare	On long PT lines, traveling to more zones allows higher fares to help cover operating costs.	When zone fares vary, it may encourage urban decentralization. Decentralization extends service distances, raising operator costs and fares.

2.2 Fare Structure Assessing Criteria

Seven most used criteria are social equity, benefit received, operator profit, ticket price, number of trips, decentralization, and urban morphology. Although not used as criteria in this study, ability to pay, operator cost/revenue, maximum profitability, complexity, passenger control, implementation difficulty, long trips, payment types, implementation costs, Gini co-efficient, train headway, and social welfare are mentioned in the literature.

This study develops a multi-criteria evaluation (BWM) for comparing fare structures and criteria. The proposed approach incorporates economic, social, and operational criteria, including social equity, benefit received, operator profit, ticket price, travel demand, decentralization, and urban morphology. By integrating these criteria into a structured decision-making framework, the study contributes to the literature by providing a wide approach for assessing fare structures and supporting optimal fare policies.

3 Data and Methodology

Istanbul has experienced significant growth in land use and population over the last five decades. With this growth, Istanbul is now Europe's most populous metropolis. Beyond its population of around 16 million, the ratio of young and working people in the population is also high. For the reasons, the transportation structure has become complicated, and traffic and problems have become the most important issues, with traffic jams every day and millions of dollars of lost time and fuel costs, ultimately leading to people become worse off regarding their quality of life [3].

De Gruyter et al. showed that Eastern Europe has higher overall performance in PT sustainability measures. In the study, eight cities were given in the Eastern European group, and the largest of these cities is Istanbul [6]. However, there are no studies that widely examine PT fares in Istanbul. This study was prepared to address a gap in the literature.

3.1 Transportation in Istanbul

For According to the TomTom Traffic Index Report 2024, the Istanbul metropolitan area ranks fifth in Europe and 19th in the world, with a congestion level of 39% (meaning that, on average, journey times across that area's road network were 39% greater than when traffic is free-flowing). Other metrics of the Traffic Index for Istanbul:

- Average travel time per 10 km = 18 min 51 s;
- Time is lost per year during rush hours = 80 h = 3.3 days [7].

Congestion cause traffic jams across Istanbul, costing more than $1.7 billion annually. Traffic jams have become a critical problem across Istanbul due to a lack of infrastructure to meet demand from rapid growth [6,7].

Public Transport in Istanbul

As of 2026, Metrobus (Bus Rapid Transit), Marmaray (commuter rail), metro (11 lines), tram (5 lines), funicular (2 lines), cable car (2 lines), buses, minibusses, taxi minibusses, and ferries are operated in Istanbul. Metrobus, Marmaray, M11 (metro line of Turkish State Railways Transport-TCDD), and some bus–minibus lines in Istanbul operate with DBF; some bus lines operate with ZBF; and the remaining lines operate with FF.

Ticket Types in Istanbul

In Istanbul, the two most frequently used transit card options are: Istanbulkart and Mavi (Blue) Kart. There are four different Istanbulkart options for passengers: Full fare, the student 30+ card (for students who have reached the age of 30), the social card, and the student card.

The Blue Card is a monthly card. Full fare, the student 30+ card, the social card, and the student card are types of Blue Cards.

All mothers (have children between 0 and 4 years), members of the press, police, veterans, veterans' families, the security service class, disabled people, soldiers, national athletes, mukhtars, martyrs' families, TUİK (TurkStat) personnel use Free Istanbulkart.

An electronic ticket is another option. Passengers can buy single, two, three, four, five, or ten use passes in the form of paper tickets. Passengers can also use their bank cards at PT.

Istanbul Metro Data

The Istanbul Metro is a rail network that serves Istanbul. Except for the M11 line, the system is operated by Metro Istanbul (company), a public enterprise of the Istanbul Metropolitan Municipality (IBB). There is a 380.70 km urban rail system operating in Istanbul. Metro Istanbul serves over 3 million passengers every day, with 18 lines, totaling 241.35 km. Istanbul in 2025:

- According to a recent urban mobility report, 48% of daily trips were made by PT;
- Rail systems account for 20.59% of all trips;
- Metro İstanbul accounts for 10% of all trips;
- The number of trips made by the Istanbul Metro (M lines) 7.4% of the total trips [8].

Metro Istanbul accounts for 63.8% of the total trips made by all rail systems and Metrobus in Istanbul. The number of trips made by the Istanbul Metro is 47.6% of the total trips made by all rail systems and Metrobus in Istanbul [8]. The oldest metro is the M1, which opened in 1989. As of 2026, the system had 11 lines and 159 stations in service, with 36 more under construction [8]. At 243.3 km, the Istanbul Metro network is the fourth-longest in Europe as of 2026. Because of Istanbul's unmatched geography and the Bosporus Strait, its European and Asian metros do not connect directly. The two side of the city are linked through the Marmaray commuter rail line.

Average metro trips in Istanbul cover more or less 5.5 stations and about 18.5 min. The average total travel time, including access to the metro station and the time required to get the

destination, is about 50 min. On average, each passenger makes more than one transfer per trip (1.42 transfers) to get their destination [3,8,9].

Nearly 67.4% of all metro trips in Istanbul during the morning and evening peak hours. The passenger densities for these metro lines are presented in Table 2 [3,8,9]. Peak passenger demand for metro was estimated using the passengers per hour per direction (PPHPD) metric.

Table 2. Peak passenger demand and capacity utilization of the Istanbul metro [5,8].

Metro Line	Avg. Daily Ridership (2024 Data)	Estimated PPHPD	Reference Capacity (PPHPD)	Capacity Utilization (%)
M1	357.116	20.058	60.000	33.4%
M2	445.763	25.037	60.000	41.7%
M3	138.821	7.797	60.000	13.0%
M4	299.659	16.831	60.000	28.1%
M5	292.945	16.454	60.000	27.4%
M6	16.469	925	60.000	1.5%
M7	218.545	12.275	60.000	20.5%
M8	62.925	3.534	60.000	5.9%
M9	49.873	2.801	60.000	4.7%

Average daily ridership data obtained from the 2024 statistics of Metro Istanbul [3,8]. Since 67.4% of trips occur during peak hours, peak demand was distributed across six peak hours and two travel directions to estimate PPHPD:

$$\text{PPHPD} = \frac{\text{Daily Ridership} \times 0.674}{6 \times 2}$$

Capacity use was then calculated by comparing the estimated PPHPD values with a reference metro capacity of 60,000 passengers per hour per direction [3,8]. As shown below M2 line has the highest peak demand, followed by M1, M4, and M5, while newer lines such as M8 and M9 currently operate at lower usage levels [3,8].

To examine Istanbul Metro, data on the week with the most travel in 2024 was get from BELBİM (Electronic Money and Payment Services Inc.). The results of the analyses performed in Excel are presented. Data for the Istanbul Metro (M lines) alone were visualized and presented below (Figures 2 and 3 displays the card type chart, and Figures 4 and 5 display the station charts for weekdays and weekends).

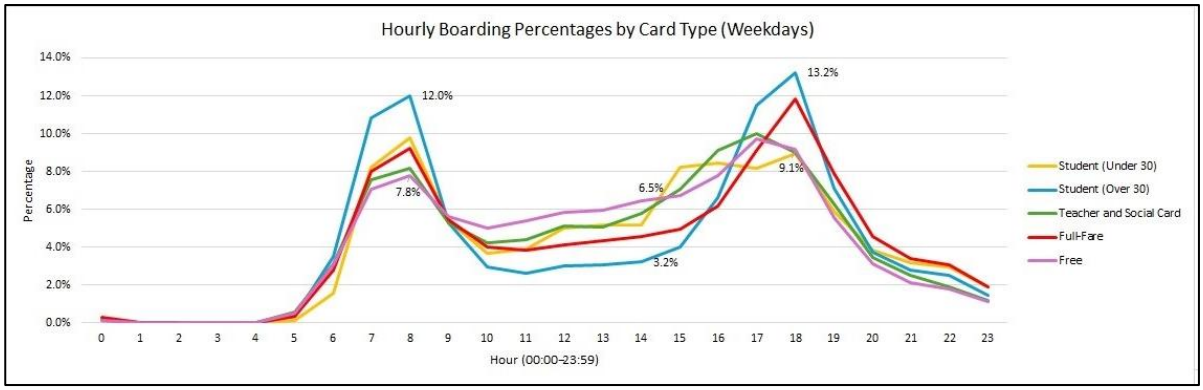

Fig. 2. Hourly boarding percentages by card type—weekdays [9].

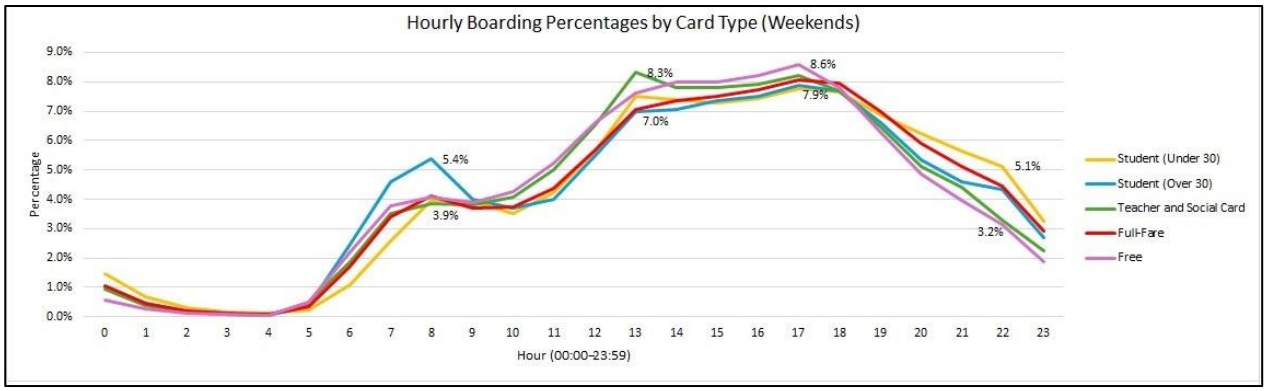

Fig. 3. Hourly boarding percentages by card type—weekends [9].

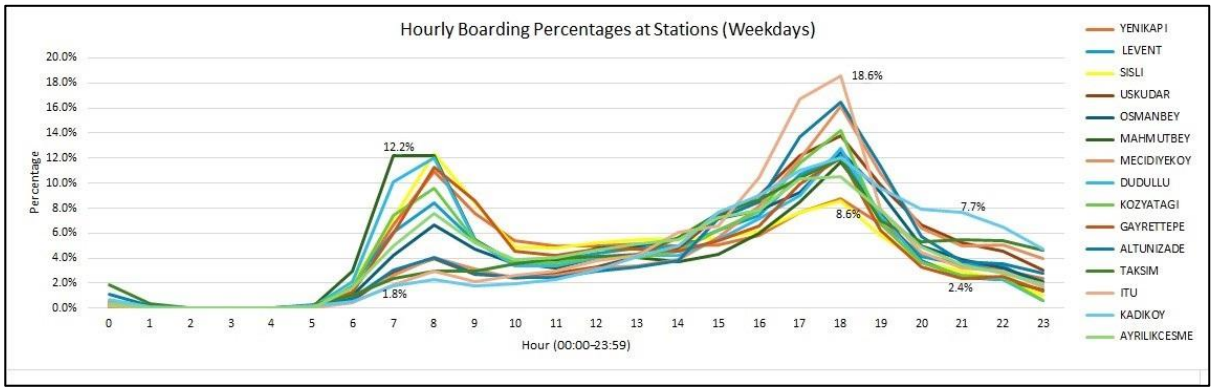

Fig. 4. Hourly boarding percentages at busiest stations—weekdays [9].

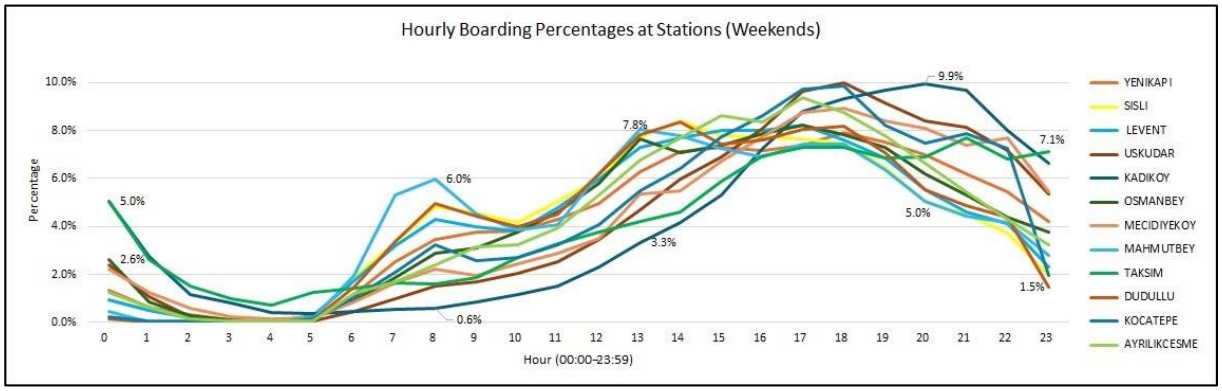

Fig. 5. Hourly boarding percentages at busiest stations—weekends [9].

For more technic analyses, interviewed many experts to collect their opinions on fare structure and criteria. For this reason, proposed using BWM to out a ranking based on fare structure and criteria. The character of Istanbul, along with insights from the literature, guided the selection of the BWM and, accordingly, the determination of the criteria. To the best of the authors' knowledge, there were no empirical studies on PT fare structures and decision criteria for Istanbul.

3.2 Best–Worst Method (BWM)

The BWM, a new and practical MCDM (multiple criteria decision-making) method, was used for the first time in this context. The previous use of AHP (Analytic Hierarchy Process) and MABAC (Multi-Attributive Border Approximation Area Comparison) disclose that MCDM is appropriate for achieving the intended targets and objectives on PT fare [6,7].

The linear BWM model defines the importance and weights of the criteria and alternatives. The BWM requires less comparisons than other MCDM tools; the final weights from the BWM are highly reliable, and the comparisons are more consistent than those in full matrix-based methods. BWM is known for its simplicity, as comparisons are made using only numbers from 1 to 9. This provides a clear benefit from other MCDM methods that require comparison matrices with integers as well as with fractional numbers [10,11]. This work provides additional proof of the method's usability for evaluating technology and its effectiveness in PT fares. Figure 6 shows example of BWM Comparisons.

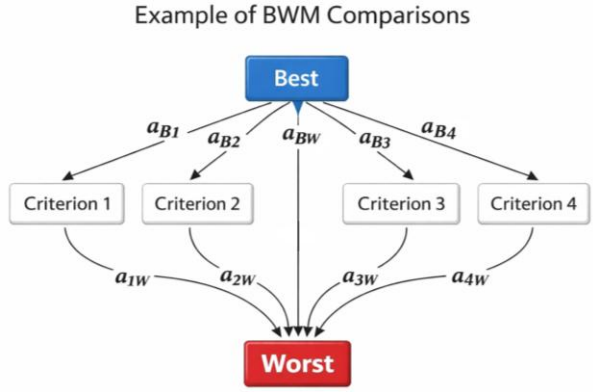

Fig. 6. Example of BWM comparisons [11].

To determine the set of decision criteria, first assessed the factors (social equity, benefit received, operator profit, ticket price, number of trips, decentralization, and urban morphology) and structures (flat fare, distance-based fare, time-based fare, zone-based fare) selected from literature. Then, they conducted a survey to collect data for applying the BWM. The survey was conducted using Microsoft® Excel®. Solver add-in used to calculate the weights in the BWM model for the entire analysis [11].

The survey was sent to more than 150 experts in the field, researchers and practitioners alike, including academics, operators, and government officials with extensive knowledge of PT fare systems. As a result, a total of 22 experts from Türkiye were selected, including 5 practitioners, 17 academics from well-established universities, and a department head.

The experts completed the survey in Excel (Solver add-in). When the Consistency Ratio exceeded 0.10 [12], the experts were asked to revise their responses. A total of 22 experts received the same survey, regardless of the group they were assigned to, and conducted the same analysis for each criterion and structure.

4 Results

The first result emerging from the experts' criteria weightings was the dominance of benefit received (24.4%) and social equity (22.7%). These two criteria represent horizontal and vertical equity, respectively. The experts emphasized that the superiority of these two criteria highlights the importance of equality in PT. The least important criteria were operator profit (8.4%), decentralization (8.8%), and urban morphology (9.4%). The scarce influence of these three criteria say that experts choose a passenger-centric perspective in PT. Even though the number of trips (14.9%) and ticket price (11.4%) showed high values, they were still less effective than the benefit received and social equity criteria.

Experts find DBF (43.7%) as the most dominant fare structure, while FF (12.2%) was the weakest. This choice was likely influenced by the benefit-received criteria—namely, that passengers pay according to their level of use—which is one of the main advantages of DBF over FF. ZBF (23.3%) and TBF (20.8%) outperformed FF, but they were far from DBF. While ZBF and TBF mean fare differentiation and offer benefits based on certain criteria, their

relationship with the benefit-received criterion is not as robust as that of DBF. The results are shown in Table 3.

Table 3. Expert survey results.

	Fare Structure * Weighting				Fare Structure Assessing Criteria Weighting						
Experts	FF	DBF	ZBF	TBF	Social Equity	Benefit Received	Operator Profit	Ticket Price	Number of Trips (Demand)	Decentralization	Urban Morphology
Expert 1	13.5%	27.0%	51.4%	8.1%	18.5%	32.6%	5.6%	12.4%	12.4%	9.3%	9.3%

As shown in Table 3, DBF is the most appropriate fare structure for the Istanbul Metro. DBF is followed by ZBF, TBF, and FF. The clear dominance of DBF, social equity, and benefit received responses indicates a strong consensus among experts. For twenty out of twenty-two experts DBF as the most superior, while TBF and ZBF were each selected by only one expert. Ten experts assigned the highest weight to the benefit received criterion, whereas eight selected social equity. Only two experts gave the highest weight to the number of trips criterion. The fact that these experts—who were not in communication with one another—have an agreement enhanced the trustworthiness of the results.

There are several reasons why expert opinion is in advantage of DBF:

1. FF is an easy-to-implement, cheap, and simple for the operator. It is also easy for passengers to understand and control. It is the optimal solution for cities with a single center that are not large enough. However, cities where the number of trips increases and distances getting longer (especially in linear cities like Istanbul), it is essential to evaluate a more customized fare structure such as DBF.
2. Istanbul operators' profits decreased because of increases in operating costs, due to the addition of new lines to the end of the metro lines operated with FF in the city in recent years. But even though the lines getting longer, long-distance travelers still pay the same fare. It's unfair for both the operator and the passenger. When DBF is implemented, passengers will pay according to the number of stations, and injustice will be eliminated.

3. In Istanbul, the operating income only covers 30%–35% monthly fixed expenditure. Its similar for the Istanbul Metro [13]. Operations can continue thanks to subsidies. But, the difference between operating income and expenses widens every year, and the subsidies also increase. Li et al. show that DBF can increase operator revenue by 5.88% [14]. DBF, which is applied to suitable fare levels after a thorough analysis of trips, will attract those who chose different modes for short distances with its affordable fares. Also, it will charge much higher fares for long-distance travelers. For sum, operating income will increase, and the need for subsidies will decrease.

From Table 3, it is seen that social equity and benefit received are the most dominant decision criteria. The other five criteria (operator profit, ticket price, number of trips (demand), decentralization, and urban morphology) are far from them. There are reasons why expert opinion is in favor of these two criteria:

1. In Istanbul and similar cities, rising land values and urban renewal in the city center are leading to new housing areas in the outskirts. This increase in land values in the center is rise housing costs. Residents, especially low-income, are moving away from the center and settling in the less-accessible suburbs [15]. This leads to difficulties in accessing urban services for low-income, increased transportation costs, longer travel times, etc. in other words, transportation poverty. For low income, where vehicle ownership rates are low, PT is the only option. With this perspective investments in PT are a useful tool for ensuring social equity.
2. In this study, social equity criteria are used in the sense of vertical, and Benefit Received criteria are used in the sense of horizontal equity. It is stunning that experts outperform the other five criteria on these two equality criteria. With these assessments, they prioritize passengers good over operators good. This can be interpreted as a reflection of the problem of social inequality in Istanbul.
3. Istanbul has the highest income inequality in Türkiye. Based on TÜİK data, the highest income inequality by province was in Istanbul (8.6) [16]. This data strongly emphasizes the importance of social equality in Istanbul. Policies in this direction will reduce social and economic inequalities.
4. The distribution of card types across income groups provides insights into the socio-economic characteristics of Istanbul Metro users. Monthly Mavikart (student and full-fare) and teacher and social cards are predominantly used by higher-income, suggesting that frequent PT usage and monthly fare products are more common among economically stable groups. In contrast, free cards, particularly the 65+ and disabled cards, exhibit relatively higher shares among lower and middle-income groups, highlighting the redistributive role of socially targeted fare policies. These findings demonstrate that fare differentiation and card-type structures serve as key policy tools to improve equity, enabling vulnerable or mobility-dependent groups to maintain access to services. Therefore, analyzing card-type usage patterns alongside income levels provides a framework for evaluating the equity performance of systems.
5. The spatial relationship between income distribution and the metro in Istanbul disclose dimension of transport equity. High-income districts are primarily concentrated along central and coastal areas where metro accessibility is relatively strong due to the presence of major corridors has the highest passenger demand and accessibility. Middle-income districts are served by expanding metro corridors, which improve accessibility between peripheral residential areas and the urban core. In contrast, lower-income districts located mainly on the western and northwestern periphery have historically experienced limited rail access, although recent infrastructure investments have significantly improved connectivity. Overall, the analysis suggests that the expansion of the metro network from M1 to M9 plays a crucial role in lower spatial inequalities in PT accessibility and contributes to the objective of enhancing social equity in urban mobility.

6. Accessible and proper travel should be considered a basic right for all citizens in modern cities. So, operators are required to ensure a minimum level of service to guarantee this. Those with incomes high enough to afford a private car can choose not to use PT. Those without a private car have only two options: PT and taxi. Istanbul has been plagued by a long-standing taxi shortage. In Istanbul, there is only one car for every three people; PT is the only option for millions. Experts recommend providing this service to low-income residents, who have no other option but PT, at a fare proportional to their budget. Higher-income residents, if charged according to their budgets, would pay more per trip than others. This, carries the risk that high-income passengers using PT will opt for their private vehicles in-stead.
7. The benefit received implies that passengers pay in proportion to the benefits they receive. It is no surprise that experts chose DBF as the superior when they chose the benefit received criterion as the superior decision criterion. Paying for the distance traveled in DBF can be interpreted as an application of the benefit received. This ensures passengers pay in proportion to the benefit they receive. Although benefit received and social equity are presented separately in our study, improving benefit received naturally contributes to social equity.

5 Discussion

Rapid urbanization has strengthened the need for PT systems that ensure social equity, economic feasibility and ecological sustainability [17]. Stereotypical fare frameworks primarily prioritize economic performance, often neglecting wider social and environmental implications. This study surveys optimal fare system with BWM for PT fare for the first time. Further, it is the first study to compare PT fare structures and criteria for Istanbul. The main target of this study is to evaluate the best fare system for the Istanbul Metro. To apply the BWM, a survey was conducted among transportation operators, academia, and government officials.

According to BWM result, social equity and benefit received are the most important criteria, with 22.7% and 24.4% [17]. DBF is the most suitable for the Istanbul Metro, while FF is the least. Many of the findings here reflect a common planning approach in developing countries, where short-term, populist measures often take priority over long-term, technically informed solutions. Widely restructuring transportation within metropolitan areas, creating diverse development and employment, and establishing new networks will help resolve the existing issues of an overly centralized system prone to frequent operational disruptions.

Designing a fare system fit to the region's specific characteristics is important for enhancing population mobility and promoting development. Istanbul is known for its lack of, or inadequate, rail systems on the city's peripheries, its planned bus system, and its high fares (relative to average salaries). These force a big portion of passengers to rely on multiple routes and modes of PT, forcing them to pay multiple fares for their daily commute.

One of the reasons for these problems is the lack of collaboration between Istanbul's local and central administrations. Most major metropolitan areas have multiple administrations, often with conflicting political interests, making the full integration of the network and fare system highly challenging. This limits population mobility and embarrass regional development. The outcomes of coordinated efforts presented as outputs for the city of Istanbul, analyzed in this study, demonstrate what can be accomplished through precise planning. This study presents findings that highlight the significance of both vertical and horizontal equity in PT fares. While the FF used in the Istanbul Metro is easy to understand and implement, modern, holistic, and tailored solutions are needed for cities of this scale.

Future research could extend the study in few directions [17]. First, passenger surveys conducted by transit operators or independent researchers could be incorporated to obtain more detailed information on passengers' socio-economic characteristics. Integrating this data into fare policy analyses would enable a more comprehensive understanding of how passenger groups respond to alternative fare structures. Second, future studies could combine survey data

with smart card and automated fare-collection datasets to analyze passenger travel behavior in greater detail. Such integration would provide valuable insights into travel demand patterns and the behavioral impacts of fare policies. Eventually, comparative analyses across different cities could further improve the generalizability of the findings and help identify how variations in urban structure, governance, and PT influence the performance of fare structures. These approaches could support the development of more equitable and efficient fare systems, including targeted discount policies for specific passenger groups such as students, elderly passengers, and disadvantaged.

Acknowledgments
This study was prepared within the scope of the findings from an ongoing Ph.D. dissertation titled 'Developing a Public Transport Pricing Method Using the Best-Worst Method: Istanbul Example' and further draws upon the content of the article 'Evaluating Fare Structure with Best–Worst Method for Improving Sustainable Transit Operations: Istanbul Metro Example', published in the journal named Sustainability.

Abstract. This study aims to model lane-changing behavior in freeway diverging areas by integrating geometric road data and traffic flow observations. Video-based trajectory extraction was used to analyze driver decisions, lane-change parameters, and safety indicators such as Time to Collision (TTC). The results show that lane changes were generally performed with an adequate safety margin, while a small subset of maneuvers, particularly those with a specific conflict configuration, exhibited lower TTC values. Based on these findings, recommendations are offered for geometric design and traffic management at diverging zones.

Keywords: Lane changing, Diverging area, Time to collision.

1. Introduction

Transportation is the movement of people and goods from one place to another for a specific purpose. In transportation, the goal is to move safely, quickly, economically, and comfortably from a source point to a destination, and this is accomplished through roads [9 - 14].

When traffic flow is disrupted and roads are forced to operate near or beyond their capacity, traffic problems tend to emerge at intersections within urban areas and at diverging and merging zones on ring roads. Particularly in areas with diverging zones, speed reductions and driver confusion caused by sudden lane changes inevitably lead to traffic problems that affect road safety and performance.

Lane changing, defined as a vehicle moving from one lane to an adjacent lane and continuing its travel, is the most critical driver decision that directly affects traffic flow, road performance, and safety. Nearly all traffic collisions are caused by driver errors, and it has been observed that 8.4–13.7% of these are lane-change-related [2]. Furthermore, lane-changing behavior also causes significant performance degradation on roads.

In this study, traffic data obtained through video camera observations at diverging zones on ring roads within the provincial boundaries of Izmir are evaluated to examine the effects of driver behavior on road performance and safety. Vehicle trajectories are extracted and used to calculate Time-to-Collision (TTC) values, which is a quantitative indicator of collision risk during lane-changing maneuvers.

By developing a model that supports and enables vehicles' lane-changing decisions, it is believed that safety and performance will improve, and effective traffic management will be achieved. The findings are intended to inform driver warning systems, as well as geometric

design and traffic management operations at diverging zones, by identifying which lane-changing configurations and conditions are associated with the lowest TTC values and there the highest collision risk.

The aim of the study is to model lane-changing behavior at diverging zones through TTC-based analysis of field-observed trajectories as a function of road geometry and traffic data.

2. Literature Review

This section reviews prior research on collision risk at diverging zones, lane-changing classifications, and the development of Time-to-Collision as a surrogate safety measure to provide the background for the present study. Zhang, Yan, An, and Zhao (2015) [16] collected data from 72 diverging zones at two highway sections in Colorado, USA, to identify the safety influence zone and collision frequencies at highway diverging areas. Traffic and road geometry data, along with fatal, injury, and property-damage collision data from 2006–2010, were obtained from the Pikes Peak Area Council of Governments. A negative binomial regression model was used to explain the relationship between collision and variables. A relationship was observed between collision frequency and ramp clearance values, which were incrementally increased from 30 to 300 ft in 30-ft intervals. The study concluded that collision frequency at diverging zones is directly proportional to the number of ramp lanes, ramp traffic volume, and speed limit, but inversely proportional to ramp length. Collision rates at multi-lane diverging zones were higher than at single-lane diverging zones, due to the confusion caused by more lanes. Additionally, lane changes increase the occurrence of sideswipe collisions.

Aydin (2012) [1] investigated the transverse and longitudinal movements of vehicles within their lanes on a multi-lane road with surface deformations under saturated traffic conditions. From speed and position data, it was observed that vehicles either reduced their speed or changed lanes before reaching the deformation points to avoid being subjected to the deformation effect. Analysis of speed data before, at, and after the deformation points revealed that the most significant parameters influencing speed reduction are driver characteristics (aggressiveness, familiarity with the road, etc.), the position of vehicles in the target lane to which the driver intends to change, and the magnitude of the deformation.

Based on the driver motivation, lane-changing maneuvers are generally grouped into two categories: Mandatory Lane Changes (MLC) and Discretionary Lane Changes (DLC). MLC occurs when the driver has no alternative but to leave the current lane in order to follow the intended route, for instance when merging from an on-ramp or preparing to exit the freeway. DLC, on the other hand, is not dictated by the route itself but is initiated voluntarily, typically to gain a speed advantage, avoid being trapped behind slower vehicles, or move into a lane offering more favorable driving conditions [2-13].

The safety implications of lane-changing activity at special freeway sections have attracted sustained research attention since the early 1970s. Diverging areas are one of the most operationally demanding segments of freeways. Empirical data indicate that crash frequency at diverging areas is typically four to six times higher than on comparable mainline segments, and freeway ramp crashes alone account for more than 30% of total annual freeway crashes [4]. The intensive lane-changing maneuvers between mainline and exiting traffic are the primary source of conflicts and, consequently, crashes at diverging areas remain a persistent safety concern [17].

Time-to-Collision (TTC) remains one of the most widely used surrogate safety measures for identifying near-miss events and quantifying collision risk in traffic conflict analysis. Zürn et al. (2026) [18] analyzed more than 10,000 lane-changing maneuvers using high-resolution drone trajectory data from highways in Germany, China, and the United States. Their analysis showed that only 32% of the maneuvers were risk-free, and they proposed a time-gap redistribution model that could significantly increase the proportion of risk-free lane changes.

Mao et al. (2025) [10] compared lane-changing behavior observed in a real-world weaving section with that reproduced in a driving simulator, using generalized time-to-collision (GTTC). Their results showed that simulated lane changes generally produced larger GTTC values than those observed in the field. Guo et al. (2023) [5] introduced a two-dimensional TTC (2D-TTC) measure to represent the two-dimensional geometry of conflicts during lane changes. They validated the measure using archived crash data from a large-scale connected-vehicle dataset and combined it with deep reinforcement learning to model drivers' evasive behavior in safety-critical lane changes. Yang et al. (2025) [15] proposed a multi-task CNN-LSTM model that jointly predicts lane-change maneuver probability, risk level, and time-to-lane-change using the HighD dataset, while Sheikh and Peng (2024) [12] developed a lane-changing risk index (LCRI) based on probabilistic threat assessment, also using HighD trajectories, combined with a random-parameter ordered logit model to relate risk levels to contributing factors. Most recently, Chen et al. (2025) [3] demonstrated that a real-time crash prediction model based on non-stationary extreme value distributions of the remaining inter-vehicle distance outperformed both traditional TTC and 2D-TTC by 75% and 49%, respectively, revealing that single-value TTC thresholds fall short in reflecting the dynamic risk evolution of lane-changing maneuvers. Focusing specifically on lane-change conflicts, Önelçin (2022) [11] analyzed field-observed lane-changing events to determine a representative TTC threshold for use in driver warning systems. Based on the minimum TTC values observed during conflicts, the study proposed 0.74 s as the most appropriate threshold for identifying critical lane-changing situations.

3. Methodology

The present study adopts a field-based trajectory extraction approach to calculate TTC values at a diverging zone in Izmir, following the TTC-based methods developed by Jimenez et al. (2013) [7]. The methodology consists of four main phases: (1) site selection and video-based field data collection, (2) vehicle trajectory extraction and data pre-processing, (3) microscopic analysis of lane-changing behavior, and (4) calculation and validation of Time-to-Collision (TTC) indicators.

3.1. Study Site

Five criteria were used to select the diverging zone: geometric suitability, traffic volume, site safety, representativeness, and favorable seasonal and lighting conditions. Geometrically, the site had to be sufficiently long to ensure that all lanes were visible from the camera position; according to Turkish standards [8], typical deceleration lane lengths at diverging zones range from 200 to 500 m. The selected site also needed to carry sufficient traffic during peak periods to provide an adequate number of lane-changing events for analysis. To ensure safe data collection, the recording equipment had to be installed without posing risks to personnel or traffic. In addition, the site was required to represent the typical geometric characteristics of the Turkish highway network, including the number of lanes, ramp length, and speed limit. Finally, data collection was conducted under favorable seasonal and lighting conditions to maximize video quality and visibility.

The field study was conducted on 25/03/2025 at the diverging section located in the Gaziemir district. A satellite image of the study area is presented in *Fig. 1*.

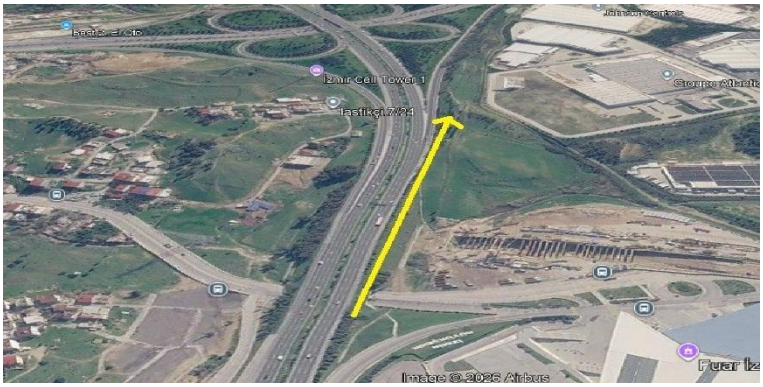

Fig. 1. Satellite image of the study area.

3.2. Data Collection

The field data was collected on 25/03/2025 during the time interval of 08.00-09.00. Observations were conducted during daylight hours to control seasonal variables, ensure consistent weather and visibility conditions, and minimize the effects of light reflections and shadows. The traffic movements were recorded using an unmanned aerial vehicle. The investigated diverging area consisted of 3 lanes, with a mainline width of 3.6 m.

To determine vehicle trajectories, the study area was divided into a series of virtual grids, as illustrated in *Fig. 2*. This grid-based segmentation enabled the precise extraction of vehicle positions and movements throughout the diverging section. By tracking the sequential movement of vehicles across the defined grid cells, trajectory data were obtained and subsequently used to analyze lane-changing behavior.

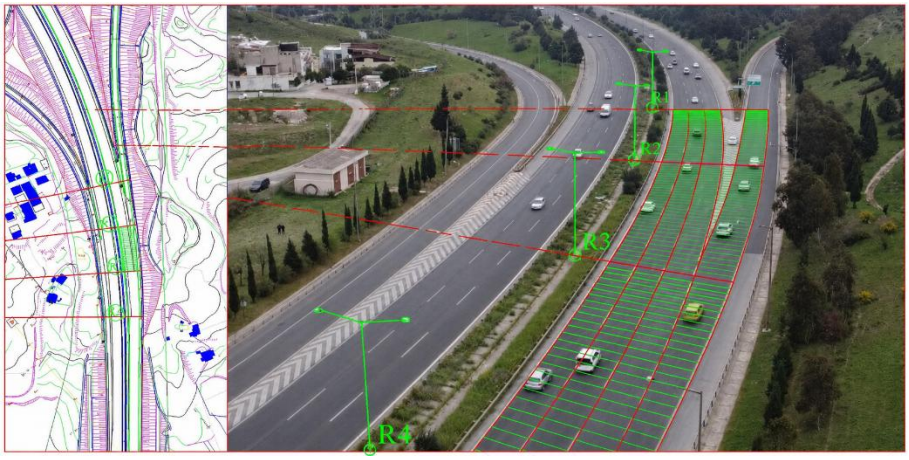

Fig. 2. Grid-based segmentation of the study area.

3.3. Speed Calculation and Surrogate Safety Measures

Longitudinal and lateral velocity components were calculated from consecutive position measurements using the central difference method:

$$v(t) = [x(t + \Delta t) - x(t - \Delta t)]/(2\Delta t) \quad (1)$$

To assess traffic safety, it is necessary to measure not only collisions but also the critical near-miss events preceding them. Traffic Conflict Techniques (TCT), which emerged in the 1970s in response to this need, led to a paradigm shift in traffic safety research. The foundational conceptual contribution in this field was made by Hayward's 1972 article published in Highway Research Record, entitled 'Near-Miss Determination Through Use of a Scale of Danger.' In that study, Hayward introduced the concept of Time to Collision (TTC) as

an objective measure of near-miss events and demonstrated that it could replace subjective observer judgment in traffic safety assessment [6].

Hayward defines TTC as follows: 'TTC is the time remaining until two vehicles collide if their current speeds and directions remain unchanged'[6]. This definition is expressed mathematically as:

$$TTC(t) = [s(t) - L]/[v_f(t) - v_l(t)] \quad (2)$$

In this formula, $s(t)$ denotes the distance between the vehicles, L is the length of the leading vehicle, $v_f(t)$ is the speed of the following vehicle, and $v_l(t)$ is the speed of the leading vehicle. TTC is meaningful only when $v_f > v_l$, i.e., when the following vehicle is traveling faster than the leading vehicle; otherwise, there is no collision risk.

Hayward classified the danger scale according to TTC value as follows: TTC = 0 (collision), 0 < TTC ≤ 1.5 s (serious conflict), 1.5 < TTC ≤ 5.0 s (potential conflict). The threshold value of 1.5 seconds marks a conceptually significant breaking point: below this value, it is anticipated that most drivers would not have sufficient time to complete an emergency evasive maneuver, and therefore TTC_{min} values below this threshold are classified as 'serious conflicts'.

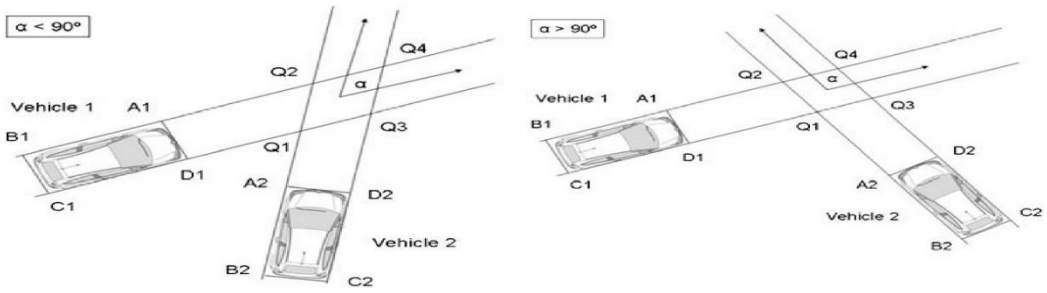
The type and number of collisions vary depending on whether the intersection angle between vehicles is greater than or less than 90 degrees. A total of 32 types of collisions are assumed to be possible depending on the collision angles of the vehicles in question. Of these, only 10 configurations are considered geometrically meaningful for lane-changing conflicts (6 for α < 90° and 4 for α ≥ 90°), and the present study focuses on the former, following Jimenez et al.'s (2013) finding that this configuration yields more realistic results.

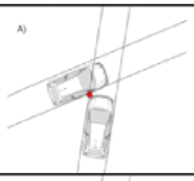
Jimenez et al. (2013) [7] calculated TTC values by combining the trajectories of the lane-changing vehicle and the vehicle following it in the target lane to determine the coordinates of the intersection point. The arrival times of both vehicles at the intersection were calculated, and when they were equal, the resulting value was accepted as the TTC.

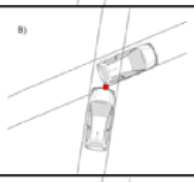
$$x_+ = \frac{(y_2 - y_1) - (x_2 tan\theta_2 - x_1 tan\theta_1)}{tan\theta_1 - tan\theta_2} \quad (3)$$

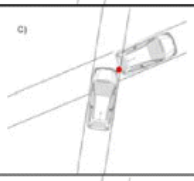
$$y_+ = \frac{(x_2 - x) - (y_2 cot\theta_2 y cot\theta_1)}{cot\theta_1 - cot\theta_2} \quad (4)$$

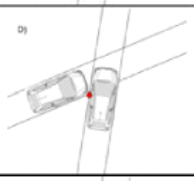
In *Fig. 3*, for the case where angle (a) is less than 90 degrees, the corner points of the lane-changing vehicle and the vehicle behind in the target lane (A1, A2, A3, A4, B1, B2, B3, B4) and the intersection points (Q1, Q2, Q3, Q4) are shown. Table 1. presents the arrival times of the vehicle corner points at the intersection points, and for the case where angle (a) is less than 90 degrees, 6 possible collision types, arrival times at the collision point, and TTC values.

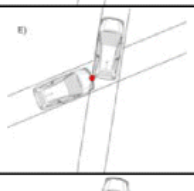












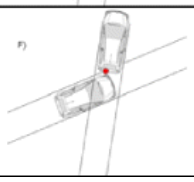


Fig. 3. Collision configuration [7].

Table 1. Collision configurations when α<90° [7].

	Situation	Diagram	Time conditions (Situation in the event the condition is not satisfied)	TTC
A)	Corner Vehicle 2 hits side Vehicle 1		TC11 > TA21 > TD11 / B D	TA21

F)	Corner Vehicle 1 hits rear part Vehicle 2		TC24 > TA14 > TA12 > TB22 / X * E	(TA12, TA14)

*=Always Occurs, X =No Collision

Within the scope of the study, the behavior of the lane-changing vehicle and the vehicle behind it in the target lane at the examined diverging zone was analyzed. The time required for both vehicles to reach the conflict zones, based on their observed and projected linear and lateral positions, was calculated. The likely collision type and Time-to-Collision (TTC) values were estimated

4. Results and Discussions

In this study, data on 40 mandatory lane changes, collected via drone observations conducted on various dates and times at diverging zones in the urban road network of Izmir province, were analyzed. To determine TTC values, starting from the moment the target vehicle's lateral speed exceeded 0.2 m/s as the initial observation time, the TTC values corresponding to the lateral and linear position data taken from the right-rear corners of the lane-changing vehicle and the vehicle behind it in the target lane at 0.5-second intervals were calculated using code written in Python. The obtained data are presented in Table 2.

Table 2. Observed TTC values by collision type.

No	Collision Type	Collision Time	TTC (s)	No	Collision Type	Collision Time	TTC (s)
1	A	TA21	6.67	21	A	TA21	13.34
2	A	TA21	3.50	22	D	TD11	0.52
3	C	TD23-TD24	5.18	23	D	TD11	0.52
4	A	TA21	6.93	24	A	TA21	3.89
5	A	TA21	3.21	25	A	TA21	6.99
6	A	TA21	4.15	26	A	TA21	3.78
7	A	TA21	5.83	27	A	TA21	3.56
8	A	TA21	1.68	28	A	TA21	9.75
9	A	TA21	9.15	29	A	TA21	5.00
10	A	TA21	2.24	30	A	TA21	2.76
11	A	TA21	3.85	31	A	TA21	3.36
12	A	TA21	12.13	32	A	TA21	9.83
13	E	TD11-TA12	1.79	33	A	TA21	3.18
14	A	TA21	6.20	34	A	TA21	10.50
15	A	TA21	6.11	35	B	TA21-TD23	10.29
16	A	TA21	6.15	36	A	TA21	7.19
17	A	TA21	12.26	37	A	TA21	3.00
18	A	TA21	3.98	38	A	TA21	7.96
19	A	TA21	13.00	39	D	TD11	3.92
20	E	TD11-TA12	1.52	40	A	TA21	15.50

Across the 40 observed lane changes, the collision type distribution followed the classification proposed by Jimenez et al. (2013): 33 events were classified as Type A, 1 as Type B, 1 as Type C, 3 as Type D, and 2 as Type E. The high proportion of Type A (82.5% of observations) indicates that most of the lane changes at the observed diverging zone follow a relatively predictable geometry.

TTC values ranged from 0.52 s to 15.50 s, with a mean of 6.32 s. According to Hayward's (1972) danger scale, none of the observed maneuvers reached the collision threshold (TTC = 0), and only Observations 22 and 23 were classified as serious conflicts (TTC $\leq$ 1.5 s). The remaining observations had TTC values either within the potential conflict range (1.5 s < TTC $\leq$ 5.0 s) or above 5.0 s. Despite their low frequency, Type D collisions exhibited the lowest TTC values among the observed lane-change types, indicating a higher collision risk.

The mean TTC of 6.32 s is well above both Hayward's (1972) [6] serious-conflict threshold of 1.5 s and the 0.74 s threshold proposed by Önelçin (2022) [11] for lane-change warning systems, indicating that most lane-changing maneuvers at the study site were performed under relatively safe conditions. However, the minimum TTC value of 0.52 s falls below both thresholds, showing that a small number of maneuvers involved critical conflict situations. A similar pattern was reported by Zürn et al. (2026) [18], who found that although most lane changes were completed safely, critical conflicts still occurred in a small proportion of maneuvers.

It should also be noted that none of the 40 observed lane-changing maneuvers resulted in an actual collision. Instead of relying on actual collisions, TTC-based traffic conflict analysis evaluates near-miss events, since collisions are relatively rare [6].

Overall, the results indicate that the geometric and operational characteristics of the studied diverging zone generally support safe lane-changing behavior. However, a small number of

maneuvers, particularly those classified as Type D, were associated with lower TTC values and therefore deserve particular attention in geometric design and traffic management.

6. Conclusions and Recommendations

This study examined lane-changing safety at a freeway diverging zone in Izmir using field-observed trajectories and Time-to-Collision analysis. Lane changes were generally performed with an adequate safety margin and no actual collisions occurred, though a small subset of maneuvers, particularly those with a Type D conflict configuration, showed lower TTC values.

The findings suggest that improving sight distance and providing sufficient deceleration length may help reduce lane-changing risk. More visible advance signing and longer deceleration lanes could give drivers additional time to assess acceptable gaps, while appropriate speed management within the diverging zone may reduce speed differences between vehicles and contribute to higher TTC values. Since the analysis was based on observations from a single diverging zone over a limited period, these recommendations should be regarded as site-specific. In addition, any increase in the number of lanes should be evaluated carefully, considering the confusion-related crash risk reported for multi-lane diverging zones by Zhang et al. (2015) [16].

Future studies should include a larger number of diverging zones with different geometric characteristics and traffic conditions. Examining the relationship between TTC and geometric variables, such as ramp length and deceleration lane width, would provide a better understanding of how roadway design influences lane-changing safety and help assess whether the findings of the present study are applicable to other diverging zones.

Acknowledgments

The authors would like to express their profound appreciation to the Graduate School of Natural and Applied Sciences at Dokuz Eylül University for its assistance with the doctoral thesis.

Abstract. Aging is a fundamental process affecting the performance characteristics of asphalt mixtures and is generally classified as short-term and long-term aging. Short-term aging is defined as changes in rheological properties occurring during production, hauling/storage, and compaction processes. Long-term aging refers to changes that occur in asphalt pavements throughout their service life. Aging is an inevitable process that influences performance of asphalt mixtures. However, there is still a lack of research on the short- and long-term aging performance of asphalt mixtures incorporating various additives. Therefore, this study aimed to identify existing gaps through a bibliometric analysis of studied investigating the short- and long-term aging performance of asphalt mixtures. A bibliometric analysis was conducted on publications investigating short- and long-term aging performance of asphalt mixtures in accordance with AASHTO R30 standard. The dataset consists of articles and review articles published between 2000 and 2026 and indexed in Web of Science database. A total of 1838 publications were retrieved and analysed. The keywords used for database search was “asphalt” OR “bitumen” OR “bituminous” AND “aging” OR “ageing” AND “short-term” OR “long-term” OR “STOA” OR “LTOA” OR “AASHTO R30”. Obtained data were analysed and visualized using VOSviewer software. Within the scope of bibliometric analysis, co-occurrence, citation, and co-authorship analyses were performed to identify keywords relationships, influential publications, and collaboration patterns. Based on the results of the analysis, key research gaps related to asphalt mixture aging were identified. This study is expected to provide a useful reference for further research on asphalt mixtures aging processes.

Keywords: Asphalt mixtures, short-term aging, long-term aging, bibliometric analysis.

1 Introduction

Asphalt obtained from crude oil through fractional distillation, is widely used in road construction, surfacing, and roofing. The properties of asphalt are altered over time by environmental factors such as oxygen, temperature, moisture and sunlight. Asphalt is composed of organic components such as asphaltene, maltenes, and resins. Asphaltenes are more susceptible to oxidation due to their polar structure, leading to the formation of carbonyl and sulfoxide compounds. These compounds contribute to an increase in the asphaltene fraction, thereby enhancing the stiffness and viscosity of asphalt. These changes in the properties of asphalt are defined as aging. Asphalt is exposed to oxidation at high temperatures during the production, storage, hauling, and paving processes as it mixed with aggregates throughout the construction stage. This process is referred to as the short-term aging of asphalt mixtures. After pavement construction, asphalt continuously reacts with oxygen, and the aging that occurs

throughout its service life is defined as long-term aging. These processes change the rheological properties of asphalt and performance of asphalt mixtures is negatively affected [1,2]. However, according to the reviewed literature, although there are studies on the aging process of asphalt, only a limited number of studies have investigated the aging performance of asphalt mixtures. Since fatigue resistance and moisture susceptibility are commonly used to represent mixture durability, aging performance is often not directly examined. In addition, aging tests of asphalt mixtures are not widely preferred due to their long testing durations [3]. For example, although numerous studies have been conducted on styrene-butadiene-styrene (SBS) and polypropylene (PP) modified asphalt mixtures, the majority have not considered the effect of aging performance. SBS and PP modified mixtures aged long-term were evaluated in terms of stability, rigidity, resilient modulus, indirect tensile strength at two temperatures (25 and 60 °C), tensile strength ratio, and rutting resistance. It has been stated that SBS and PP modified mixtures show higher moisture and rutting resistance than the reference mixtures after long-term aging [4].

The effect of aging on the fatigue performance of asphalt mixtures has been examined under laboratory conditions. Short-term aging of loose mixtures was carried out in a draft oven at 135 °C for 2, 3, and 4 hours, while long-term aging was performed in oven at 85 °C for 3, 5, and 7 days. An increase in the short-term aging duration at the same temperature resulted in an increase in the fatigue life of asphalt mixtures. Asphalt mixtures aged for 7 days under long-term aging conditions exhibited reduced fatigue life due to increased stiffness [5]. The aging behavior of asphalt mixtures incorporating organic warm-mix additives was evaluated, and the results demonstrated that these mixtures may constitute an effective alternative to conventional hot asphalt mixture (HMA) with respect to aging performance [6]. It has been determined that aged and unaged mixtures containing Sasobit and Rheofalt warm-mix additives significantly affect ITS, resilient modulus, and fatigue behavior of mixtures [7]. In addition to this study, the effect of short-term aging temperature (112, 129, and 146 °C) and duration (2, 4, and 8 h) on the moisture susceptibility of asphalt mixtures incorporating Sasobit were evaluated. It was observed that moisture susceptibility of mixtures containing Sasobit subjected to short-term aging at 146 °C for 2 hours decreased [8]. Rad et al. [9] were evaluated the performance of asphalt mixtures subjected to long-term aging at 95 °C and 135 °C temperatures. When the aging temperature increased from 95 °C and 135 °C, significant changes were observed in the rheological and chemical properties of asphalt. The performance of asphalt mixtures aged at 135 °C temperature was adversely affected. Therefore, an aging temperature of 135 °C is not recommended for performance evaluation of asphalt mixtures. The influence of aggregate gradation on the mechanical properties of aged HMA was evaluated. Mixtures prepared with three different gradations (HMA-10, HMA-19, HMA-25) were subjected to short- and long-term aging in accordance with AASHTO R30 standard, after which Marshall, indirect tensile strength (ITS), resilient modulus, permanent deformation, and fatigue were assessed. Mixtures designed in accordance with HMA-19 gradation exhibited the best performance. The results of the tests and measured properties of asphalt mixtures indicate that aggregate gradation has a significant influence on performance [10]. The effects of recycled concrete aggregates (RCAs) ratios (0%, 12%, 21%) on the short-and long-term aging performance of asphalt mixture were investigated. Asphalt mixtures incorporation RCA reduced the aging susceptibility of mixtures while enhancing their strength performance. In particular, asphalt mixtures containing 12% RCA exhibited the highest stiffness, flexibility, and resistance to aging. The use of RCA is beneficial because it reduces the aging sensitivity of asphalt mixtures and improves their strength and performance [11]. The behavior of asphalt mixtures containing glass fibre (0.3%, 0.6% and 6 mm, 12 mm) under short- and long-term aging conditions has been examined. The properties of asphalt mixtures containing glass fibre improved after long-term aging. Therefore, the use of glass fibre in asphalt mixtures contributes to reduced maintenance costs [12]. In

addition, ITS values of mixtures subjected to different aging methods (NCHRP 09-52, NCHRP 09-54, RILEM, and AASHTO R30) were compared with those of field-sampled materials. As no significant differences were observed among the aging methods examined, the ITS values of short-term aged asphalt mixtures were found to be similar. Based on the ITS results, short-term aging in forced draft oven at 135 °C for 2 hours for asphalt mixtures is recommended. Furthermore, the results support the use of AASHTO R30 and NCHRP 09-52 standards for long-term aging [13]. In order to simulate long-term aging, both loose and compacted samples were subjected to oven ageing and pressure ageing vessel ageing in the laboratory. The results indicate that oven aging of loose asphalt mixtures is the most promising method in terms of efficiency, sample integrity, versatility, and cost [14]. Furthermore, aging processes for compacted samples at 85 °C and loose mixtures at 135 °C in laboratory were compared to simulate long-term field aging of asphalt mixtures in Qatar. It was stated that the 5-day oven aging period of compacted samples at 85 °C should be increased to 75 days for the wearing course and 45 days for the base course to better simulate long-term field aging. Conditioning loose mixtures at 135 °C has been suggested an alternative option in terms of time and cost [15]. Consistent with the results of this study, it has been emphasized that further research is required to develop and validate laboratory predictive methodologies capable of accurately representing the initial construction stages of asphalt pavements [16]. Without evaluating laboratory aging tests at different temperatures, it is not possible to accurately predict how the performance of asphalt mixtures will change under varying temperature conditions. Therefore, more dependable results can be achieved by considering the combined effects of time and temperature parameters [17].

The reviewed literature indicated that research on aging of asphalt mixtures is limited. Accordingly, in this study, a bibliometric analysis was conducted on mixtures subjected to short- and long-term aging in accordance with AASHTO R30. The dataset consists of articles and review articles published between 2000 and 2026 and indexed in Web of Science database. A total of 1838 publications were retrieved and analysed. The keywords used for database search was “asphalt” OR “bitumen” OR “bituminous” AND “aging” OR “ageing” AND “short-term” OR “long-term” OR “STOA” OR “LTOA” OR “AASHTO R30”. Obtained data were analyzed and visualized using VOSviewer software. Within the scope of bibliometric analysis, co-occurrence, citation, and co-authorship analyses were performed to identify keywords relationships, influential publications, and collaboration patterns. Based on the results of the analysis, key research gaps related to asphalt mixture aging were identified.

2 Methodology

Bibliometric analysis employs statistical and quantitative methods to evaluate the development of scientific disciplines and structure of knowledge within research fields. This analysis enables identification of relationships among authors, countries, organizations, and keywords, thereby revealing the knowledge structure of subject. In addition, scientific mapping and visualization techniques are used to present these relationships such as VOSviewer [18]. In this study, a bibliometric analysis was conducted on publications investigating short- and long-term aging performance of asphalt mixtures in accordance with AASHTO R30 standard. The dataset consists of articles and review articles published between 2000 and 2026 and indexed in Web of Science database. A total of 1838 publications were retrieved and analyzed. The keywords used for database search was “asphalt” OR “bitumen” OR “bituminous” AND “aging” OR “ageing” AND “short-term” OR “long-term” OR “STOA” OR “LTOA” OR “AASHTO R30”. The obtained data were analyzed and visualized using VOSviewer software. Within the scope of bibliometric analysis, co-occurrence, citation, and co-authorship analyses were performed to identify keywords relationships, influential publications, and collaboration patterns. The present study aims to address following research questions:

1) How has the annual publication trend evolved in studies examining short- and long-term aging performance of asphalt mixtures between 2000 and 2026?

2) Which authors and countries have contributed most significantly to this field, and what are the collaboration patterns among them?

3) Which journals publish the most on aging of asphalt mixtures, and how are these journals interconnected?

4) What are the main research gaps in literature, and what directions can be suggested for future studies?

3 Results of Bibliometric Analysis

This section is discussion the interpretation of graphs obtained using VOSviewer software.

3.1 Publication Year Analysis

Fig. 1 illustrates the annual trend of publications examining short- and long-term aging of asphalt mixtures from 2000 to 2026. A limited number of studies were published between 2000 and 2010, indicating that the topic received relatively little attention during this period. A gradual increase in the number of publications is observed between 2011 and 2019. However, a more pronounced growth trend emerges after 2019, reflecting a rapidly increasing academic interest in the field. The peak in the number of publications in 2025 underscores growing importance of aging performance of asphalt mixtures. The lower number of publications in 2026 may be attributed to the incomplete indexing of the year.

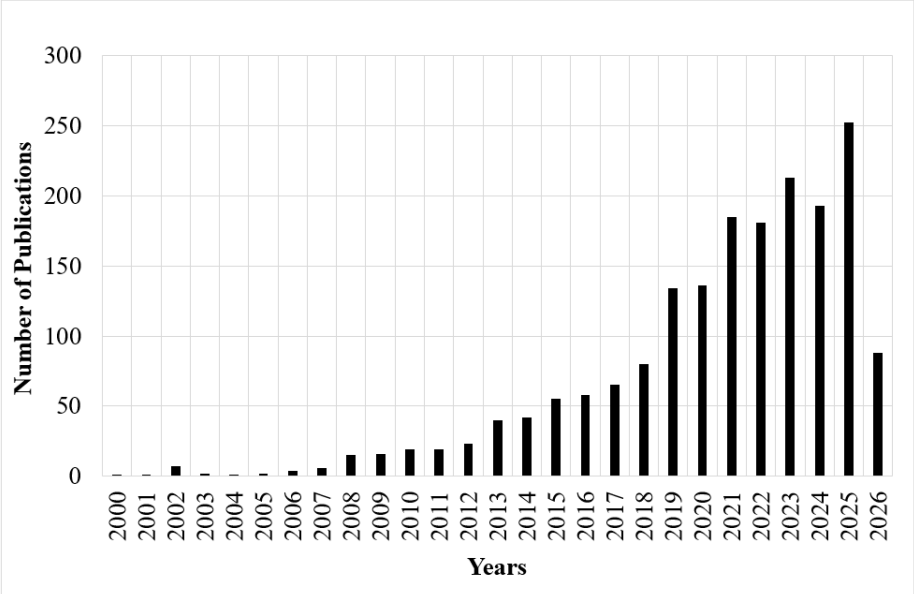

Fig. 1. The trends of annual publications from 2000 to 2026

3.2 Co-authorship Analysis

The authors who have contributed to research on the aging performance of asphalt mixtures and their collaboration patterns were identified (Fig. 2). Authors such as Hofko, Bernhard; Xiao, Feipeng; and Zhang, Henglong stand out in terms of citation impact, while Lee, Soon-Jae exhibits the highest total link strength. In co-authorship networks, a shorter distance between nodes indicates stronger collaborative relationships between authors, whereas a greater distance reflects weaker or more limited collaboration [19].

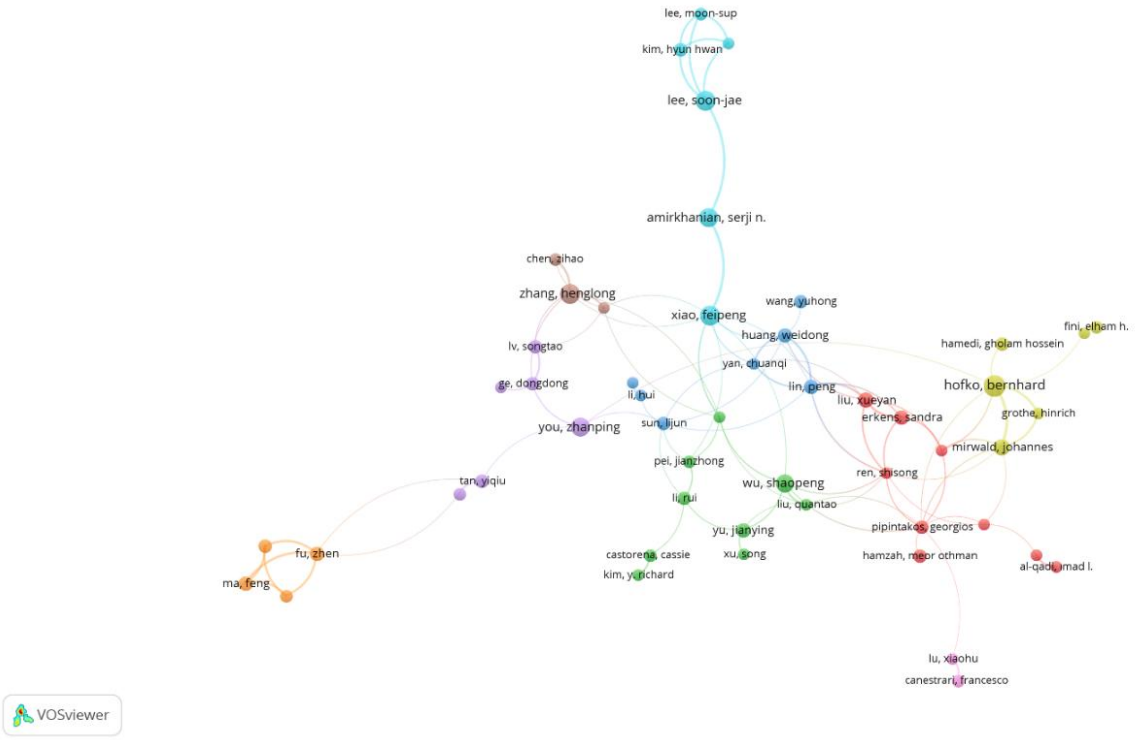

Fig. 2. Co-authorship network of authors in studies on asphalt mixture aging

3.3 Distribution of Publications by Country

Fig. 3 illustrates the international collaboration network among countries in the research field. China and the United States appear as the most prominent and influential countries in the network. Their large node sizes and strong intercountry connections indicate a high level of citation influence and collaboration.

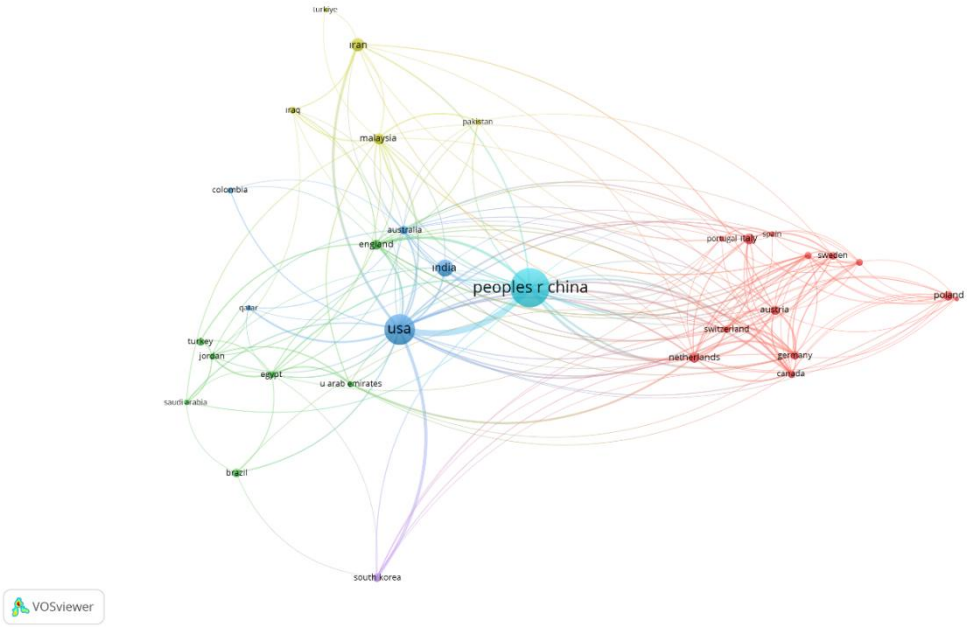

Fig. 3. Visualization of relationships between studies from different countries

3.4 Institutional Collaboration Analysis

The co-authorship network reveals that the literature is clustered around several key centers. In particular, Changan University, Wuhan University of Technology, and Southeast University emerge as the most prominent nodes in the network (Fig. 4). The network structure also highlights the presence of distinct clusters. This indicated that research activities are organized within specific collaborative groups. Moreover, certain institutions act as bridging nodes connecting different clusters, thereby facilitating knowledge exchange across the network.

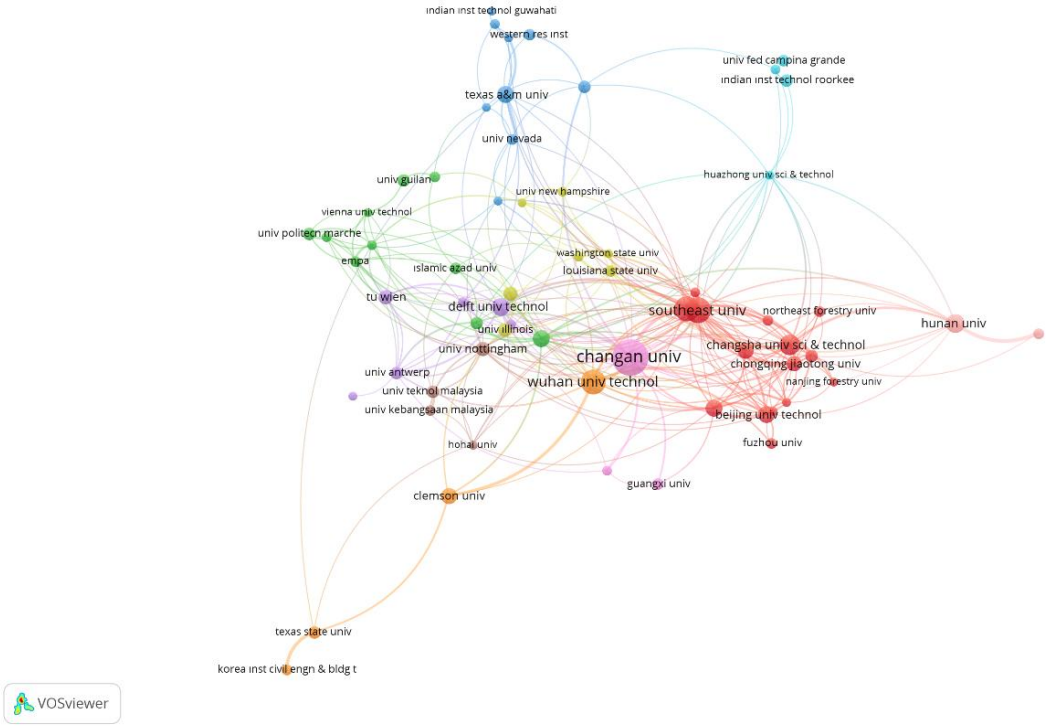

Fig. 4. Co-authorship network of institutions

3.5 Journal Analysis and Impact

The analysis of journals reveals the structural organization and the distribution of scientific publications (Fig. 5). Construction and Building Materials and Journal of Materials in Civil Engineering emerge as the most productive and influential sources in literature. These journals not only publish a higher number of studies but also play a central role in shaping the intellectual structure of the field. Clusters (red, blue, and purple) appear to reflect thematic groupings within the field. The red cluster is primarily associated with construction materials and civil engineering research, as evidenced by core journals such as Construction and Building Materials and Journal of Materials in Civil Engineering. In contrast, the blue cluster is more closely related to transportation infrastructure and pavement engineering, represented by journals such as Road Materials and Pavement Design and Transportation Research Record.

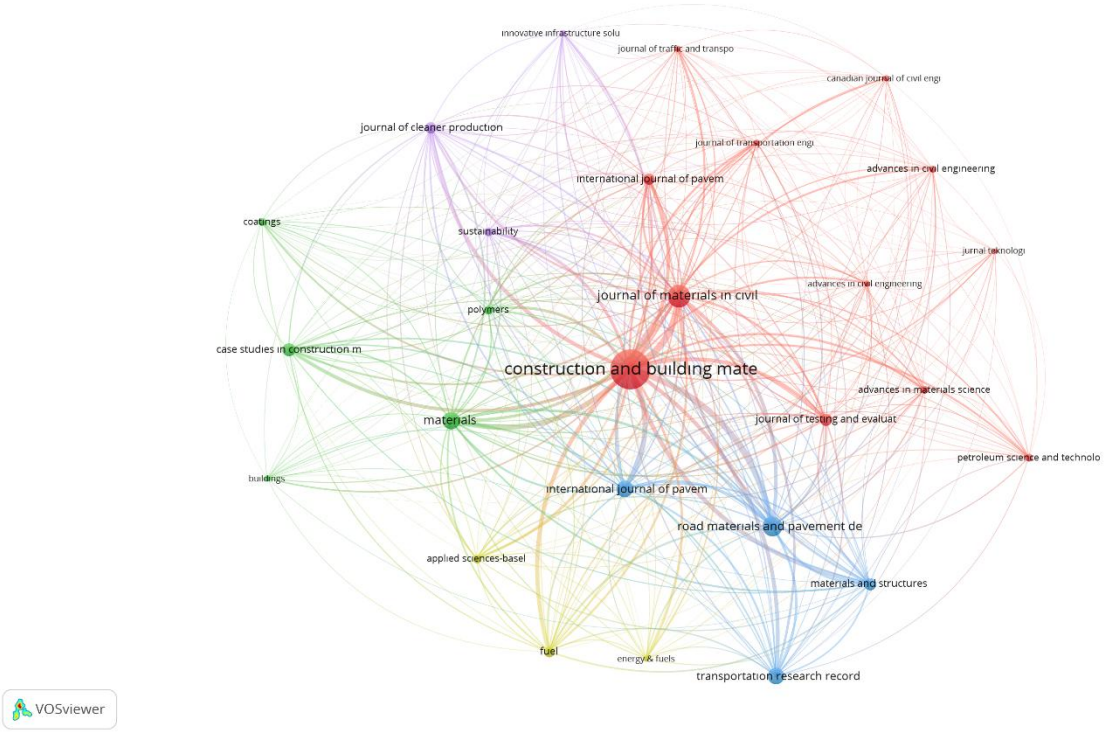

Fig. 5. Distribution of the most influential journals

3.6 Co-occurrence Network of Author Keywords

The co-occurrence network of author keyword reveals the conceptual structure and main research themes within the field (Fig. 6). Nodes represent keywords, while node size is proportional to keyword frequency. The links (edges) indicate co-occurrence relationships between keywords, and the thickness of the links reflects the strength or frequency of co-occurrence [20]. Keywords such as “aging”, “bitumen”, “asphalt”, and “rheology” are characterized by large node size indicating their high frequency of occurrence. The red cluster, which is the largest among the identified clusters, encompasses studies focusing on fatigue, rutting, durability, and rejuvenation which influenced the performance of asphalt mixtures. The green cluster representing aging, demonstrates that bitumen, asphalt binder, and rheology are strongly co-occurring themes. The blue cluster which represents research on rheological properties, demonstrates strong co-occurrence relationships with parameters such as modified asphalt, aging resistance, modification, and oxidation.

The clusters in purple and blue, representing topics such as aging, rheology, rutting, fatigue, asphalt and bitumen, correspond to well-established and extensive studies research themes in the literature (Fig. 6). In contrast, the yellow cluster including rheological properties, aging resistance, asphalt pavement performance, and fatigue resistance reflects more recent and emerging research interests. According to the bibliometric analysis, although the aging behavior and rheological properties of asphalt binders have been extensively investigated, studies addressing the short- and long-term aging performance of asphalt mixtures are comparatively limited. This suggests that the relationship between changes in the rheological properties of asphalt binders and the short-and long-term aging performance of asphalt mixtures has been sufficiently investigated.

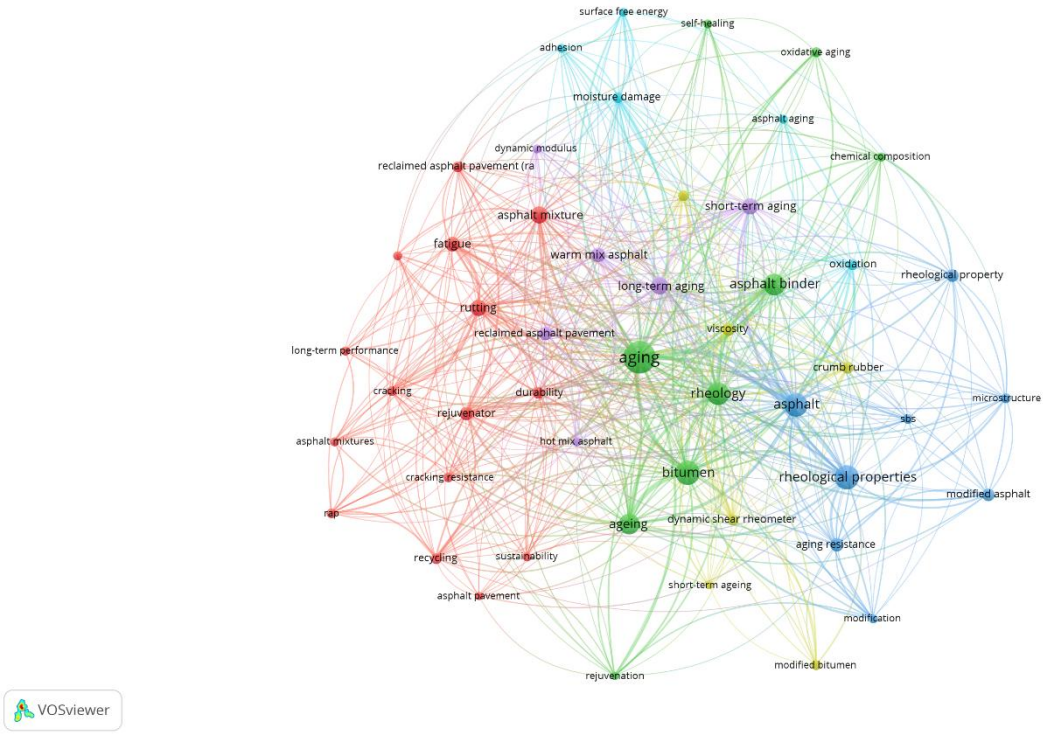

Fig. 6. Co-occurrence network of author keywords

4 Results

A bibliometric analysis was conducted on studies examining the short- and long-term aging performance of asphalt mixtures in accordance with AASHTO R30 standard. Co-occurrence, citation, and co-authorship analyses were performed to identify keyword relationships, influential publications, and collaboration patterns. The results revealed thematic patterns and research trends in literature. The findings indicate that although the aging behavior and rheological properties of asphalt binders have been extensively investigated, studies focusing on the short- and long-term aging performance of asphalt mixtures remain limited. This highlights significant research gaps regarding aging, a critical factor affecting the performance of asphalt mixtures.

Abstract. Unsignalized intersections are among the most common at-grade intersections where vehicle–vehicle and vehicle–pedestrian interactions directly affect operational performance. Although STOP and YIELD control are widely used to regulate right-of-way, the effects of pedestrian demand on different traffic movements have received limited attention. This study investigates the effects of pedestrian demand on the operational performance of STOP- and YIELD-controlled three-leg unsignalized intersections.

A total of 100 simulation scenarios, including 50 STOP-controlled and 50 YIELD-controlled intersections with identical geometric characteristics, were developed using SIDRA Intersection. Different combinations of major-road traffic volume, minor-road traffic volume, and pedestrian demand were evaluated. Pearson correlation analysis indicated substantial multicollinearity among the explanatory variables; therefore, Partial Least Squares (PLS) regression was employed to develop prediction models for movement-specific delays.

The developed PLS models were statistically significant and achieved satisfactory predictive performance, with R^2 values ranging from 0.638 to 0.944, demonstrating that delay data obtained from SIDRA simulations could be reliably modelled using the PLS approach. Comparison of paired STOP and YIELD scenarios showed that YIELD control reduced minor-road left-turn, minor-road right-turn, and major-road left-turn delays by approximately 43%, 40%, and 20%, respectively, whereas major-road right-turn delay increased by approximately 79%. Response surface analyses further indicated that increasing pedestrian demand and major-road through traffic increased delays under both control types, although YIELD control generally produced lower delay levels for minor-road movements.

The findings demonstrate that integrating SIDRA simulation with PLS regression provides a reliable framework for evaluating the combined effects of traffic demand, pedestrian demand, and intersection control type, and may support the selection of appropriate control strategies for unsignalized intersections

Keywords: Unsignalized intersections, gap acceptance, pedestrians, traffic delay, delay prediction

1 Introduction

Unsignalized intersections are one of the at-grade intersection types commonly used in urban and rural road networks with low to moderate traffic volumes. Unlike signalized intersections, traffic flow at these intersections is regulated by right-of-way rules rather than traffic signals, with priority assigned through STOP control, YIELD control, or uncontrolled operation. They are widely preferred worldwide due to their low construction and operating costs, the absence of energy requirements, and their ability to provide lower delays under appropriate traffic

conditions. However, since right-of-way decisions must be evaluated instantaneously by drivers, the operational performance of unsignalized intersections largely depends on driver behavior. In particular, the imbalance between major- and minor-road traffic volumes, turning movements, geometric design characteristics, and pedestrian activity play a decisive role in determining the capacity, delay, queue formation, and traffic safety of these intersections. Therefore, understanding drivers' minor-road entry behavior and the decision-making mechanisms governing this behavior is essential for accurately evaluating the operation of unsignalized intersections [1].

Minor-road entry behavior is one of the fundamental processes determining the operational performance of unsignalized intersections. Drivers approaching the intersection from the minor road must enter the intersection by identifying and accepting suitable gaps in the major-road traffic stream. Therefore, this decision-making process is influenced not only by the major-road traffic flow but also by the type of intersection control. At STOP-controlled intersections, drivers are required to come to a complete stop at the stop line and wait until an acceptable gap becomes available. In contrast, at YIELD-controlled intersections, drivers evaluate available gaps while slowing down or stopping only when necessary. These different control types influence drivers' gap acceptance behavior and, consequently, may lead to significant differences in intersection capacity, control delay, queue length, and overall operational performance. Therefore, the operational performance of unsignalized intersections largely depends on drivers' minor-road entry behavior, the gap acceptance mechanism underlying this behavior, and the type of control applied at the intersection. [2-3].

Critical gap is regarded as one of the fundamental performance indicators for describing drivers' gap acceptance behavior under different unsignalized intersection control types. Studies on critical gap estimation are generally classified into two main approaches: empirical and behavioral. Empirical models attempt to estimate the critical gap statistically by evaluating accepted and rejected gaps obtained from field observations. These models treat the minor-road entry process as a "black box" and estimate the critical gap solely based on drivers' acceptance and rejection decisions [4]. In contrast, behavioral models seek to explain the reasons underlying drivers' acceptance or rejection of available gaps. Within these models, the critical gap is not considered a fixed value but rather a dynamic decision variable that may vary depending on drivers' risk perception, experience, waiting time, vehicle type, traffic conditions, and environmental factors [5]. Since empirical models primarily focus on the outcome of the minor-road entry process, whereas behavioral models emphasize the decision-making mechanism, both approaches should be considered together when evaluating critical gap behavior [6].

Classical gap acceptance theory has been the basis of numerous studies assuming that drivers make their entry decisions solely according to the available gaps between vehicles in the major-road traffic stream by considering only vehicle–vehicle interactions. However, the high presence of pedestrians, particularly at urban unsignalized intersections, indicates that this assumption is insufficient. Therefore, pedestrian presence should be considered as a factor that directly influences drivers' minor-road entry decisions [7]. Pedestrian activity not only affects critical gap acceptance behavior but also plays an important role in the operational performance of unsignalized intersections. Consequently, vehicle–pedestrian interactions should be evaluated as an integral component of operational performance assessment [8].

The aim of this study is to investigate the effects of vehicle–pedestrian interactions on the operational performance of STOP- and YIELD-controlled three-leg unsignalized T-intersections under different traffic and pedestrian demand conditions. To this end, STOP- and YIELD-controlled intersection models with identical geometric characteristics were developed using SIDRA Intersection, and a series of scenarios representing different major-road traffic volumes, minor-road traffic volumes, and pedestrian demand levels were analyzed. Major-road

and minor-road delays were evaluated separately for each scenario. In this context, the study considers vehicle–pedestrian interaction as an integral component of the minor-road entry process and evaluates the effects of different intersection control types on operational performance.

2 Methodology

In this study, the operational performance of STOP- and YIELD-controlled unsignalized T-intersections under different traffic and pedestrian demand conditions was comparatively evaluated. The analysis was conducted using the SIDRA Intersection software. Two intersection models with identical geometric characteristics were developed, and their operational performance was compared by varying only the intersection control type. Accordingly, the effects of intersection control type and variations in traffic and pedestrian demand on the operational performance of unsignalized intersections were comparatively assessed. Figure 1 presents the methodological framework of the study.

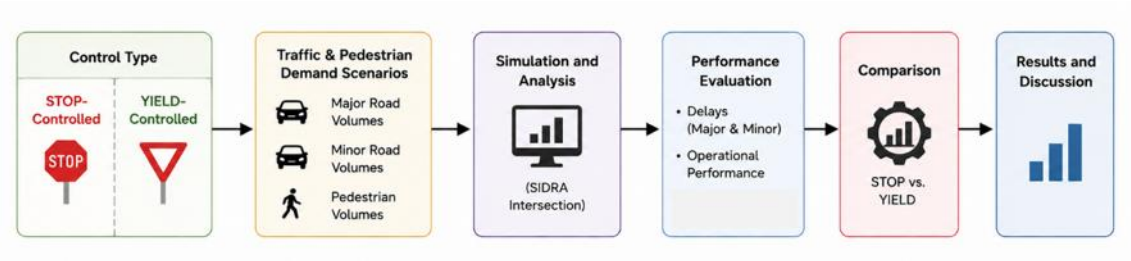

Fig.1. Methodological framework of the study.

2.1 Intersection Geometry and Modeling

The intersection model used in this study was developed as a three-leg unsignalized T-intersection consisting of a two-way major road and a two-way minor road, each providing one lane in each direction. All lane widths were designed as 3.30 m. Without modifying the intersection geometry, the same traffic scenarios were analyzed under two different control types: STOP and YIELD.

Through, right-turn, and left-turn movements were defined for both directions of the major road, whereas only right-turn and left-turn movements were assigned to the minor-road approach in accordance with the T-intersection geometry. To evaluate vehicle–pedestrian interactions, a pedestrian crossing was introduced at the minor-road approach near the intersection entry. This configuration allowed both vehicles entering the intersection from the minor road and vehicles performing right- and left-turn maneuvers from the major road to be affected by pedestrian activity. The intersection geometry and traffic movements adopted in this study are illustrated in Figure 2.

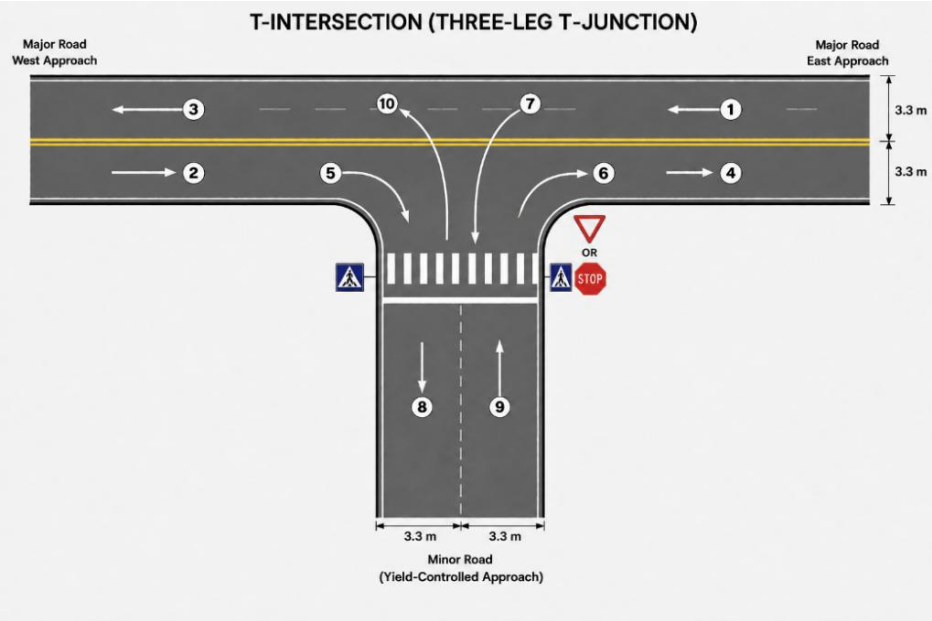

Fig.2. Geometry and traffic movements of the three-leg (T) unsignalized intersections with STOP and YIELD control modeled in SIDRA Intersection.

2.2 Scenarios

A total of 100 simulation scenarios were developed to evaluate the operational performance of STOP- and YIELD-controlled three-leg unsignalized T-intersections. The first 50 scenarios were prepared for the STOP-controlled intersection model, whereas the remaining 50 scenarios were developed for the YIELD-controlled intersection model. Accordingly, each STOP-controlled scenario was replicated under identical geometric and traffic conditions for the YIELD-controlled intersection, enabling the direct comparison of the effects of intersection control type on operational performance.

Table 1. Traffic demand, geometric characteristics, and analysis parameters adopted for the simulation scenarios.

Parameter	**Value / Range**
Intersection control type	STOP / YIELD
Total number of scenarios	100
STOP-controlled scenarios	50
YIELD-controlled scenarios	50
Major-road traffic volume	≤ 1000 veh/h
Minor-road traffic volume	≤ 600 veh/h
Pedestrian volume	50–300 ped/h
Analysis software	SIDRA Intersection 6.1
Intersection geometry	Three-leg (T) unsignalized intersection
Lane configuration	One lane per direction on both major and minor roads
Lane width	3.3 m

During scenario development, major-road traffic volume, minor-road traffic volume, and pedestrian volume were considered as the independent variables. To represent realistic urban traffic conditions, the total major-road traffic volume was limited to 1000 veh/h, while the minor-road traffic volume was restricted to a maximum of 600 veh/h. Pedestrian demand was varied between 50 and 300 ped/h to represent different pedestrian activity levels. This enabled the evaluation of intersection performance under various pedestrian demand conditions. The parameters adopted in the study and their corresponding value ranges are summarized in Table 1.

Considering that individual traffic movements may be affected differently by pedestrian interactions, the analysis results were evaluated separately for delays associated with major-road right-turn and left-turn movements, as well as minor-road right-turn and left-turn movements entering the major traffic stream. The obtained data were transformed into a multi-parameter model using PLS regression. The model used to predict delays in this study was developed based on intersection control type, vehicle and pedestrian demands.

This approach enabled an independent assessment of the effects of intersection control type and pedestrian demand on each turning movement. Movement-specific average delay was adopted as the primary performance measure. Accordingly, delay values for right-turn and left-turn movements on both the major and minor approaches were analyzed separately to compare the effects of pedestrian demand and intersection control type on each traffic movement.

3 Results and Evaluation

Pearson correlation analyses were conducted for the STOP- and YIELD-controlled intersection scenarios to define appropriate regression model for analyzing the simulation outputs considered in this study. Based on Pearson correlation results, PLS regression was identified as the most appropriate method to evaluate the study results. Accordingly, PLS regression analysis was performed to investigate the effects of traffic volume, pedestrian volume, and intersection control type on delays associated with major-road and minor-road movements. The detailed correlation matrices for both intersection control types are presented in Appendix A.

The Pearson correlation analysis revealed strong linear relationships between minor-road traffic volumes and turning movements. In addition, positive correlations were observed between pedestrian volume and delays associated particularly with turning movements. Although some differences in the correlation coefficients were observed between the two intersection control types, both analyses indicated a high degree of correlation among the traffic and pedestrian variables. These findings suggest the presence of substantial multicollinearity among the explanatory variables. Since multicollinearity may reduce the reliability of coefficient estimates in conventional multiple linear regression models, the Partial Least Squares (PLS) regression method, which is capable of producing reliable models in the presence of highly correlated predictors, was adopted in the subsequent analysis.

Table 2. Performance statistics of the developed PLS regression models

Response Variable	Number of Latent Components	R^2	Predicted R^2	F-value	p-value
Major Road Right Delay	4	0.711	0.658	58.53	<0.001
Major Road Left Delay	4	0.874	0.851	164.64	<0.001
Minor Road Left Delay	4	0.638	0.569	41.94	<0.001
Minor Road Right Delay	4	0.944	0.931	397.91	<0.001

Table 2 presents the performance statistics of the PLS regression models developed for the four delay variables. Cross-validation results indicated that four latent components provided the optimum model structure for all models. Furthermore, all developed models were found to be statistically significant ($p < 0.001$).

The explanatory performance of the developed PLS models was evaluated using the coefficient of determination (R^2) and Predicted R^2 values. Among the developed models, the Minor Road Right Delay model exhibited the highest explanatory and predictive performance, with an R^2 value of 0.944 and a Predicted R^2 value of 0.931. This was followed by the Major Road Left Delay ($R^2 = 0.874$), Major Road Right Delay ($R^2 = 0.711$), and Minor Road Left Delay ($R^2 = 0.638$) models. The high explanatory power achieved for the Minor Road Right Delay model indicates that intersection control type, traffic volumes, and pedestrian volume collectively explain a substantial proportion of the variability in this delay component.

These findings suggest that delays experienced by drivers making left-turn movements from the minor road may be influenced not only by traffic and pedestrian volumes but also by behavioral factors that were not included in the model, such as driver behavior, gap acceptance characteristics, and decision-making processes as in this study behavioral approaches are not considered whereas the empirical models are the main concern.

The regression coefficients of the developed PLS models are presented in Table 3. Using these coefficients, prediction equations were established for each delay variable. The sign of each coefficient indicates the direction of the relationship between the corresponding independent variable and the delay component, whereas its magnitude represents the change in the predicted delay associated with a one-unit change in the independent variable while all other variables are held constant.

Prediction equations for the four delay components were developed using the unstandardized regression coefficients presented in Table 3.

Table 3. Regression coefficients of the developed PLS models

Predictor	Major Road Right Delay	Major Road Left Delay	Minor Road Left Delay	Minor Road Right Delay
Constant	1.13546	0.79526	-5444.94	7.00816
Control Type	5.06771	-2.90113	-735.13	-4.18640
Main Road W–E Through	0.00201	0.01504	5.163	0.00373
Main Road W–E Right	-0.00011	0.01281	-1.764	-0.00391
Main Road E–W Through	0.00701	0.00161	4.377	0.00036
Main Road E–W Left	0.00687	0.00657	7.003	-0.00188
Minor Road Left	-0.00144	-0.00054	3.645	0.00028
Minor Road Right	0.00045	0.00308	5.318	0.00143
Pedestrian Volume	0.00162	0.00837	2.937	0.00781

In the developed models, the dependent variables were generally expressed using the linear regression model given in Equation (1). The unstandardized regression coefficients for each model are presented in Table 3, and the prediction equations for Major Road Right Delay, Major Road Left Delay, Minor Road Left Delay, and Minor Road Right Delay can be obtained by substituting the corresponding coefficients into Equation (1).

$$Delay = \beta_0 + \beta_1 CT + \beta_2 V_{WE,T} + \beta_3 V_{WE,R} + \beta_4 V_{EW,T} + \cdots + \beta_5 V_{EW,L} + \beta_6 V_{M,L} + \beta_7 V_{M,R} + \beta_8 P \quad (1)$$

Where, Delay is predicted delay (sec), CT is control type, $V_{WE,T}$ is main road W–E Through Volume (veh/h), $V_{WE,R}$ is Main Road W–E Right-Turn Volume (veh/h), $V_{EW,T}$ is Main Road E–W Through Volume (veh/h), $V_{EW,L}$ is Main Road E–W Left-Turn Volume (veh/h), $V_{M,L}$ is Minor Road Left-Turn Volume (veh/h), $V_{M,R}$ is Minor Road Right-Turn Volume (veh/h), P is Pedestrian Volume (ped/h), β_0 is constant, and β_0-β_8 is Unstandardized Regression Coefficient.

Figure 3 presents the standardized regression coefficients of the developed PLS models, allowing the relative effects of the explanatory variables on the delay components to be directly compared.

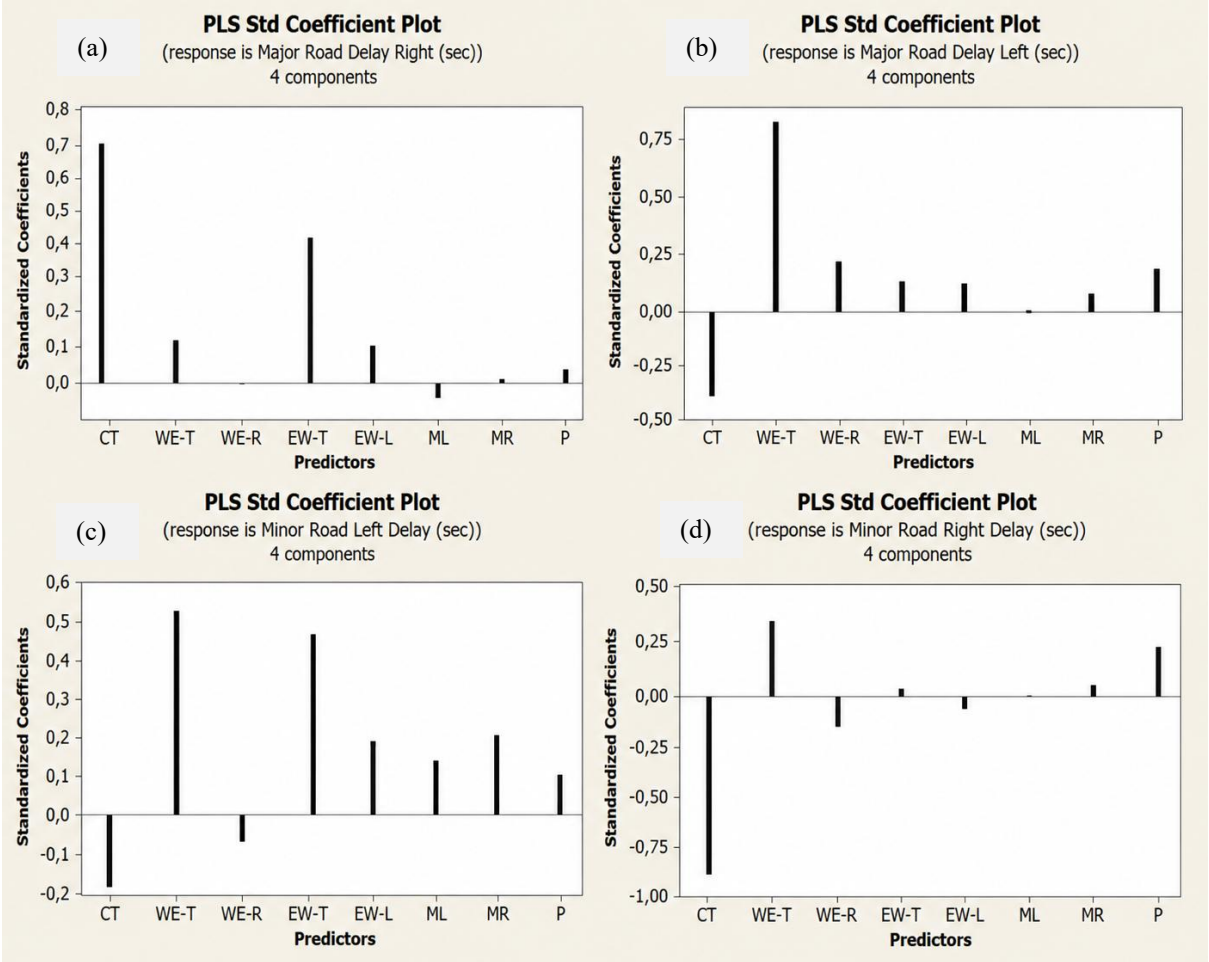

Fig.3. Standardized regression coefficient plots of the developed PLS models for (a) Major Road Right Delay, (b) Major Road Left Delay, (c) Minor Road Left Delay, and (d) Minor Road Right Delay.

For major-road right-turn delays, intersection control type was identified as the most influential variable. In contrast, major-road through traffic volume exhibited the strongest effect

on major-road left-turn delays. For minor-road right-turn delays, the most influential variables were, respectively, intersection control type, major-road through traffic volume, and pedestrian volume. Conversely, major-road through traffic volume was found to be the dominant factor affecting minor-road left-turn delays. Overall, the results indicate that intersection control type is the dominant factor affecting right-turn movements, whereas major-road through traffic volume has a more pronounced influence on left-turn delays.

Figure 4 illustrates the predictive performance of the developed PLS models. Overall, the model predictions and cross-validation results exhibit trends consistent with the observed delay values, indicating reasonable compatibility between the observed and predicted responses. However, the degree of compatibility varies among the developed models. In particular, the Minor Road Left Delay model presented in Figure 4(c) shows a noticeable clustering and wider dispersion of predicted values at relatively low observed delay levels. This behavior may be associated with the wider and more heterogeneous distribution of Minor Road Left Delay values compared with the other delay variables, including considerably high delay values under certain traffic demand conditions. Such a distribution is more difficult to represent using a linear PLS model structure, resulting in greater prediction errors, particularly within the lower-delay range. This observation is consistent with the comparatively lower explanatory and predictive performance of the Minor Road Left Delay model, with R^2 and Predicted R^2 values of 0.638 and 0.569, respectively. Nevertheless, the overall trend between the observed and predicted values is maintained, and the similar distributions of the fitted and cross-validation results indicate that the model is still capable of capturing the general variation in Minor Road Left Delay, despite its lower predictive performance compared with the other delay models.

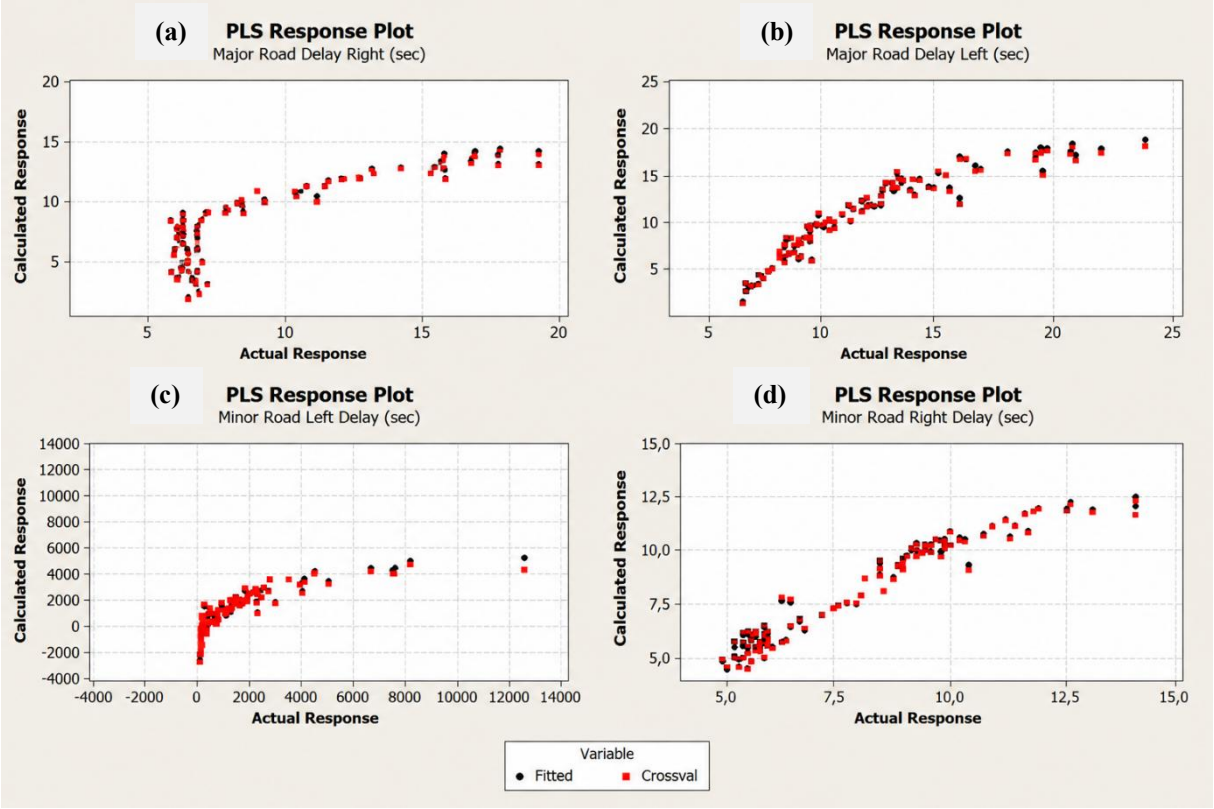

Fig.4. Response plots of the developed PLS regression models for (a) Major Road Right Delay, (b) Major Road Left Delay, (c) Minor Road Left Delay, and (d) Minor Road Right Delay, comparing observed and predicted delay values for both fitted and cross-validation datasets.

Figure 5 illustrates the effects of major-road W–E through traffic volume and pedestrian volume on minor-road left-turn and right-turn delays under STOP- and YIELD-controlled

intersection conditions. For both control types, minor-road delays increased with increasing major-road traffic volume and pedestrian volume. However, the STOP-controlled intersection exhibited substantially higher delay levels, whereas the YIELD-controlled intersection produced lower delays under the same traffic and pedestrian demand conditions. These findings are consistent with the results obtained from the PLS regression analysis and confirm that intersection control type is a key factor influencing delays associated with minor-road movements.

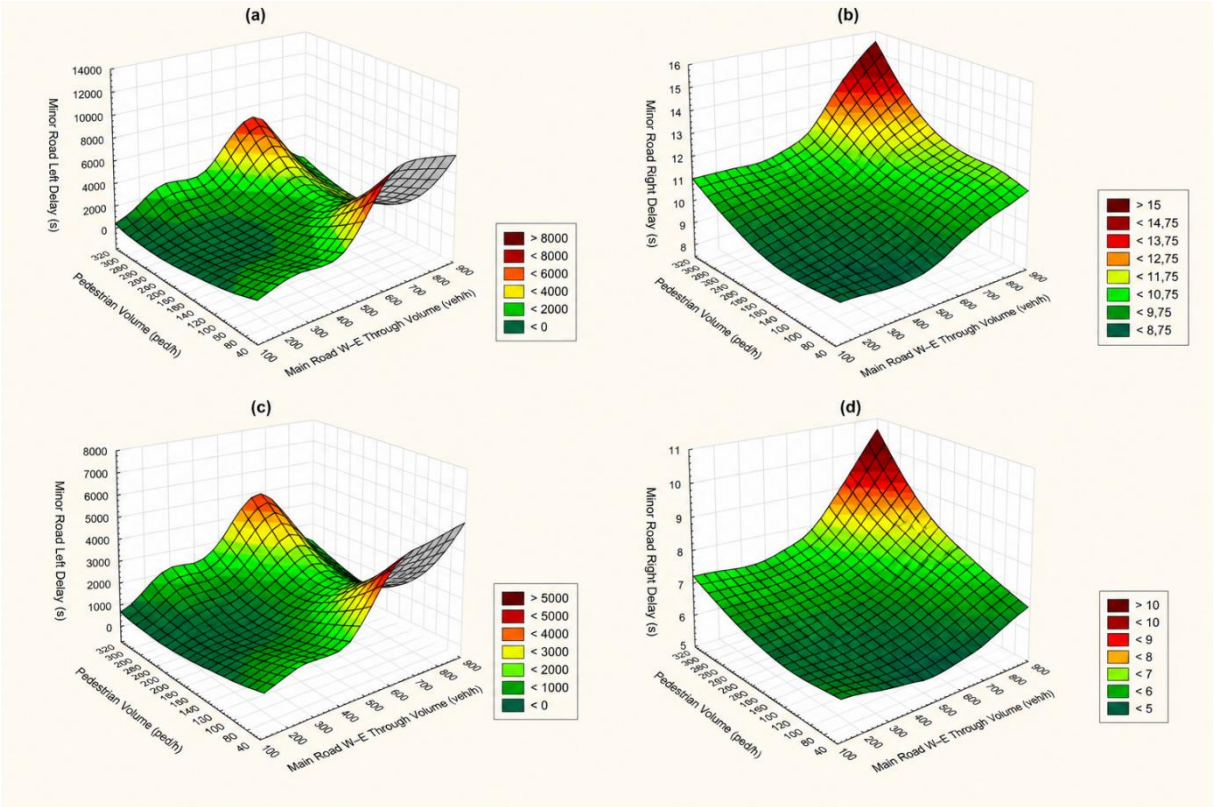

Fig.5. Response surface plots illustrating the combined effects of main-road W–E through traffic volume and pedestrian volume on minor-road left-turn and minor-road right-turn delays under STOP and YIELD control conditions: (a) Minor Road Left Delay under STOP control, (b) Minor Road Right Delay under STOP control, (c) Minor Road Left Delay under YIELD control, and (d) Minor Road Right Delay under YIELD control.

Overall, the developed PLS models provided reliable predictive performance for the different delay components and successfully captured the relationships among intersection control type, traffic volumes, and pedestrian volume. When the standardized regression coefficients and response surface analyses are considered together, the effects of the explanatory variables change according to movement type. In particular, minor-road movements were more sensitive to changes in intersection control type and pedestrian demand, whereas major-road movements were predominantly influenced by major-road traffic volume. Furthermore, the comparative analysis of paired STOP- and YIELD-controlled scenarios (Table 4) revealed substantial differences in operational performance between the two control types.

As presented in Table 4, comparison of the paired scenarios showed that YIELD control reduced minor-road left-turn and minor-road right-turn delays by approximately 43% and 40%, respectively. In addition, major-road left-turn delay decreased by approximately 20%, whereas major-road right-turn delay increased by approximately 79%. These findings indicate that the

effect of intersection control type is movement-dependent and that YIELD control provides considerable operational benefits, particularly for minor-road movements.

Table 4. Comparative delay changes between STOP- and YIELD-controlled intersections

Delay Measure	Mean Change (%)
Average Control Delay	−39.1
Major Road Right Delay	+78.6
Major Road Left Delay	−20.0
Minor Road Left Delay	−43.2
Minor Road Right Delay	−40.2

4 Conclusion and Future Works

In this study, the operational performance of STOP- and YIELD-controlled three-leg unsignalized T-intersections under different traffic and pedestrian demand conditions was evaluated using SIDRA Intersection, and the resulting simulation data were analyzed by means of PLS regression. Pearson correlation analysis revealed a high degree of multicollinearity among the explanatory variables; therefore, PLS regression was adopted to develop delay prediction models.

The developed PLS models were statistically significant for all delay components, with R^2 values ranging from 0.638 to 0.944. The high predictive performance of the models demonstrates that the delay data obtained from SIDRA Intersection simulations can be acceptably modeled using the PLS regression approach, providing a reliable representation of intersection operational performance under varying traffic and pedestrian demand conditions.

Comparison of the paired STOP- and YIELD-controlled scenarios showed that YIELD control reduced minor-road left-turn delays by approximately 43%, minor-road right-turn delays by 40%, and major-road left-turn delays by 20%. In contrast, major-road right-turn delays increased by approximately 79% under YIELD control. Furthermore, the response surface analyses demonstrated that increasing major-road traffic volume and pedestrian demand resulted in higher delays under both control types. However, under the same traffic and pedestrian demand conditions, the YIELD-controlled intersection consistently produced lower delays for minor-road movements than the STOP-controlled intersection. These findings indicate that the effect of intersection control type varies according to movement type and that pedestrian demand has a more pronounced influence on delays associated with minor-road movements.

In conclusion, this study demonstrated that the PLS regression approach provides an effective framework for analyzing data obtained from SIDRA Intersection simulations and for developing reliable models to evaluate the operational performance of unsignalized intersections under varying traffic and pedestrian demand conditions. The findings of this study may contribute to engineering decision-making regarding the selection of appropriate intersection control strategies and the improvement of intersection operational performance. Future research should focus on validating the developed models using field data and incorporating surrogate safety measures, such as Time-to-Collision (TTC) and Post-Encroachment Time (PET), to establish more comprehensive models that jointly evaluate operational performance and traffic safety.

Abstract. Asphalt pavements are subjected to various distresses, such as permanent deformation, cracking, and aging, due to increasing traffic loads, temperature variations, and environmental effects throughout their service life. Therefore, improving the physical properties of bituminous binders is considered an important research area for enhancing pavement performance. In this study, the effect of composite modification obtained through the combined use of polyolefin elastomer (POE) and nanoclay additives on the physical properties of 50/70 penetration grade bitumen was investigated. For this purpose, modified bitumen samples coded as P1, P3, P5, and P1N1–P5N3 were prepared using different POE and nanoclay contents. The physical properties of the prepared binders were evaluated through penetration, softening point, and penetration index tests. The experimental results showed that the POE/Nanoclay composite additive had a pronounced effect on the consistency and temperature susceptibility of bitumen. The penetration value of the base bitumen decreased from 53.0 dmm to 24.8 dmm for the P5N3 sample, indicating that the binder became stiffer with the addition of the additive. In contrast, the softening point increased from 50.2 °C to 66.1 °C, demonstrating an improvement in the binder's resistance to softening at elevated temperatures. The penetration index results revealed that temperature susceptibility decreased, particularly in the P3 and P5 groups, and that the modified binders exhibited more stable behavior against temperature variations. Overall, the findings indicate that the POE/Nanoclay composite additive improved the physical stability of bitumen and may provide beneficial effects in terms of high-temperature performance. However, in order to determine the optimum additive content, the physical test results should be supported by further investigations, including aging, storage stability, and mixture performance tests.

Keywords: Bitumen; POE; Nanoclay; Composite additive; Bitumen modification; Penetration; Softening point; Penetration index.

1 Introduction

Asphalt pavements are widely used in highway pavement structures due to their advantages, such as providing comfortable driving conditions, high abrasion resistance, and relatively easy maintenance and repair operations [1, 2]. However, asphalt binders are exposed to

environmental effects such as light, heat, oxygen, and water throughout their service life. These effects cause changes in the physical and chemical structure of the binder, leading to a gradual reduction in pavement performance [3, 4]. Therefore, the modification of bitumen with various additives has become a widely investigated approach to improve the durability of asphalt pavements.

One of the most commonly used polymer additives in bitumen modification is styrene-butadiene-styrene (SBS) block copolymer, which has long held an important place in asphalt engineering [5]. However, the unsaturated double bonds in the molecular structure of SBS are prone to degradation under ultraviolet radiation and high-temperature effects, which may lead to a decrease in binder performance during aging [6, 7]. At this point, polyolefin elastomers (POE) stand out as an alternative polymer additive due to their ability to exhibit elastomeric behavior similar to SBS and the absence of unsaturated bonds in their structure. Owing to these characteristics, POE is reported to provide a more resistant structure against heat, oxygen, and ultraviolet aging [8].

In recent years, studies have increasingly focused on composite additive systems formed with nanomaterials to further enhance the performance of polymer-modified bitumens. In this context, nanoclay is one of the notable nanomaterials due to its potential to improve the performance properties of both asphalt binders and asphalt mixtures [9]. It has been reported that nanoclay, when used at appropriate contents, can have positive effects on the storage stability, aging resistance, and high-temperature performance of polymer-modified bitumens [9]. In addition, the literature indicates that nanoclay can provide significant improvements in bitumen and mixture performance, particularly when used as a composite additive together with polymers [10–18].

In this study, the effect of a composite additive system consisting of POE and nanoclay on the physical properties of 50/70 penetration grade bitumen was experimentally investigated. For this purpose, modified bitumens prepared with different POE and nanoclay contents were evaluated through penetration, softening point, and penetration index tests. The obtained results were comparatively interpreted to reveal the effects of the POE/Nanoclay composite additive on the consistency, resistance to softening at elevated temperatures, and temperature susceptibility of bitumen.

2 Materials and Methods

2.1 Bitumen

In this study, neat bitumen with a 50/70 penetration grade (B 50/70), produced by Tüpraş refineries, was used as the binder material. This bitumen grade was selected because it is one of the commonly used binder types in wearing course mixtures within the scope of the Turkish Highway Technical Specification (KTŞ) and provides a suitable reference for evaluating the stiffening and stabilizing effects of POE/Nanoclay additives.

2.2 POE (Polyolefin Elastomer)

Polyolefin elastomers are elastomeric polymers obtained through the copolymerization of ethylene and an α-olefin. Depending on the ethylene-to-α-olefin ratio, structures with different molecular weights and degrees of crystallinity can be produced. Accordingly, POE exhibits properties such as high elasticity, flexibility at low temperatures, resistance to UV radiation, and good aging resistance. The absence of unsaturated double bonds in its molecular structure makes POE a more resistant alternative polymer additive to heat, oxygen, and ultraviolet aging compared with SBS.

In this study, a polyolefin elastomer commercially coded as ENGAGE™ 8003 (Dow Chemical), based on an ethylene-octene copolymer, was used. The POE used has a density of 0.885 g/cm³ and a Shore A hardness of 84. Owing to its elastomeric structure and processing characteristics, it is considered a suitable material for use with bituminous binders.

2.3 Nanoclay

In this study, a montmorillonite-based organically modified nanoclay was used. Nanoclays have nanoscale layer thickness and a high specific surface area due to their layered silicate structure, and they are widely preferred as reinforcing additives in polymer and bituminous binder systems. In montmorillonite-based nanoclays, the initial interlayer spacing is approximately 15 Å, while this distance can increase to the range of 38–40 Å after organic modification. The increase in interlayer spacing allows the nanoclay to be more homogeneously dispersed within the binder or polymer matrix.

The nanoclay used in this study is a commercial product named esanNANO 1-140, produced by Eczacıbaşı Esan. This additive, obtained by purifying and organically modifying montmorillonite mineral, has been developed particularly for polypropylene (PP)- and polyethylene (PE)-based nanocomposite applications and contains approximately 44 wt.% SiO_2 and 6 wt.% Al_2O_3. Through organic modification, the layered structure is made compatible with polymeric systems.

2.4 Preparation of Modified Bitumens

POE/Nanoclay composite-modified bitumens were prepared using the melt blending approach, which is based on dispersing the additives within the bitumen matrix through mechanical interaction rather than dissolution. For this purpose, 50/70 penetration grade bitumen was heated under controlled conditions before additive incorporation to bring it into a fluid state and enable it to act as the carrier matrix. A Silverson L5M high-shear mixer was used to ensure homogeneous dispersion of the additives within the binder. The modification process was carried out at 170 °C, at a mixing speed of 4000 rpm, for a total duration of 90 min.

In the prepared samples, the POE contents were coded as P1, P3, and P5, while the nanoclay contents were coded as N1, N2, and N3. In the coding system, “P” represents the POE additive, and “N” represents the nanoclay additive. The samples coded as P1, P1N1, P1N2, P1N3, P3, P3N1, P3N2, P3N3, P5, P5N1, P5N2, and P5N3 were evaluated.

2.5 Conventional Bitumen Tests

The consistency of the modified binders was determined using the penetration test. The test was conducted in accordance with the TS EN 1426 standard, in which the depth of penetration of a standard needle into the bitumen sample is measured at 25 °C under a load of 100 g for 5 s [19]. A higher penetration value indicates a softer bitumen consistency, whereas a lower value indicates a stiffer binder.

The change in binder consistency under temperature effects was evaluated using the softening point test. The test was performed in accordance with the TS EN 1427 standard and is based on determining the temperature at which a steel ball placed on the bitumen sample travels a specified distance in a liquid medium heated at a constant rate [20]. A higher softening point indicates that the binder has greater resistance to softening at elevated temperatures.

2.6 Temperature Sensitivity Index

The temperature susceptibility of bitumen was evaluated using the penetration index (PI), which is calculated based on the values obtained from the penetration and softening point tests. The PI value is an important parameter indicating the extent to which the binder can maintain its consistency against temperature variations. An increase in the PI value indicates lower temperature susceptibility and a more stable behavior against temperature changes. The PI value was calculated using Equation (1).

$$PI = \frac{1952 - 500 \times \log(pen) - 20 \times SP}{50 \times \log(pen) - SP - 120} \quad (1)$$

where $\log(pen)$ represents the logarithm of penetration at 25 °C and SP denotes the softening point temperature in degrees Celsius.

3 Results and Discussion

3.1 Penetration Test Results

The penetration test results of the neat and POE/Nanoclay composite-modified bitumens are presented in Figure 1. The penetration value of the neat bitumen was determined as 53.0 dmm. With the incorporation of POE and nanoclay additives, a general decrease in penetration values was observed. This indicates that the additive incorporation increased the consistency of the bitumen and transformed the binder into a stiffer structure.

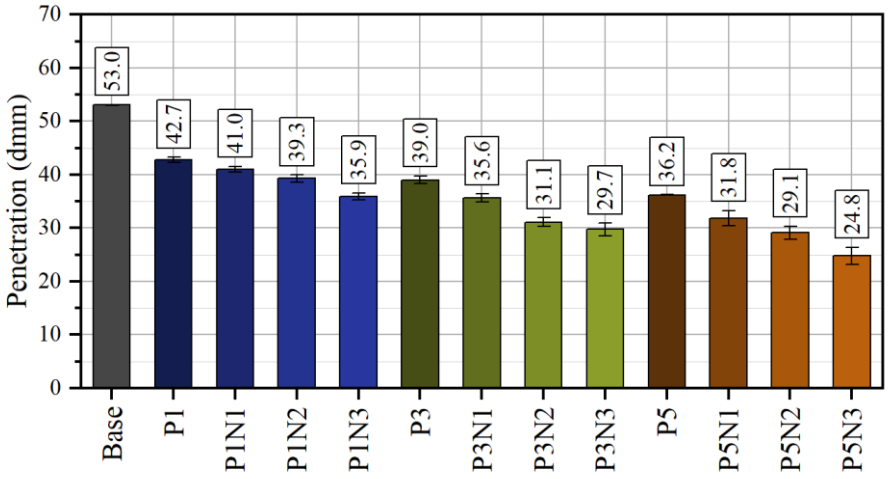

Fig. 1. Penetration test results.

In the P1 group, the penetration value was 42.7 dmm for the P1 sample and decreased to 35.9 dmm for the P1N3 sample with increasing nanoclay content. Similarly, in the P3 group, the penetration value decreased from 39.0 dmm for P3 to 29.7 dmm for P3N3. In the P5 group, the penetration value of 36.2 dmm for the P5 sample decreased to 24.8 dmm for P5N3 with the increase in nanoclay content. These results indicate that increasing both POE and nanoclay contents reduced the penetration value, with the lowest penetration obtained for the P5N3 sample, in which both additives were used at their highest dosages. Compared with the neat bitumen, the penetration value of the P5N3 sample decreased by approximately 53%, indicating that the composite system had a pronounced effect on binder consistency even when evaluated only in terms of penetration.

The reduction in penetration can be explained by two complementary mechanisms. The first is the elastomeric network structure formed by POE within the bitumen. As the polymer phase approaches a more continuous structure within the binder matrix, the resistance against needle penetration increases [8]. The second mechanism is related to the layered silicate structure and high specific surface area of nanoclay, which may promote strong interfacial interactions with bitumen components and stiffen the matrix by restricting the mobility of free-moving fractions [9]. The fact that nanoclay reduced the penetration value at each POE level indicates that this reinforcing effect was maintained within the POE network as well. Similar stiffening behavior has also been reported in the literature for nanoclay-modified binders [10–18].

From an engineering perspective, this reduction in penetration suggests that the binder may exhibit improved resistance to permanent deformation, particularly rutting, at high service temperatures. However, the increase in binder consistency may also make the binder more brittle at low temperatures and increase the risk of thermal cracking. Therefore, the decrease in penetration should not be interpreted as a solely positive indicator; the low-temperature behavior of the modified binders should also be evaluated in subsequent stages.

3.2 Softening Point Test Results

The softening point results of the neat and modified bitumens are presented in Figure 2. The softening point of the neat bitumen was determined as 50.2 °C. With the incorporation of POE and nanoclay additives, a gradual increase in softening point values was observed. This increase indicates that the modified bitumens became more resistant to softening at elevated temperatures.

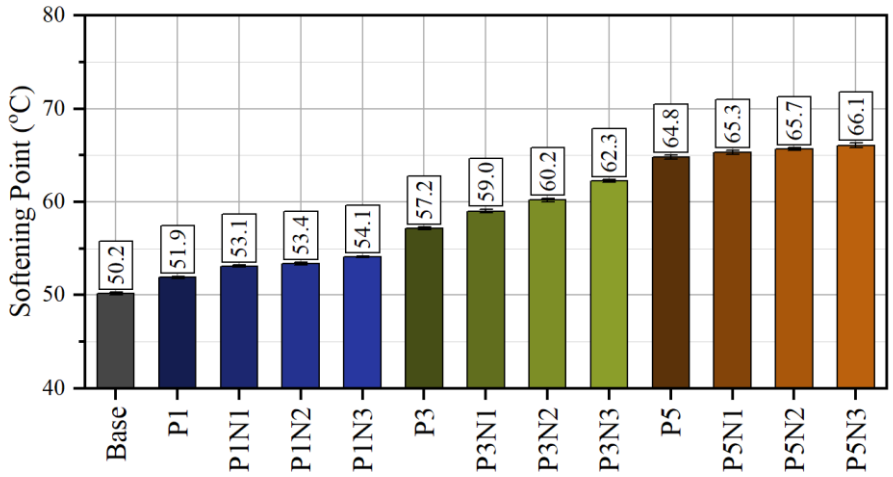

Fig. 2. Softening point test results.

In the P1 group, the softening point was 51.9 °C for the P1 sample and increased to 54.1 °C for P1N3. In the P3 group, the softening point values were obtained as 57.2 °C for P3 and 62.3 °C for P3N3. The highest values were observed in the P5 group, where the softening point increased from 64.8 °C for P5 to 66.1 °C for P5N3. Compared with the neat bitumen, the highest increase was again obtained for the P5N3 sample, with an increase of 15.9 °C.

The findings indicate that the POE content was the dominant component governing the increase in softening point. As the POE level increased from P1 to P5, the improvement in softening point became more pronounced. Nanoclay, on the other hand, played a complementary role by slightly increasing the softening point within each POE group.

However, the contribution of nanoclay remained more limited compared with that of POE; for example, in the P5 group, the increase from N1 to N3 was restricted to only a few degrees Celsius. This suggests that the dominant effect on the softening point originated from the polymer phase, while nanoclay mainly served as a supporting component.

The consistency between the penetration and softening point results indicates that the composite additive consistently improved the high-temperature performance of the binder. A higher softening point suggests the potential of the binder to limit consistency loss under hot climatic conditions and heavy traffic loading. In this respect, the POE/Nanoclay system can be considered a modification approach that enhances the thermal stability of bitumen.

3.3 Penetration Index Results

To evaluate the temperature susceptibility of bitumen in a more comprehensive manner, the penetration index (PI) values calculated from the penetration and softening point results are presented in Figure 3. The PI value of the neat bitumen was calculated as -1.07. The same PI value was also obtained for the P1 sample, while only a limited improvement was observed in the P1N1 and P1N2 samples with the addition of nanoclay. The fact that the PI values of the P1 group remained in the negative range indicates that temperature susceptibility could not be sufficiently reduced at low POE content. This suggests that the polymer network formed at this level was insufficient to balance the temperature-dependent changes in binder consistency.

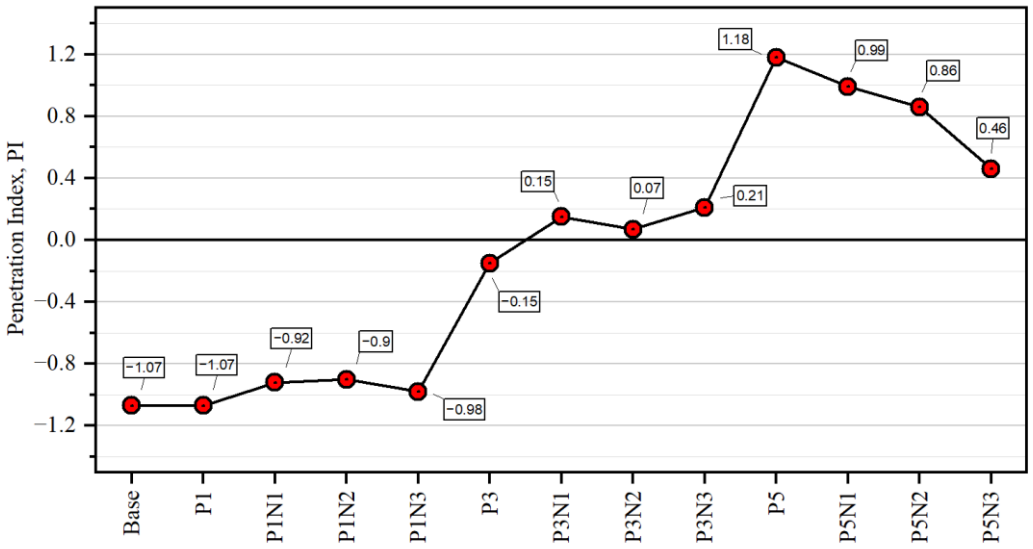

Fig. 3. PI values.

A more pronounced improvement was observed in the P3 group. While the PI value of the P3 sample was -0.15, the PI values of P3N1, P3N2, and P3N3 were calculated as 0.15, 0.07, and 0.21, respectively, shifting into the positive range. The transition of PI from negative to positive indicates that the binder can better maintain its consistency against temperature variations and exhibits a less temperature-susceptible behavior. This finding suggests that the use of POE at an intermediate content, particularly in combination with nanoclay, creates an effective threshold for reducing temperature susceptibility.

The P5 group exhibited the highest PI values. The PI value was determined as 1.18 for the P5 sample, while values of 0.99, 0.86, and 0.46 were obtained for P5N1, P5N2, and P5N3, respectively. Although this group generally showed the lowest temperature susceptibility, a

gradual decrease in PI was notably observed with increasing nanoclay content. Therefore, at high POE dosage, excessive nanoclay addition does not always provide an additional benefit in terms of temperature susceptibility, despite increasing binder stiffness. Similarly, it has been reported in the literature that excessive nanoclay dosage may increase the tendency for interlayer agglomeration, thereby limiting the expected contribution [9].

These findings emphasize the need for a multi-criteria approach in determining the optimum additive content. When the highest stiffness (lowest penetration) or the highest softening point is considered alone as a performance indicator, the composition providing the most balanced behavior in terms of temperature susceptibility may be overlooked. When the three parameters are evaluated together, the most balanced behavior between temperature stability and stiffness improvement appears to be achieved in the P3 group, particularly in the compositions where POE was used together with nanoclay. Although the P5 group provided the lowest temperature susceptibility, it should be further examined in terms of low-temperature performance due to its high stiffness level.

4 Conclusions

In this study, the effect of the POE/Nanoclay composite additive on the physical properties of 50/70 penetration grade bitumen was evaluated through penetration, softening point, and penetration index tests. The modified binders prepared with different POE and nanoclay contents were comparatively examined with the neat bitumen, and the main findings are summarized below:

- The combined use of POE and nanoclay additives caused a significant decrease in penetration values. The penetration value of the neat bitumen, which was 53.0 dmm, gradually decreased with increasing additive content, and the lowest value was obtained as 24.8 dmm for the P5N3 sample. This decrease indicates that the composite additive increased the consistency of the bitumen and transformed the binder into a stiffer structure. The decrease in penetration with increasing nanoclay content in each POE group demonstrates that nanoclay produced a stiffening and structure-reinforcing effect within the composite system.
- The softening point results supported the penetration findings. The softening point of the neat bitumen, which was 50.2 °C, increased steadily with additive incorporation and reached 66.1 °C for the P5N3 sample. This increase indicates that the modified binders softened at higher temperatures compared with the neat bitumen. It was determined that the POE content was the dominant component governing the increase in softening point, while nanoclay played a complementary role.
- The penetration index results more clearly revealed the effect of the composite additive on temperature susceptibility. In the P1 group, the PI values remained in the negative range, indicating that temperature susceptibility could not be sufficiently reduced at this additive level. In contrast, in the P3 group, particularly with the addition of nanoclay, the PI values shifted into the positive range, showing that this level provided a more balanced binder behavior against temperature variations. The P5 group exhibited the highest PI values and, therefore, the lowest temperature susceptibility.
- However, in the P5 group, a gradual decrease in PI values was observed with increasing nanoclay content. This finding indicates that increasing nanoclay content at a high POE level does not always produce a more favorable result and that the optimum additive content should not be determined solely based on the highest stiffness or the highest softening point. Therefore, penetration, softening point, and penetration index results should be considered together when evaluating additive contents.

Overall, the POE/Nanoclay composite additive improved the physical stability of bitumen, increased its stiffness, and enhanced its resistance to softening at elevated temperatures. The results obtained especially in the P3 and P5 groups indicate that composite modification is effective in reducing temperature susceptibility. However, physical test results alone are not sufficient to determine the optimum modification content. In future studies, aging resistance, storage stability, rheological properties, and asphalt mixture performance should be evaluated together. In this context, it was concluded that the POE/Nanoclay composite additive is a usable and promising additive system for bitumen modification.

Abstract. Closely spaced signalized intersections are characterized by strong operational interactions that may lead to queue spillbacks, increased delays, and reduced capacity. Despite the importance of driver behavior in intersection performance, limited attention has been given to start response times in such systems. This study examines driver start response times and queue discharge headways at closely spaced signalized intersections located on an urban arterial in İzmir, Türkiye. Approximately 14 hours of video recordings were analyzed to obtain start response times, traffic volumes, vehicle compositions, cycle lengths, and queue characteristics. A total of 3173 start response time observations were extracted. Statistical analyses were conducted to compare upstream and downstream intersections, evaluate distributional characteristics, and quantify influencing factors. Lane-based t-tests revealed statistically significant differences between upstream and downstream intersections at the 95% confidence level for all lane groups, with downstream drivers exhibiting longer start response times. Distribution fitting results showed that start response times are positively skewed and are best represented by Lognormal distributions in most cases, while Gamma and Weibull distributions provided acceptable fits for selected lane groups. These findings indicate that start response time should be treated as a stochastic variable in capacity analysis and microscopic traffic simulation. Multiple regression analysis further demonstrated that vehicle type, signal location, traffic period, and lane type significantly influence driver start response time. In particular, downstream location and heavy vehicles were associated with increased response times. The findings contribute practical implications for signal coordination, capacity estimation, and simulation modeling of closely spaced signalized intersections.

Keywords: closely spaced intersections; start response time; queue discharge headway; driver behavior.

1 Introduction

Closely spaced intersections are defined as signalized intersections located close to another one such that they may mutually influence traffic operations. These intersections may operate either under a single signal control system utilizing offset timing within the same cycle length or under different signal [1]. In such systems, the short distance between intersections, low travel speeds, and vehicle interactions contribute significantly to increase delays. In addition, queues formed between adjacent intersections may restrict minor street traffic movements, while vehicles entering between upstream and downstream signals from minor approaches may block the progression of major traffic streams [2]. Therefore, coordinated signal control systems should be properly designed to minimize excessive stop-and-go movements and delays while

maximizing uninterrupted vehicle movement through closely-spaced intersections [3]. Recent studies have emphasized that queue spillbacks and downstream congestion can significantly affect the performance of coordinated arterial systems and may reduce the effectiveness of conventional signal timing strategies [4].

The capacity and operational performance of signalized intersections largely depend on driver's behavior. Previous studies have demonstrated that the most critical driver-related parameters at signalized intersections are start-up lost time and saturation headway [5]. Both parameters are directly influenced by the start response time of the leading drivers within a queue [6]. Although these parameters have been extensively investigated for isolated intersections, studies focusing on closely spaced intersections remain limited.

Within the scope of this study, driver start response times and queue discharge headways at closely spaced signalized intersections located on an urban arterial in İzmir, Türkiye, were investigated. Approximately 14 hours of video recordings were analyzed to obtain start response times, queue discharge headways, traffic volumes, vehicle compositions, cycle lengths, and queue lengths. Statistical analyses were conducted to examine differences between upstream and downstream intersections and to evaluate the effects of vehicle type, traffic conditions, and lane characteristics on driver behavior. The findings are expected to contribute to capacity analysis, microscopic traffic simulation, and signal optimization applications for closely spaced signalized intersections.

2 Study Area and Data Collection

2.1 Study Area

This study was conducted on a closely spaced signalized intersection system located in Karabağlar, İzmir, Türkiye. The study area consists of two adjacent signalized intersections operating under coordinated traffic control. The intersections are located on a major urban arterial characterized by high traffic demand and heterogeneous traffic composition. Fig. 1 presents the closely spaced intersection system, where the upstream intersection (K1) and downstream intersection (K2) are indicated. The distance between the stop lines of the upstream and downstream intersections is approximately 50 m, resulting in strong operational interactions between the two signalized junctions.

Fig. 1. Study area of closely spaced signalized intersection system in Karabağlar, İzmir, Türkiye.

The study site was selected due to its high traffic demand and representative urban corridor characteristics. The selected configuration represents a typical closely-spaced intersection system where upstream and downstream signals may interact through queue formation and spillback effects. Detailed geometric and operational characteristics of the study intersections are provided in Table 1.

Table 1 Geometric and operational characteristics of study K1 and K2 intersections.

Intersection	Approach	Volume (veh/h/lane)	Lane Movement	Cycle Length (s)
K1 (Upstream)	Left	1353	Through (TR)	85
	Through	1185	TR	85
	Right	1124	TR / Right-turn (RT)	85
K2 (Downstream)	Left	1342	TR	85
	Through	1132	TR	85
	Right	859	TR / RT	85

2.2 Data Collection Procedure

Traffic data was collected using fixed-positioned video camera recordings under dry weather conditions and during typical weekday traffic operations [7]. A total of approximately 14 hours of continuous video data were recorded, covering morning, midday, and evening peak periods.

The study area consists of two closely spaced signalized intersections, and data were collected from both upstream and downstream approaches. A total of 17 video segments were analyzed, each with an average duration of approximately 53 minutes, ensuring a balanced temporal distribution across different traffic states.

From the recorded videos, the following traffic parameters were extracted for subsequent analysis: driver start response times, queue discharge headways, traffic volumes with turning movement (left, through, right), vehicle composition, signal cycle lengths, phase structures, and queue lengths at each approach. In total, start response time observations were obtained from the analyzed video data, enabling a detailed lane-based and intersection-level evaluation of driver behavior under closely-spaced intersection conditions.

2.3 Data Extraction Process

Microscopic traffic variables were extracted using a frame-by-frame analysis of video recordings. Vehicle movements and signal phase transitions were manually identified, and the occurrence time of each event was determined from the video data. These measurements enabled the derivation of time-dependent traffic parameters, including start response time and vehicle headways, which were subsequently used in the saturation flow analysis [5].

The start response time was defined as the time interval between the onset of the effective green indication and the initiation of movement of the first queued vehicle [5]. Similarly, queue discharge headway was defined as the time difference between successive departing vehicles within the same queue [8].

Although minor measurement errors can be observed in video-based traffic studies, special attention was given to the extraction of traffic variables from the recordings. The collected data were carefully reviewed and cross-checked during the analysis process to improve accuracy and minimize potential observational biases [9].

3 Methodology

The study follows a multi-stage analytical framework. The methodology begins with data preparation, where the dataset is classified according to intersection location (upstream and downstream) and lane type (left, through, right). This classification allows the examination of

driver behavior under different spatial and operational conditions within the closely spaced intersection system.

In the second stage, descriptive statistical analysis and probability distribution fitting are conducted to characterize the statistical properties of driver start response times and queue discharge headways. Common probability distributions, including Lognormal, Gamma, Weibull, and Exponential distributions, are evaluated. The best-fitting distribution for each dataset is selected based on goodness-of-fit measures, including the Kolmogorov-Smirnov, Anderson-Darling, and Chi-square tests.

The third stage involves statistical analysis to examine differences between upstream and downstream intersections across lane groups. Independent samples t-tests are conducted under a 95% confidence level to determine whether statistically significant differences exist between mean start response times.

In the final stage, multiple linear regression analysis is performed to quantify the effects of traffic-related and operational variables on driver start response time. The dependent variable is start response time, while explanatory variables include vehicle type, traffic period (peak/off-peak), lane type, and intersection location. The model is used to quantify behavioral differences and their impact on intersection performance.

3.1 Statistical Analysis

Descriptive statistical analyses were first performed to summarize the characteristics of the collected start response time and queue discharge headway data. Mean, standard deviation, minimum, maximum, skewness, and kurtosis values were calculated to examine the central tendency, variability, and distributional properties of the observations.

3.2 Distribution Fitting

Probability distribution fitting is conducted using EasyFit software to identify distributions that best represent driver start response times [10]. Candidate distributions include Lognormal, Gamma, Weibull, and Exponential distributions. Goodness-of-fit evaluation is performed using Kolmogorov-Smirnov, Anderson-Darling, and Chi-square tests, and the best-fitting distribution is selected based on combined statistical performance.

3.3 Hypothesis Testing

t-tests are conducted to examine whether statistically significant differences exist between upstream and downstream intersections using SPSS software. The analyses are performed separately for left, through, and right lanes. The null hypothesis assumes no difference in mean start response times between intersection locations, while the alternative hypothesis assumes a statistically significant difference at the 95% confidence level.

3.4 Multiple Regression Analysis

Multiple linear regression analysis was employed to evaluate the effects of several explanatory variables on driver start response time. The dependent variable is start response time, while vehicle type, signal location, peak-period category, and lane type were considered as independent variables. The regression model was used to quantify the relative contribution of each factor and to identify the variables significantly influencing driver behavior.

4 Results and Discussion

Within the scope of this study, driver start response times and queue discharge headways at closely-spaced signalized intersections located on an urban arterial in the city center of İzmir, Türkiye, were investigated, and the effects of these parameters on intersection performance were examined. Interactions between upstream and downstream intersections in closely-spaced

systems may result in significant operational consequences, particularly in terms of queue spillbacks, delays, and capacity reductions.

4.1 Queue Discharge Headway

Left-turn lanes generally exhibited shorter discharge headways than through and right-turn lanes. As presented in Table 2, the mean queue discharge headways ranged from 2.30 s to 3.28 s. These findings are consistent with the ranges reported by Jin, et al. [11] and Çalişkanelli and Tanyel [5]. These differences may be attributed to lane-specific saturation behavior and varying driver aggressiveness across turning movements.

Table 2 Mean queue discharge headways by lane and intersection.

Lane	Signal 1 Mean (s)	Signal 2 Mean (s)
Left	2.46	2.30
Through	2.76	2.58
Right	3.15	3.28

4.2 Descriptive Statistics of Start Response Times

The findings indicated that drivers at the downstream signal exhibited longer start response times compared with drivers at the upstream signal. Mean response times ranged between 0.99 s and 1.26 s which can be seen in Table 3. All distributions exhibited positive skewness, indicating that most drivers respond quickly after green onset, while a smaller portion exhibits delayed reactions. The peaks of the distributions correspond to the modal values, indicating the most frequently observed start response times.

Table 3 Descriptive statistics of start response times.

Lane	N	Mean	Std. Dev.	Skewness	Kurtosis	Peak
Left 1	601	1.04	0.50	2.48	10.10	0.80
Left 2	392	1.11	0.47	1.41	2.54	0.82
Through 1	604	0.99	0.40	1.36	2.08	0.95
Through 2	496	1.19	0.57	2.58	12.98	0.90
Right 1	602	0.99	0.44	1.88	5.86	0.82
Right 2	478	1.26	0.55	1.79	5.99	0.98

Based on the results of the t-test conducted to examine differences between groups, statistically significant differences were identified between the two groups (K1 and K2) for each lane type. Therefore, the data from the two signals were analyzed separately. Subsequently, the observations were grouped according to peak periods (morning, midday, and evening), and probability density functions were re-established for each peak period.

4.3 Comparison of Upstream and Downstream Intersections

t-test results confirm statistically significant differences between upstream and downstream intersections for all lane groups at the 95% confidence level (Table 4). Downstream intersections consistently show higher start response times, indicating delayed driver reactions under downstream operational conditions.

These differences may be explained by residual queue effects and upstream platoon dispersion, which increase driver hesitation at downstream intersections.

The presence of two local peaks in the response time distribution which can be seen in Fig. 2 suggests the possibility of heterogeneous driver response behavior. Fig. 2a presents the probability density function (PDF) distributions of start response times, and Fig. 2b, Fig. 2c, and Fig. 2d illustrate the distribution of start response times for the left-turn, through, and right-

turn lanes, respectively. This bimodal tendency may be associated with differences in driver attentiveness, vehicle type, traffic demand conditions, or operational interactions between the upstream and downstream intersections. In closely-spaced signalized systems, residual queue effects and platoon progression may contribute to the formation of distinct response patterns.

Table 4 Lane-based t-test results.

Lane	Mean K1	Mean K2	t-statistic	p-value
Left	1.04	1.11	-2.08	0.038
Through	1.01	1.19	-6.03	<0.001
Right	1.04	1.26	-6.71	<0.001

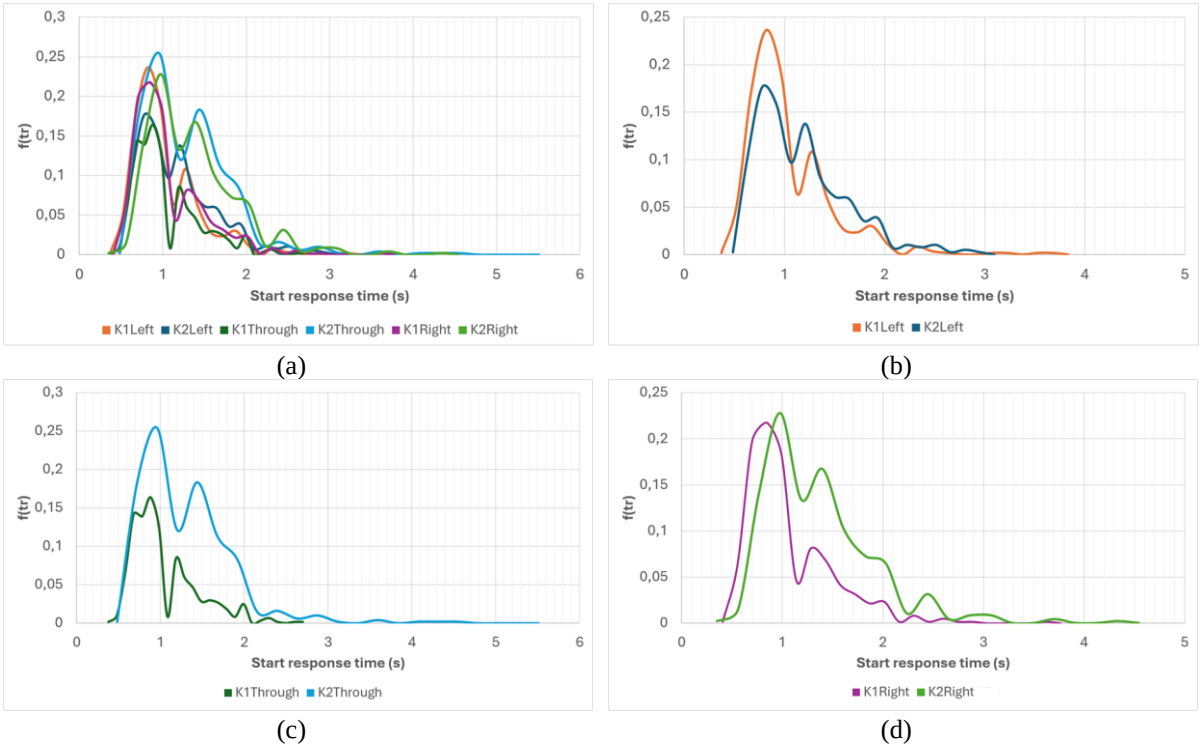

Fig. 2 Probability density functions of start response times for (a) all lane groups, (b) left lane groups, (c) through lane groups, and (d) right lane groups.

As shown in Fig. 3, the probability density functions of start response times vary across peak periods and lane groups. The distributions are presented separately for the K1 and K2 intersections for the left-turn, through, and right-turn movements. The secondary peak becomes more pronounced during the evening peak period, suggesting the presence of heterogeneous driver response behavior under higher traffic demand and more complex operational conditions.

4.4 Distribution Characteristics

Start response time data were found right-skewed. In most lane groups, the Lognormal distribution provided the best fit, while Gamma and Weibull distributions were more suitable for selected cases. These results suggest that driver response behavior is not adequately represented by a normal distribution and is better characterized by asymmetric probability distributions. Table 5 presents the best-fitting distributions obtained for each lane group.

The identification of suitable probability distributions is important because start response times directly affect queue discharge processes and intersection capacity. The results indicate that driver response behavior is generally stochastic and cannot be adequately represented by a

single deterministic value. Therefore, incorporating probabilistic representations of start response times may improve the realism of capacity analyses and microscopic traffic simulation models for closely-spaced signalized intersections.

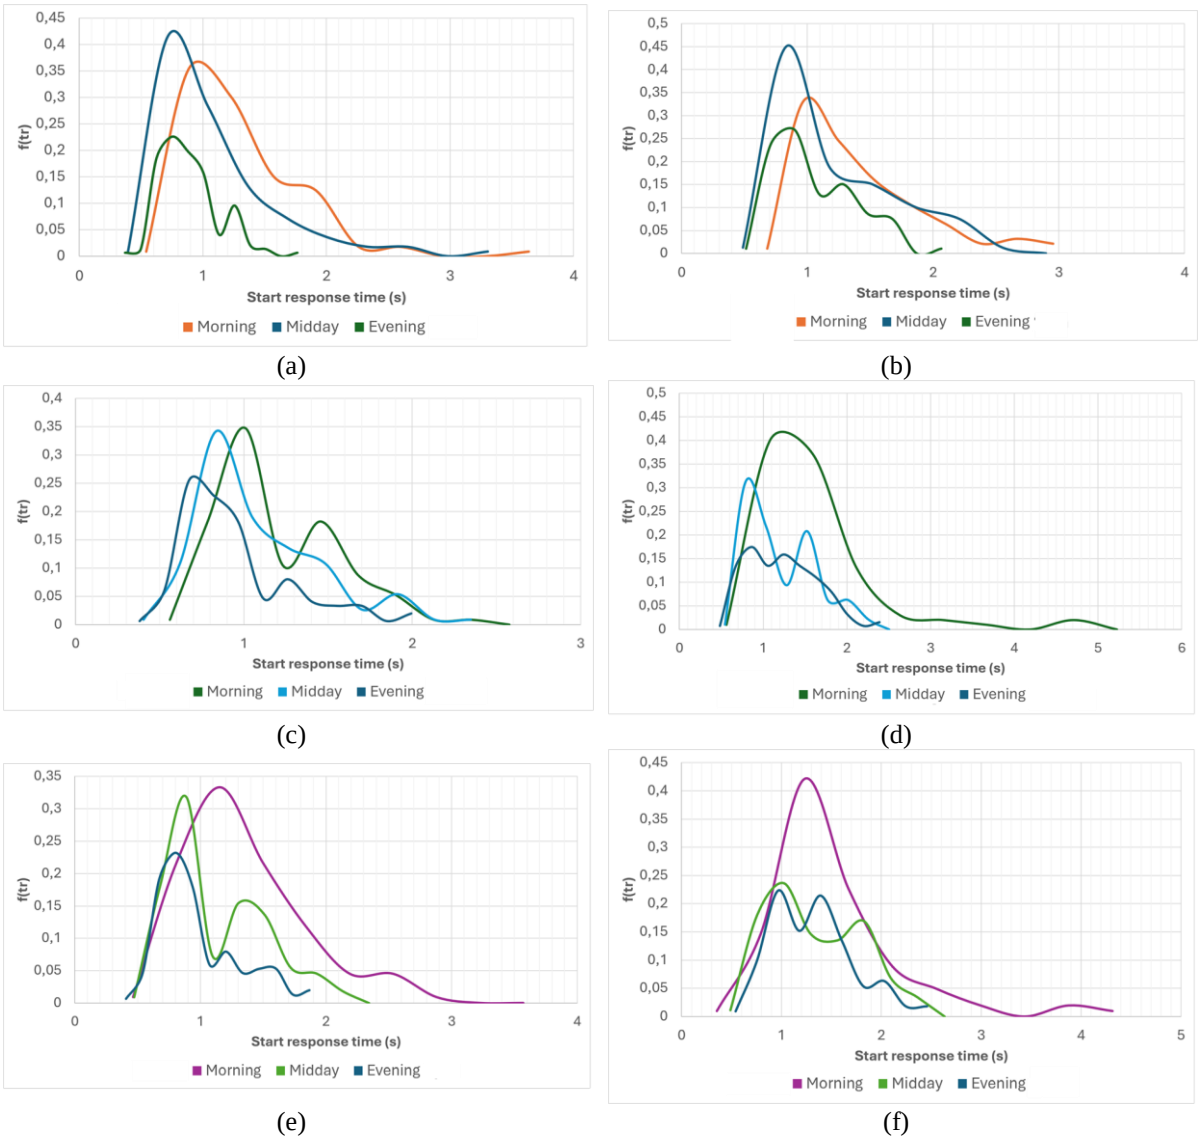

Fig. 3 Probability density functions of start response times during different peak period for (a) K1 left lane group, (b) K2 left lane groups, (c) K1 through lane groups, (d) K2 through lane groups, (e) K1 right lane groups and (f) K2 right lane groups.

Table 5 Best-fitting distributions.

Lane Group	**Best-fitting distribution**
Left 1	Lognormal
Left 2	Gamma
Through 1	Lognormal
Through 2	Weibull
Right 1	Lognormal
Right 2	Lognormal

4.5 Regression Model Results

Previous studies have shown that driver start response time may be affected by both behavioral and operational factors. While Akçelik, et al. [12] treated start response time as a constant parameter, Çalişkanelli and Tanyel [5] demonstrated that factors such as turning movement, driver characteristics, lane geometry, and signal timing may significantly influence driver response behavior. Therefore, multiple regression analysis was employed to investigate the effects of vehicle type, signal location, traffic period, and lane type on start response time. Table 6 presents the descriptive statistics of the variables included in the regression analysis.

Multiple linear regression analysis was conducted to quantify the effects of explanatory variables on start response time. The model is statistically significant, and all included variables were found to be significant predictors ($p < 0.05$).

Table 6 Descriptive statistics of variables used in the regression model.

Variable	**Mean**	**Std. Dev.**
Start response time (t_r) (s)	1.108	0.524
Vehicle type (VT)	1.42	0.875
Signal location (SL)	1.54	0.498
Traffic period (TP)	2.06	0.836
Lane type (LC)	1.79	0.730

Table 7 presents the regression coefficients. Vehicle type, signal location, traffic period, and lane type were all found to be statistically significant predictors of start response time ($p < 0.05$). The independent variables considered in the regression analysis were vehicle type (VT), signal location (SL), traffic period (TP), and lane category (LC). Vehicle type was coded as passenger car = 1, bus = 2, minibus = 3, and truck = 4. Traffic period was coded as morning peak = 1, midday peak = 2, and evening peak = 3, while lane category was coded as left = 1, through = 2, and right = 3. Signal location was used as upstream = 1, and downstream = 2.

Table 7 Multiple regression results.

Variable	**Coefficient**	**p-value**
Vehicle Type	0.065	<0.001
Signal Location	0.178	<0.001
Traffic Period	-0.113	<0.001
Lane Category	0.037	0.046

The estimated regression model is given in Equation (1).

$$t_r = 0.909 + 0.065VT + 0.178SL - 0.113TP + 0.037LC \quad (1)$$

Signal location emerges as the most influential variable, indicating that downstream intersections are associated with systematically higher response times. This may be attributed to cumulative queuing effects and reduced driver expectation consistency in downstream operations. Vehicle type also significantly affects response behavior, with heavy vehicles exhibiting longer reaction times due to increased inertia and lower acceleration capability. Lane category and traffic period show comparatively smaller but still statistically significant effects.

Traffic period exhibits a negative coefficient, suggesting that response times slightly decrease during later peak periods, possibly due to increased driver familiarity and adaptation under congested conditions. Although categorical variables were encoded numerically, sensitivity checks confirm that model stability remains acceptable and multicollinearity effects are not dominant.

4.6 Implications of Start Response Time Variability in Closely-Spaced Signalized Intersections

The findings indicate that downstream intersections consistently exhibit longer start response times, with log-normal distributions best representing driver behavior in most cases. Vehicle type, lane configuration, and traffic period significantly influenced driver response characteristics. These results suggest that start response time should not be treated as a constant parameter in capacity and simulation models, particularly for closely spaced signalized intersections. Instead, it should be modeled as a stochastic and context-dependent variable influenced by traffic composition and spatial signal interactions.

5 Conclusion

Start response time and headway observations were analyzed from a closely spaced signalized intersection system in İzmir, Türkiye, covering different vehicle types and traffic conditions across upstream and downstream locations. The descriptive statistics indicated that drivers at the downstream intersection generally exhibited longer start response times than those at the upstream intersection. This finding suggests that operational interactions between adjacent signalized intersections may influence driver response behavior.

Distribution analyses showed that all start response time datasets were positively skewed. Most datasets were adequately represented by lognormal distributions, while Gamma and Weibull distributions provided satisfactory fits for selected lane groups. These results indicate that start response times should be treated as stochastic variables rather than fixed values in capacity analysis and traffic simulation applications. Therefore, fixed-value assumptions may not fully capture driver start-up behavior in capacity and simulation models.

To investigate differences between the two signal locations, lane-based hypothesis tests were conducted. The results demonstrated statistically significant differences between the upstream and downstream intersections at the 95% confidence level for all analyzed lane groups. This finding supports the hypothesis that closely-spaced signalized intersections may generate distinct driver response characteristics depending on their position within the coordinated intersection system.

Regression results indicated that start response times were influenced by vehicle type, signal location, traffic period, and lane category. Overall, the findings highlight the importance of considering driver response variability when analyzing and coordinating closely-spaced signalized intersections. The results may contribute to more realistic capacity estimation, traffic simulation, and signal timing applications.

These findings demonstrate that start response time is influenced by intersection location within a closely spaced signalized system and can be treated as a stochastic parameter in capacity analysis, traffic simulation, and signal timing applications. Future studies may investigate the effects of additional traffic, geometric, and behavioral factors using more advanced data-driven modeling approaches.

ABSTRACT

This study investigates university students' travel mode choices and their associations with socio-demographic characteristics, infrastructure conditions, and built-environment perceptions within the context of sustainable urban mobility. Primary data collected through an online survey of 1,087 students from seven universities representing different urban scales in Türkiye were analyzed using a multinomial logit (MNL) model in RStudio. Travel mode was classified into three categories: active transport, public transport, and private vehicle, with private vehicle serving as the reference category. The model results indicate that residing in a dormitory, having access to a personal micromobility vehicle, and holding a public transport subscription are positively associated with the relative likelihood of choosing active or public transport over a private vehicle. Conversely, car availability, higher income, holding a driving license, and residing with family are associated with a greater relative preference for private vehicle use. More favorable perceptions of pedestrian path quality, sidewalk conditions, ramp availability, and route safety are positively associated with active transport choice relative to private vehicle use. Unexpectedly, bicycle infrastructure quality was negatively associated with the relative likelihood of choosing active and public transport over private vehicles. This counterintuitive relationship warrants further investigation and should be interpreted cautiously.

Keywords: University students; Travel mode choice; Pedestrian and bicycle infrastructure; Sustainable transport, Multinomial logit.

1 Introduction

Rapid urbanization, increasing population density, and rising motor vehicle ownership contribute to serious environmental and socio-economic problems in urban areas, such as traffic congestion, air pollution, noise, and greenhouse gas emissions [1]. To reduce these negative externalities and improve urban quality of life, reducing dependence on private vehicles has become a fundamental objective of urban transportation policies [2]. Within

sustainable urban mobility policies, promoting shifts from private car use toward public transport, active modes such as walking and cycling, and emerging micromobility options such as e-scooters and e-bikes has become increasingly important [1], [3]. In particular, using sustainable modes for first- and last-mile trips can improve the accessibility, inclusivity, and efficiency of public transportation systems [3], [4].

Individuals' choices among sustainable transport alternatives depend not only on physical accessibility and travel distance but also on their perceptions of the built environment and available infrastructure [2], [5]. Research in the literature indicates that the quality of pedestrian paths, the presence of standardized sidewalks, ramp accessibility, and the general sense of route safety (perceived safety) have been identified as important factors associated with travel mode choice [5], [6]. Inadequate infrastructure, high levels of motorized traffic, and routes perceived as unsafe may discourage active travel and increase the attractiveness of motorized alternatives [7].

In this process, university students and young adults constitute an important user group of urban transportation networks and micromobility systems due to their vehicle ownership constraints, financial status, propensity for technological innovations, and campus-oriented travel patterns [1], [8]. Students' residential status, access to personal micromobility vehicles, and transit pass ownership have been found to be associated with their travel behavior [1], [9]. Conversely, dissatisfaction with infrastructure and safety concerns may reduce the attractiveness of active transport among current users [7].

This study examines university students' choices among active transport, public transport, and private vehicles and investigates their associations with socio-demographic, travel-related, infrastructural, and perceptual characteristics. Survey data were collected from 1,087 students enrolled at seven universities located in cities of different urban scales in Türkiye: Yildiz Technical University in Istanbul; Eskişehir Osmangazi University, Anadolu University, and Eskişehir Technical University in Eskişehir; Dumlupınar University and the University of Health Sciences in Kütahya; and Bayburt University in Bayburt. A multinomial logit (MNL) model was estimated in RStudio to examine factors associated with the three-category travel mode outcome [10]. By jointly considering individual and travel characteristics together with built-environment and infrastructure perceptions, the study seeks to provide evidence that can support targeted policies aimed at promoting sustainable travel choices in both campus and urban transportation planning.

2 Literature Review

In the transportation planning literature, sustainable urban mobility is commonly understood as the outcome of interactions between the objective characteristics of the built environment and travelers' subjective perceptions of those characteristics [2]. To clarify how these interactions are associated with travel behavior, the following sections review evidence on built-environment perceptions, pedestrian–micromobility interactions, and the travel behavior of university students.

2.1 Sustainable Transportation and Built Environment Perception

Individuals' decisions to use active transport modes are closely associated with how they perceive the opportunities and constraints of the surrounding built environment [2], [3], [11].While active transport modes such as walking and cycling are promoted in the literature as environmentally friendly, economical, and healthy options, whereas private vehicles and

public transport are generally considered motorized or non-active modes [2], [3], [11]. As travel distance increases, active transport generally becomes less attractive, whereas public transport and other motorized alternatives tend to become more competitive [9]. Built-environment characteristics such as population density, land-use mix, and street design can influence the use and integration of active transport and public transport [2]. Mixed land use is generally associated with shorter travel distances and improved accessibility, which can facilitate the use of sustainable transport modes [2]. However, the presence of physical infrastructure alone is not sufficient; perceptions of sidewalk quality, ramp accessibility, and pedestrian infrastructure have also been positively associated with active transport use [2], [3]. In contrast, unplanned neighborhood development, non-standard narrow sidewalks, and infrastructural deficiencies may discourage active transport use [2], [3], [6].

2.2 Pedestrian and Micromobility Interactions

Recent research suggests that perceived safety can be as important as, and in some contexts more influential than, objective crash risk in shaping travel behavior and mode choice Perceived safety, which differs from objective accident statistics, expresses an individual's level of concern about being involved in an accident or getting injured [3], [5]. Particularly in micromobility modes, perceived safety and comfort are directly linked; perceived safety and comfort are closely related and can jointly influence route and mode choice [5] The additional travel distance or time that travelers are willing to accept to avoid unsafe routes and use safer infrastructure is measured by the concept of "Value of Safety" (VoS) Research conducted within this scope shows that while e-bike users are highly willing to extend their travel times for a safer route, e-scooter users may be less willing to accept route extensions and may instead avoid the mode when routes are perceived as unsafe [3]. The proliferation of micromobility vehicles such as e-scooters and e-bikes in urban areas has given rise to new safety and comfort dynamics between pedestrians and these vehicle riders on sidewalks or shared spaces [3], [5]. When examining pedestrian perceptions and behavioral responses regarding the use of shared spaces, pedestrians' sense of safety in these interactions is directly dependent on the speed of the approaching vehicle and the lateral clearance left to the pedestrian [5]. Experiments conducted in a virtual reality environment show that when the micromobility vehicle speed is 10 km/h or less, and a lateral clearance of at least 0.86 m for e-scooters and 1.11 m for bicycles is maintained, high reported levels of comfort and perceived safety (≥99%) [5]. Based on the experimental conditions examined in that study, net sidewalk widths of approximately 2.00 m and 2.30 m, respectively, were suggested for maintaining comfortable interactions [5]. Finally, although shared spaces offer a middle ground that reduces differences in individuals' safety perceptions, it has been found that heavy e-scooter use in mixed traffic decreases pedestrians' subjective safety perception [3].

2.3 University Students' Travel Behaviors and Mode Shift Risk

University students represent a population with considerable potential for sustainable transport use because of their age profile and socio-demographic characteristics. However, infrastructure dissatisfaction may reduce their willingness to continue using active transport modes [3], [9]. Studies conducted to explain these dynamics and behavioral patterns show that socio-demographic characteristics and built environment factors have been found to be significantly associated with individual travel mode choices [2], [9]. When socio-demographic variables are examined: as age increases, students tend to steer toward active transport, while female students, individuals with high-income levels, those with a driving license, automobile or motorcycle ownership, and students living with their families show a

significantly lower propensity to prefer active transport and public transport options [1]. In contrast, students residing in dormitories, having access to personal micromobility vehicles, or holding public transport passes have been found to exhibit a greater propensity to use sustainable modes [1], [8]. As travel distance increases, the likelihood of choosing active transport generally decreases, while some studies have reported no statistically significant association between regional density and travel mode choice. [8] When pedestrian and bicycle infrastructure variables are considered, perceived pedestrian path quality, sidewalk availability, ramp accessibility, and route safety have been positively associated with active transport use [4], [5]. Previous studies also suggest that cyclists' evaluations of infrastructure conditions may be related to their travel behavior, particularly where discontinuous facilities, poor road conditions, or safety concerns reduce the attractiveness of cycling [1], [6]. Such dissatisfaction may discourage continued use of active modes and increase the relative attractiveness of more comfortable or protected motorized alternatives [6]. Therefore, campus and urban transportation planning should prioritize improvements in the continuity, quality, and safety of pedestrian and bicycle infrastructure to support the retention of active transport users and reduce the potential for shifts toward motorized modes [4], [7].

3 Data Description and Methodology

3.1 Study Area and Data Collection Process

Data were collected through an online survey of students from seven universities located in cities with different urban scales and infrastructural characteristics in Türkiye (Fig. 1). Within the scope of the study, Yildiz Technical University (Istanbul), Eskişehir Osmangazi University, Anadolu University, Eskişehir Technical University (Eskişehir), Dumlupınar University, University of Health Sciences (Kütahya), and Bayburt University were selected as the study sites.

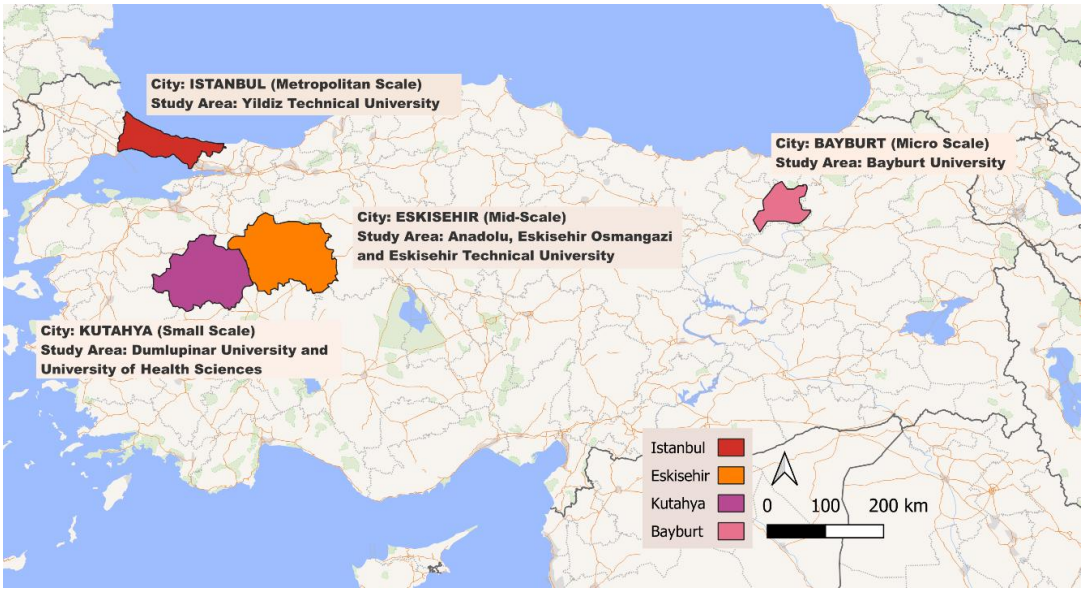

Fig. 1. Geographical distribution and urban scale classification of the seven surveyed universities in Türkiye.

The final analytical sample consisted of 1,087 students enrolled at these universities. The survey collected information on students' socio-demographic characteristics, daily campus

travel and vehicle-access characteristics, and perceptions of pedestrian and bicycle infrastructure and route safety.

Definitions and descriptive statistics of the variables used in the study are presented in Table 1. As the dependent variable, a three-category transportation mode choice was used (active transport, public transport, and private vehicle as the reference category). The independent variables consist of socio-demographic characteristics, transportation characteristics, and perceptual environmental variables.

Table 1. Variable definitions and descriptive statistics

Variable	Mean / Freq.	Type	Description
Dependent Variable			
Mode Choice		**Categorical**	Transportation mode chosen by the traveler.
Active transport	20.06%		Active transport (walking/cycling) is chosen.
Public transport	71.76%		Public transport is chosen.
Private vehicle	8.19%		Private vehicle is chosen (Reference category).
Independent Variables			
Density	1485.32	Numerical	Population or built environment density (×100 persons km^2).
Age	21.04	Numerical	Age of the traveler.
Female	50.69%	Dummy	1 if female, 0 if male.
Income	10.60	Numerical	Monthly income of the traveler (×1000 TL).
Resides with family	38.18%	Dummy	1 if the traveler resides with their family, 0 otherwise.
Resides in dormitory	24.56%	Dummy	1 if the traveler resides in a dormitory, 0 otherwise.
Driving license	54.37%	Dummy	1 if the traveler holds a driving license, 0 otherwise.
Car availability	12.88%	Dummy	1 if the traveler has access to / onws a car, 0 otherwise.
Micromobility availability	11.96%	Dummy	1 if the traveler has access to /owns a micromobility vehicle (e.g. e-scooter), 0 otherwise.
Motorbike availability	3.68%	Dummy	1 if the traveler has access to / owns a motorbike, 0 otherwise.
Travel distance	10.10	Numerical	Travel distance for the trip (km).
Public transport subscription	62.28%	Dummy	1 if the traveler holds a public transport subscription/pass, 0 otherwise.
Bicycle infrastructure quality	3.32	Ordinal	Perception of bicycle infrastructure quality (Likert scale 1-5).
Pedestrian path quality	3.78	Ordinal	Perception of pedestrian path quality (Likert scale 1-5).
Sidewalk quality	3.58	Ordinal	Perception of sidewalk availability and quality (Likert scale 1-5).
Ramp availability	3.14	Ordinal	Perception of ramp availability (Likert scale 1-5).
Safety perception	3.40	Ordinal	Perceived safety level of the route (Likert scale 1-5).

Note: All perception variables were measured on a five-point Likert scale (1 = very poor, 2 = poor, 3 = moderate, 4 = good, and 5 = very good) and were treated as continuous variables in the MNL model.

3.2 Multinomial Logit (MNL) Modeling

In this study, an MNL model was utilized to determine the factors affecting university students' transportation mode choices. The multinomial logit model is widely used to model discrete outcomes with more than two unordered alternatives and is grounded in random utility maximization theory [8], [10].

The MNL model is formulated within a linear utility function framework along with observable attributes and individual-specific characteristics. The systematic utility associated with alternative *j* for individual *i* can be expressed as: [8], [10]:

$$V_{ij} = \beta_{j0} + \Sigma_k \beta_{jk} \cdot x_{ijk} \quad (1)$$

where β_{j0} represents the alternative-specific constant for mode *j*, β_{jk} represents the alternative-specific parameters for mode *j* in the dataset with k explanatory variables, and x_{ijk} represents the vector of explanatory variables. The probability P_{ij} of individual *i* choosing mode *j* is expressed as follows [8], [10]:

$$P_{ij} = e^{(Vij)} / \Sigma_J e^{(ViJ)} \quad (2)$$

The parameters of the MNL model are estimated using the maximum likelihood method. To facilitate the estimation process, the log-likelihood (*LL*) function, which converts the product of probabilities into sums, is utilized [8], [10]:

$$LL = ln(L(\beta)) = \Sigma_i \Sigma_j \delta_{ij} \times ln(P_{ij}(\beta)) \quad (3)$$

where δ_{ij} is the choice indicator; it takes the value of 1 if individual i chooses mode *j*, and 0 otherwise.

The goodness-of-fit of the model is evaluated using the likelihood ratio (*LR*) test and *McFadden's pseudo-R²* metric. The *LR* test compares the estimated model with a reference model containing only the constant term [8], [10]:

$$LR = -2 \times (LLnull - LLmodel) \quad (4)$$

The calculated *LR* value is compared with the critical Chi-square value determined according to the degrees of freedom; if the *LR* value exceeds the critical value, it is concluded that the estimated model performs statistically significantly better than the reference model. *McFadden's pseudo-R²*, used to evaluate the model's goodness-of-fit, is defined as follows [8], [10]:

$$McFadden\text{-}R^2 = 1 - (LLmodel / LLnull) \quad (5)$$

$$Adjusted\ McFadden\text{-}R^2 = 1 - (LLmodel\ -K) / (LLnull) \quad (6)$$

Unlike the traditional R^2, which explains variance, *McFadden's pseudo-R²* values in the range of approximately 0.20–0.40 are often regarded as indicative of a relatively strong fit for discrete choice models, although interpretation is context dependent [8], [10]. All analyses were performed in RStudio using the mlogit package in R.

4 Findings

The estimation results of the MNL model, conducted in R Studio, analyze university students' transportation mode choices (active transport and public transport) compared to the private vehicle option, which was set as the reference group. All findings related to the model are presented in Table 2.

Table 2. Multinomial Logit model results

Variables	Active Transport		Public Transport	
	Estimate	**p-value**	**Estimate**	**p-value**
Constant (Intercept)	3.290 *	<0.001	4.181 *	<0.001
Density (×100 persons/km^2)	0.011	0.516	0.011	0.422
Age	0.052 *	0.002	-0.014	0.376
Female	-0.579 *	<0.001	-0.833 *	<0.001
Income (×1000 TL)	-0.083 *	<0.001	-0.055 *	<0.001
Resides with family	-1.267 *	<0.001	-0.946 *	<0.001
Resides in dormitory	2.318 *	<0.001	1.742 *	<0.001
Driving license	-0.297 *	<0.001	-0.843 *	<0.001
Car availability	-2.499 *	<0.001	-2.765 *	<0.001
Micromobility availability	1.478 *	<0.001	0.743 *	<0.001
Motorbike availability	-3.678 *	<0.001	-2.878 *	<0.001
Travel distance (km)	-0.579 *	<0.001	0.028	0.152
Public transport subscription	1.343 *	<0.001	2.843 *	<0.001
Bicycle infrastructure quality	-0.256 *	<0.001	-0.228 *	<0.001
Pedestrian path quality	0.088 *	<0.001	0.088 *	<0.001
Sidewalk quality	0.027 *	0.004	0.104 *	<0.001
Ramp availability	0.158 *	<0.001	-0.085 *	<0.001
Safety perception	0.271 *	<0.001	0.004	0.691

*Note: * p<0.05. Reference category is Private Vehicle.*

The estimated MNL model provided a substantially better fit than the intercept-only model ($LL = -478.10$ vs. -831.85; $LR\ \chi^2(34) = 707.50$, $p < 0.001$). The model yielded a *McFadden pseudo-R^2* of 0.425 and an adjusted *McFadden pseudo-R^2* of 0.382, indicating a relatively strong model fit.

4.1 Evaluation of The Socio-Demographic and Travel Variables

When the Multinomial Logit model coefficients are examined, it is observed that socio-demographic characteristics have statistically strong and significant effects on university students' sustainable transportation mode preferences. Older students are more likely to choose active transport relative to private vehicles, whereas age is not significantly associated with public transport choice. Female students exhibit significantly lower relative odds of choosing either active or public transport rather than a private vehicle compared with male students. This finding is consistent with previous research highlighting gender differences in perceived safety; however, the present model does not directly test whether safety perceptions mediate the relationship between gender and mode choice.

When students' economic characteristics and vehicle availability are considered, higher income is associated with lower relative odds of choosing both active transport and public transport rather than a private vehicle. Similarly, holding a driving license and having access

to a car or motorcycle are associated with substantially lower relative odds of choosing sustainable transport modes compared with private vehicle use. Students residing with their families also exhibit significantly lower relative odds of choosing active or public transport. In contrast, dormitory residence is strongly and positively associated with both active and public transport choices relative to private vehicle use. Micromobility availability and public transport subscription are likewise associated with greater relative odds of choosing sustainable transport modes. Greater travel distance from home to campus is negatively associated with active transport choice, whereas its association with public transport choice is not statistically significant. Regional population density is also not significantly associated with either active transport or public transport choice.

4.2 Role of Built Environment and Infrastructure Perceptions

Several built-environment perception variables are significantly associated with students' travel mode choices. According to the model results: higher perceived pedestrian path quality is positively associated with both active and public transport choices relative to private vehicles. Similarly, the perception of sidewalk availability in compliance with standards significantly increases active transport and public transit probabilities. Perceived ramp accessibility and barrier-free sidewalk design are positively associated with active transport choice, while the corresponding coefficient for public transport is negative and statistically significant. Similarly, higher perceived route safety is positively associated with active transport choice, whereas its association with public transport is not statistically significant. These findings suggest that perceived accessibility and safety conditions are important correlates of walking and cycling among university students.

4.3 Bicycle Infrastructure Perceptions and Mode Shift

A notable and counterintuitive result concerns the bicycle infrastructure quality variable. Bicycle infrastructure quality exhibited negative coefficients for both active and public transport relative to private vehicle use. This pattern may suggest that current bicycle users are dissatisfied with existing road conditions and infrastructure deficiencies. In light of the findings, discontinuities in bicycle infrastructure and concerns related to safety may increase the likelihood that some active transport users consider shifting toward private vehicles, which may be perceived as more comfortable and protected, particularly if infrastructure conditions are not improved. Although the present analysis does not directly observe future mode switching, the results point to a potential risk of such a transition. Therefore, campus and urban transportation planning should give priority to improving the continuity, quality, and safety of pedestrian and bicycle infrastructure, including the provision of segregated bicycle facilities where appropriate, in order to support the continued use of active transport and reduce the potential shift toward motorized modes.

5 Discussion and Suggestions

The MNL model findings obtained in this study reveal that university students' travel behaviors are strongly shaped by both socio-demographic variables and built environment perceptions. Specifically, older students and students residing in dormitories exhibit a greater relative propensity to choose active transport, while dormitory residence is also positively associated with public transport use. Conversely, holding a driving license and having access to a car or motorcycle are associated with substantially lower relative odds of choosing sustainable transport modes. These findings are consistent with previous studies identifying

vehicle availability as an important barrier to the use and integration of sustainable transport modes.

The significantly lower probability of female students using active transport and public transit compared to male students draws attention to the relationship between gender equality and subjective safety in transportation planning. In the literature, it is frequently emphasized that women feel less safe than men during pedestrian and bicycle travel and are more sensitive to environmental quality. Particularly dim or isolated routes, irregular pedestrian infrastructure, and uncontrolled crossing points create a deterrent effect on female users and steer them toward private vehicle types perceived as more sheltered. In this context, lighting urban and campus travel routes, increasing security measures, and establishing continuous pedestrian connections are primary policy steps for female students to adopt sustainable transport.

The positive association between perceived pedestrian path quality and active transport choice highlights the potential relevance of micro-scale built-environment characteristics to travel behavior. Features such as sidewalk width, ramp accessibility, and pavement condition can influence pedestrian comfort and perceived accessibility. Especially when sidewalks are shared with micromobility vehicles (e-scooters, bicycles, etc.), lateral distances and vehicle speeds must be kept under control to protect pedestrian safety. Virtual reality studies suggest that safe interactions on shared sidewalks may be supported by net sidewalk widths of approximately 2.00–2.30 m and micromobility speeds of no more than 10 km/h. [5]. Therefore, expanding the pedestrian corridors around campus areas in accordance with these standards and making them barrier-free will directly increase active travel rates.

The most critical planning warning of the study is that the perception of bicycle path availability produces negative coefficients. This counterintuitive result indicates that higher bicycle-infrastructure ratings are associated with lower relative odds of active and public transport use. As explained by the concept of “Value of Safety” in the literature, although users are willing to extend their routes to avoid unsafe routes, they completely abandon using sustainable modes when infrastructural inadequacy exceeds a certain threshold [5]. Cyclists feeling unsafe due to the current poor-quality infrastructure triggers the potential for this sensitive user group to shift to other private vehicles in the near future. To prevent users from turning to car dependency due to this dissatisfaction, merely preserving the status quo is insufficient; building bicycle paths physically separated from motorized vehicle traffic and ensuring network continuity is crucial.

6 Conclusion

In this study, the effects of socio-demographic characteristics and built environment perceptions on transportation mode choice were analyzed using an MNL model with data obtained from 1,087 students studying at seven different universities in Türkiye. The results indicate that individual characteristics, vehicle availability, and perceptions of route safety and infrastructure quality are significantly associated with students’ travel mode choices. Dormitory residence, public transport subscription, and micromobility availability are positively associated with the relative likelihood of choosing sustainable transport modes. Conversely, car availability, higher income, and holding a driving license are associated with a greater relative preference for private vehicle use.

To promote sustainable urban mobility and reduce the risk of shifts toward private vehicle use in campus travel, the findings of this study, together with evidence from the literature,

suggest several planning interventions that decision-makers may consider:

- *Keeping Active Transport Users in the System:* To prevent loyal users who currently prefer walking and cycling from shifting to private vehicles due to infrastructure dissatisfaction, existing pedestrian and bicycle paths must be improved.
- *Physical Separation and Standard-Compliant Design:* Bicycle and e-scooter lanes should be physically separated from motorized vehicle traffic and pedestrian sidewalks. The net width of pedestrian sidewalks should be maintained at a minimum of 2.00 meters, and ramp accessibility should be provided continuously.
- *Enhancing Perceived Safety:* To enable female students, in particular, to safely use sustainable transport modes, improved lighting, visibility, and pedestrian-oriented safety measures should be widespread along the routes.

In conclusion, increasing the share of sustainable transportation in university campuses and surrounding urban areas requires not only adequate infrastructure provision but also environments that users perceive as safe, accessible, continuous, and comfortable.

Declaration of Generative AI and AI-assisted technologies in the writing process

During the preparation of this manuscript, the authors used Google NotebookLM, ChatGPT, and Abacus AI for language editing, structural review, clarity checks, translation, and grammar correction. The authors subsequently reviewed and verified all AI-assisted content and assume full responsibility for the final manuscript.

Abstract
Bicycle transportation is an important component of sustainable urban mobility; however, bicycle use intensity varies across neighborhoods according to their socioeconomic, demographic, mobility-related, and built-environment characteristics. This study investigates neighborhood-level Bicycle Use Intensity (BUI) in Eskişehir and compares the predictive performance of different regression-based modelling approaches. The analysis is based on the 2015 Eskişehir Household Travel Survey conducted for the Eskişehir Transportation Master Plan, using 56 neighborhoods as the unit of analysis. BUI was calculated as the number of bicycle trips made by neighborhood residents divided by the number of surveyed residents. Eleven explanatory variables representing socioeconomic, demographic, mobility-related, and built-environment characteristics were included. Multiple Linear Regression (MLR), Ridge Regression (RR), Least Absolute Shrinkage and Selection Operator (Lasso), and Elastic Net (EN) were compared using 5-fold cross-validation repeated with 100 fixed random seeds. Model tuning was based on the lambda.min criterion, and performance was primarily evaluated using the Cross-Validated Root Mean Squared Error (CV-RMSE). RR achieved the lowest mean CV-RMSE (13.55) and was the best-performing model in all cross-validation runs. A sensitivity analysis using an extended lambda search path produced the same model ranking. Standardized RR coefficients showed positive associations of BUI with driver's license ownership, average age, residential building density, automobile ownership, and population density, whereas workplace building density, employment ratio, homeownership, student ratio, public building density, and average number of trips showed negative associations. The findings demonstrate that RR provides a robust modelling framework for neighborhood-level bicycle use analysis using small-sample zonal transport data.

Keywords: Bicycle use intensity; Ridge Regression; Penalized regression; Neighborhood-level analysis; Sustainable urban mobility

1 Introduction

Bicycle transportation is an important component of sustainable urban mobility because of its environmental, economic, and social benefits. As an environmentally friendly, affordable, and accessible travel mode, cycling contributes to reducing traffic congestion, lowering energy consumption, and promoting physical activity. Increasing bicycle use in urban areas is closely associated with the provision of safe, continuous, and accessible cycling infrastructure. Recent evidence from Türkiye similarly indicates that cycling infrastructure remains fragmented and

insufficiently standardized in many cities, emphasizing the need for continuous and connected networks and the integration of micromobility into transportation master plans [1]. However, the existence of cycling infrastructure alone is insufficient to explain bicycle use. Cycling behaviour is also influenced by individuals' socioeconomic and demographic characteristics, general travel behaviour, and the built-environment characteristics of the neighborhoods in which they live [2, 3].

Previous studies have shown that bicycle use is determined by a wide range of interacting factors. Demographic characteristics such as age, gender, educational attainment, and household composition, together with socioeconomic indicators including income, employment status, automobile ownership, driver's license ownership, and homeownership, have frequently been examined as determinants of bicycle use [2, 4, 5]. Recent research from Türkiye has further shown that cycling is influenced by socio-cultural conditions, including peer effects, concerns related to physical appearance, and perceived societal pressure [6]. In addition, built-environment characteristics play an important role in shaping cycling behaviour. Previous research has identified cycling infrastructure, land-use patterns, residential and employment density, accessibility, network connectivity, travel distance, topography, and street design as important determinants of bicycle use [3, 7-9]. Recent spatially explicit research has also demonstrated that bicycle users' routes, trip durations, and station locations may generate substantial differences in environmental exposure across urban areas [10]. Recent bike-sharing research has also shown that the relative importance of temporal, weather-related, station-level, and nearby spatial characteristics may vary across systems, highlighting the context-dependent nature of bicycle demand [11].

These factors are often interrelated rather than independent. For example, the relationship between urban density and bicycle use may vary depending on automobile ownership, age structure, household characteristics, employment patterns, or the socioeconomic composition of neighborhoods. Consequently, bicycle use should be analysed using modelling approaches that simultaneously consider multiple groups of explanatory variables rather than individual variables in isolation. This issue becomes particularly important in neighborhood-level analyses, where the relatively small sample size and correlations among explanatory variables may lead to coefficient instability in conventional regression models. Penalized regression techniques provide useful alternatives under such conditions. Ridge Regression (RR) improves model stability by shrinking regression coefficients while retaining all variables in the model. The Least Absolute Shrinkage and Selection Operator (Lasso) performs variable selection by shrinking some coefficients exactly to zero. Elastic Net (EN) combines the penalties used in RR and Lasso. In addition, Multiple Linear Regression (MLR) was included as the baseline comparison model in this study [12-14].

The objective of this study is to investigate neighborhood-level bicycle use intensity in Eskişehir using socioeconomic, demographic, mobility-related, and built-environment indicators. To this end, the predictive performance of MLR, RR, Lasso, and EN models is compared to identify the most appropriate modelling approach for small-sample neighborhood-level bicycle use data.

2 Study Area and Data

The study was conducted in the central districts of Odunpazarı and Tepebaşı in Eskişehir, Türkiye. Eskişehir is a medium-sized city where bicycle use is observed in daily urban travel and where cycling infrastructure has been progressively expanded in different parts of the city.

These characteristics make Eskişehir an appropriate case study for examining the factors associated with neighborhood-level bicycle use intensity.

The analysis is based on data obtained from the 2015 Eskişehir Household Travel Survey, which contains information on individuals' daily travel behaviour as well as their socioeconomic and demographic characteristics. Neighborhoods were selected as the unit of analysis. After data aggregation and missing-value screening, the final modelling dataset consisted of 56 neighborhoods.

The dependent variable was defined as resident-based Bicycle Use Intensity (BUI). BUI was calculated by dividing the total number of bicycle trips made by residents of each neighborhood by the number of surveyed individuals living in that neighborhood. Therefore, the indicator represents the relative bicycle use intensity of neighborhood residents rather than bicycle trips attracted to or passing through a neighborhood.

The explanatory variables were generated at the neighborhood level to represent socioeconomic structure, demographic composition, general mobility characteristics, and built-environment conditions. The variables included in the modelling process and their abbreviations are presented in Table 1 and Figure 1 illustrates the study area and the neighborhood boundaries used in the analysis.

Table 1. Variables used in the modelling process and their abbreviations

Variable	Abbreviation	Description	Dimension
Bicycle use intensity	BUI	Number of bicycle trips made by neighborhood residents divided by the number of surveyed individuals	Dependent variable
Automobile ownership	AOW	Neighborhood-level automobile ownership indicator	Socioeconomic/Mobility
Homeownership ratio	HOR	Homeownership ratio	Socioeconomic
Driver's license ownership	DLO	Driver's license ownership ratio	Mobility-related socioeconomic
Average number of trips	ANT	Average daily trip-making indicator	General mobility
Employment ratio	EMP	Share of employed individuals	Socioeconomic
Average age	AAG	Average age of surveyed residents	Demographic
Student ratio	STU	Share of students	Demographic/Socioeconomic
Population density	PDN	Population density indicator	Built environment / Density
Residential building density	RBD	Residential building density	Built environment
Workplace building density	WBD	Workplace building density	Built environment / Land use
Public building density	PBD	Public building density	Built environment / Land use

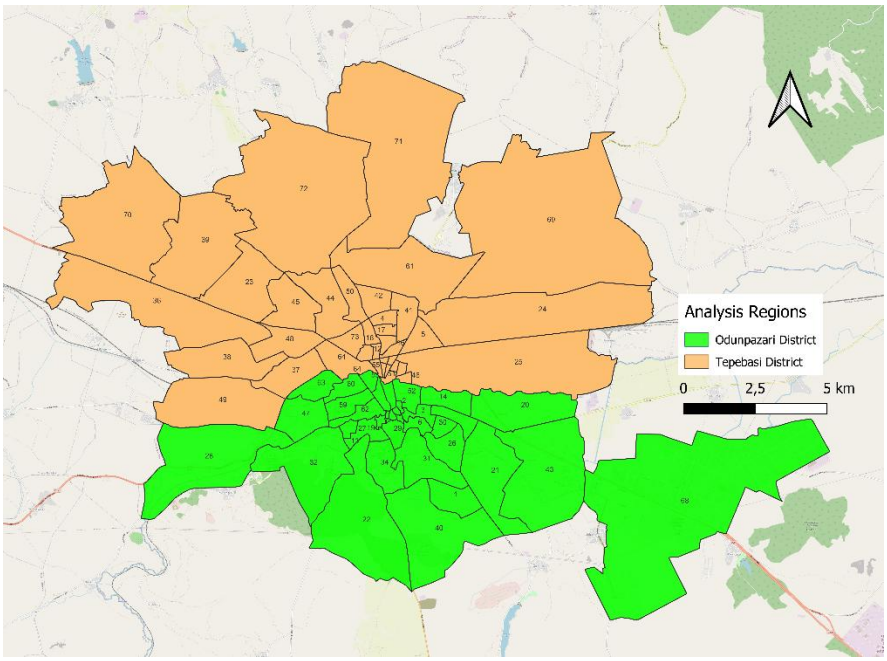

Fig. 1. Study area in Eskişehir and neighborhood boundaries used in the analysis.

3 Methodology

This study compares MLR, RR, Lasso, and EN models to predict BUI. MLR was used as the baseline comparison model, whereas RR, Lasso, and EN were employed to improve coefficient stability and predictive performance in a small-sample dataset with correlated explanatory variables [12-14].

The penalized regression models are based on the following objective function:

$$\min_{\beta_0,\beta}\left\{\frac{1}{N}\sum_{i=1}^{N}(y_i-\beta_0-x_i^T\beta)^2+\lambda\left[\frac{1-\alpha}{2}\sum_{j=1}^{p}\beta_j^2+\alpha\sum_{j=1}^{p}|\beta_j|\right]\right\} \quad (1)$$

The dependent variable is denoted by y_i, x_i represents the vector of explanatory variables, $\beta = (\beta_1, \beta_2, \ldots, \beta_p)$ denotes the vector of regression coefficients, λ is the regularization parameter, and α controls the balance between the RR and Lasso penalties. When $\alpha = 0$, the model corresponds to RR; when $\alpha = 1$, it becomes Lasso; and $0 < \alpha < 1$ represents EN models [9–11]. RR shrinks regression coefficients without performing variable selection, whereas Lasso and EN may set some coefficients exactly to zero, thereby performing variable selection.

All models were estimated in R using the glmnet package [15]. The dependent variable was retained on its original scale, whereas explanatory variables were standardized internally by glmnet during model estimation. This enabled RMSE values to be interpreted in the original units of BUI. The α parameter was evaluated from 0.00 to 1.00 in increments of 0.05, while the default lambda sequence generated by glmnet was adopted.

To reduce the dependence of model performance on a single random data partition, repeated 5-fold cross-validation was performed using 100 fixed random seeds. For each seed, the same fold assignment was used across all α values, ensuring that RR, Lasso, and EN were evaluated under identical training and validation partitions. Model performance was assessed using CV-RMSE, CV-MAE, and CV-R^2, with the mean CV-RMSE adopted as the primary model selection criterion.

To evaluate the adequacy of the lambda search path, an additional sensitivity analysis was conducted using 300 lambda values and a smaller lambda.min.ratio. The ranking of model performance remained unchanged.

Coefficient stability of the best-performing model was evaluated using the results obtained from the 100 repeated cross-validation runs. Since RR does not perform variable selection, the number of selected variables was not reported for the RR model. Instead, the coefficient directions and standardized coefficient magnitudes of all candidate variables were examined. Standardized RR coefficients were calculated as follows:

$$\beta_{std,j} = \bar{\beta}_j \frac{sd(x_j)}{sd(y)} \tag{2}$$

where $\bar{\beta}_j$ denotes the average RR coefficient of the j-th explanatory variable across the 100 repeated cross-validation runs, $sd(x_j)$ is the standard deviation of the corresponding explanatory variable, and sd(y) is the standard deviation of the dependent variable. Standardized coefficients facilitate comparison of the relative contributions of variables measured on different scales. In this study, variable importance was evaluated using the absolute standardized coefficients.

4 Results and Discussion

During model tuning, the lambda.min criterion, which selects the regularization parameter (λ) that minimizes the cross-validation error in each cross-validation run, was adopted.

Table 2 summarizes the representative model performance results obtained from the repeated 5-fold cross-validation procedure. A total of 22 models (RR, 19 EN models, Lasso, and MLR) were evaluated. To improve readability, only the best-performing and representative models are presented.

Table 2. Representative model performance results based on repeated 5-fold cross-validation**.**

Method	Alpha	Median selected λ	Mean CV-RMSE	SD CV-RMSE
RR	0.00	6.70	13.55	0.36
EN	0.05	4.60	13.66	0.37
EN	0.10	3.50	13.73	0.38
EN	0.20	2.54	13.82	0.39
Lasso	1.00	0.85	14.04	0.43
MLR	—	—	15.29	1.02

As shown in Table 2, RR produced the lowest CV-RMSE in all 100 repeated cross-validation runs based on the lambda.min criterion. Although EN models with low alpha values achieved prediction errors close to those of RR, none of them outperformed RR in any repetition. As the alpha value increased, the prediction error of EN models gradually increased, whereas Lasso and MLR produced the highest prediction errors.

These findings indicate that the L2 regularization employed by RR provided more stable predictive performance than the sparser models obtained through variable selection for this dataset.

An additional sensitivity analysis was conducted to examine whether the results depended on the lambda search path. Instead of the default lambda sequence generated by glmnet, an extended search path consisting of 300 lambda values and a wider search range was used. The

ranking of the competing models remained unchanged, and RR was again identified as the best-performing model in all 100 repetitions. This finding confirms that the superior performance of RR was not attributable to the selected lambda search range.

Table 3 presents the standardized RR coefficients. These coefficients were obtained by standardizing the average RR coefficients estimated across the 100 repeated cross-validation runs. Since RR retains all variables in the model, the coefficients should not be interpreted as evidence of variable selection but rather as indicators of the relative direction and magnitude of the associations between the explanatory variables and BUI.

Table 3. Standardized RR coefficients.

Abbreviation	Variable	Standardized coefficient
DLO	Driver's license ownership	0.193
WBD	Workplace building density	-0.183
EMP	Employment ratio	-0.164
AAG	Average age	0.141
RBD	Residential building density	0.121
HOR	Homeownership ratio	-0.104
STU	Student ratio	-0.099
AOW	Automobile ownership	0.074
PDN	Population density	0.065
PBD	Public building density	-0.054
ANT	Average number of trips	-0.047

The coefficients presented in Table 3 were derived from aggregated neighborhood-level data. Therefore, they should be interpreted as spatial associations reflecting the demographic, socioeconomic, mobility, and land-use characteristics of neighborhoods rather than as direct or causal relationships at the individual level.

Positive associations were observed for DLO, AAG, RBD, AOW, and PDN, whereas WBD, EMP, HOR, STU, PBD, and ANT exhibited negative associations with BUI.

The positive coefficient of DLO does not imply that possessing a driver's license directly increases bicycle use at the individual level. One possible explanation is that neighborhoods with higher driver's license ownership in Eskişehir also tend to have lower student concentrations and relatively older populations, reflecting broader neighborhood characteristics rather than individual travel behaviour.

The negative coefficients of WBD and EMP may indicate that neighborhoods characterized by high workplace density and employment concentration function primarily as employment centers. In such areas, mandatory commuting trips may be more frequently made by company shuttle services, public transport, or private automobiles, thereby limiting bicycle use.

The positive association of AAG suggests that cycling in Eskişehir is not limited to younger populations. In several neighborhoods with relatively older or retired residents, bicycle use for short-distance daily trips appears to remain common, which may partly explain this relationship.

The positive coefficient of RBD may reflect the greater prevalence of short-distance local trips in neighborhoods with high residential density. In contrast, the negative coefficient of STU may be explained by the fact that student-dominated neighborhoods are generally located close to universities and the city center, where many short trips can be completed on foot rather than

by bicycle. This finding also suggests that future studies could incorporate explicit spatial indicators representing proximity to universities and the city center.

Similarly, the positive coefficient of AOW should not be interpreted as evidence that automobile ownership promotes bicycle use at the individual level. Rather, neighborhoods with relatively high automobile ownership are often located in outer residential areas where bicycles may still be frequently used for short local trips.

The negative coefficient of PBD may indicate that neighborhoods with high concentrations of public buildings primarily function as service destinations that attract trips rather than generate bicycle trips by residents. Likewise, the negative association of ANT may reflect that individuals making multiple or chained trips throughout the day tend to rely more heavily on public transport or private automobiles than bicycles.

Overall, the findings indicate that neighborhood-level bicycle use intensity is shaped not by a small number of dominant predictors but by the combined influence of demographic, socioeconomic, mobility-related, and built-environment characteristics. The superior performance of RR, which retained all explanatory variables while producing the lowest prediction error, further supports the multidimensional nature of neighborhood-level bicycle use.

5 Conclusions

This study modeled neighborhood-level bicycle use intensity (BUI) in Eskişehir using data from the 2015 Eskişehir Household Travel Survey. Neighborhoods were adopted as the unit of analysis, and BUI was explained using socioeconomic, demographic, mobility-related, and built-environment indicators. MLR, RR, Lasso, and EN models were compared using repeated 5-fold cross-validation with 100 fixed random seeds.

Model tuning was performed using the lambda.min criterion, which selects the lambda value that minimizes the cross-validation error in each repetition. The results demonstrated that RR achieved the lowest and most stable prediction error among the evaluated models. RR attained a mean CV-RMSE of 13.55 on the original scale of the dependent variable and was identified as the best-performing model in all 100 repeated cross-validation runs. Although low-alpha EN models produced prediction errors close to those of RR, their performance gradually deteriorated as the alpha value increased, while Lasso and MLR exhibited weaker predictive performance.

In addition to the default lambda sequence generated by glmnet, an additional sensitivity analysis using 300 lambda values and lambda.min.ratio = 10^{-6} produced the same model ranking. This confirms that the superiority of RR was not attributable to an insufficient lambda search range for EN or Lasso.

Based on the standardized RR coefficients, DLO, AAG, RBD, AOW, and PDN were positively associated with BUI, whereas WBD, EMP, HOR, STU, PBD, and ANT showed negative associations. Since these relationships were obtained from aggregated neighborhood-level data, they should not be interpreted as individual-level causal effects. Instead, they should be understood in the context of neighborhood demographic composition, the spatial distribution of students and workers, centrality, residential structure, and land-use characteristics.

The findings suggest that neighborhood-level bicycle use intensity is influenced by the combined contribution of multiple neighborhood characteristics rather than a small number of dominant predictors. In this context, the L2 regularization employed by RR improved predictive stability by retaining all theoretically relevant variables in the model and outperformed Lasso and high-alpha EN models, which place greater emphasis on variable selection. Consequently,

RR appears to be an appropriate modelling approach for neighborhood-level transportation datasets characterized by relatively small sample sizes and correlated explanatory variables.

The primary limitation of this study is that the analysis was conducted using aggregated neighborhood-level data. Furthermore, the current model does not explicitly include spatial variables such as proximity to universities and the city center, cycling infrastructure availability, terrain slope, pedestrian accessibility, or land-use diversity. Incorporating these variables in future research may provide a more comprehensive explanation of the observed relationships, particularly those involving student concentration, automobile ownership, population density, and driver's license ownership.

Abstract. Bitumen is a viscoelastic material whose temperature-dependent behavior directly affects the workability and field performance of asphalt pavements. Therefore, evaluating the conventional properties and temperature susceptibility of modified bitumens provides a practical basis for understanding their suitability for pavement applications. This study investigates the effect of calcium lignosulfonate (CLS) modification on the conventional properties and temperature susceptibility of bitumen. For this purpose, a neat bitumen sample and CLS-modified bitumen samples containing 3%, 5%, 7%, and 9% CLS by weight of bitumen were prepared. The experimental program included penetration, softening point, and rotational viscosity tests at 135 °C. Based on the obtained experimental results, the penetration index (PI) and penetration-viscosity number (PVN) were calculated to evaluate the changes in the temperature susceptibility and consistency characteristics of the samples. The penetration and softening point results were used to assess the effect of CLS addition on bitumen under conventional test conditions, while the rotational viscosity values were considered in terms of high-temperature flow behaviour and workability. In addition, PI and PVN values provided complementary indicators for interpreting the sensitivity of the modified bitumens to temperature changes. Through a comparative evaluation of the neat and CLS-modified samples, this study aims to determine whether CLS primarily acts as a stiffening, stabilizing, or temperature-sensitivity-modifying additive within the investigated dosage range. The findings of this study are expected to contribute to the preliminary assessment of CLS as a potential bitumen modifier and to provide a basis for future rheological and mixture-scale performance investigations.

Keywords: Bitumen Modification; Calcium lignosulfonate; Conventional bitumen tests

1 Introduction

The global transition toward sustainable infrastructure has motivated extensive inquiry into bio-based additives for asphalt binders, primarily to mitigate the environmental impact of petroleum-derived bitumen [1]. As bitumen is a finite, non-renewable resource, the

development of sustainable, high-performance binders has become essential for ensuring long-term road pavement durability [2]. The valorization of industrial waste byproducts as modifiers represents a strategic approach to addressing both resource scarcity and ecological footprints, while simultaneously enhancing the mechanical integrity of asphaltic materials [3-4].

Calcium lignosulfonate, a byproduct derived from the pulp and paper industry, has garnered significant attention as a viable organic modifier [4]. Characterized as a phenylpropane-based polymer with reactive phenolic and hydroxyl functional groups, CLS demonstrates potential compatibility with the bitumen matrix, thereby facilitating structural reinforcement [5]. Furthermore, the integration of CLS into bitumen has been shown to improve consistency and structural rigidity at elevated temperatures, which is critical for mitigating permanent deformation in asphalt pavements [6]. The adoption of this abundant byproduct adheres to circular economy principles, offering a cost-effective and environmentally sound alternative for large-scale engineering applications [7-8].

Despite evidence suggesting that lignin derivatives enhance rutting resistance and oxidative stability, the correlation between additive dosage and binder brittleness necessitates further empirical examination [1, 9-10]. The inherent variability in lignin-based materials, contingent upon their specific source, production methods, and chemical composition, complicates the standardization of these additives [11]. While lignosulfonates are well-established as effective adhesive agents and soil stabilizers [12-13], their systematic application as rheological modifiers in neat bitumen—specifically concerning conventional consistency and temperature susceptibility parameters—remains insufficiently explored in current literature [14-15].

Consequently, this research investigates the mechanical reinforcement and thermal response mechanisms of bitumen binders modified with varying concentrations of CLS. By correlating specific dosage levels with temperature susceptibility indicators, this study aims to refine the binder's physical properties through the utilization of this sustainable industrial byproduct. Ultimately, this investigation underscores the feasibility of employing lignosulfonate as an environmentally benign and cost-effective additive within modern asphalt paving technologies [16-17].

2 Materials and Methods

2.1 Bitumen

The base binder utilized for this experimental program consists of a standard 50/70 penetration grade bitumen. This binder was selected as it represents a widely adopted grade in pavement construction, providing a suitable baseline to evaluate the hardening and stiffening effects of CLS incorporation.

2.2 Calcium Lignosulfonate

The calcium lignosulfonate (CLS) used in this investigation was procured commercially in powder form from Kimya Deposu. This fine-particulate additive was selected for its potential to integrate homogeneously with the bituminous matrix, facilitating a uniform dispersion of the modifier.

2.3 Preparation of CLS Modified Bitumen

The modified binder samples were prepared by incorporating the CLS into the base bitumen at a temperature of 160 °C using a mechanical mixer operating at a constant speed of 1500 rpm for a duration of 30 minutes, ensuring a homogeneous distribution of the additive within the

bituminous matrix. Following the blending process, the samples were subjected to an immediate cooling phase at room temperature to preserve the integrity of the dispersion. The homogeneity of the resulting mixtures was further verified through visual inspection to confirm the absence of modifier agglomeration or phase separation prior to subsequent laboratory testing. Subsequently, these samples were stored in tightly sealed containers to prevent oxidative hardening before undergoing standard penetration, softening point, and rotational viscosity testing.

2.4 Conventional Bitumen Tests

The consistency of the modified binders is characterized through the penetration test, which measures the depth of needle penetration into the sample under specific load and time conditions. This procedure, conducted in accordance with ASTM D5, provides a quantitative assessment of bitumen hardness at a standard temperature of 25 °C. Concurrently, the softening point test, performed as per ASTM D36, is utilized to determine the temperature at which the bitumen reaches a specific state of flow, serving as a primary indicator of its thermal stability.

Furthermore, the flow behavior and workability of the binders at high temperatures were evaluated using rotational viscosity measurements in accordance with ASTM D4402, providing critical data on the binder's resistance to shearing during production and placement. These experimental procedures were performed in triplicate for each specimen to ensure statistical reliability and to minimize the impact of inherent material variability.

2.5 Temperature Susceptibility Indices

Temperature susceptibility refers to the rate at which bitumen consistency varies with fluctuations in service temperature, thus serving as a critical indicator for assessing the binder's performance range. To quantify this sensitivity, the Penetration Index is employed—an empirical metric derived from the relationship between penetration and softening point, which effectively reflects the binder's propensity for thermal deformation. The *PI* values for the CLS-modified bitumen binders are calculated using the following equation:

$$PI = \frac{1952 - 500 \times \log(pen) - 20 \times SP}{50 \times \log(pen) - SP - 120} \tag{1}$$

where $\log(pen)$ represents the logarithm of penetration at 25 °C and *SP* denotes the softening point temperature in degrees Celsius.

Complementing the *PI*, the Penetration-Viscosity Number (*PVN*) is utilized to assess the binder's rheological stability across a broader temperature range by correlating penetration values at 25 °C with rotational viscosity measurements obtained at 135 °C. The *PVN* values for the CLS-modified bitumen binders are calculated using the following equation:

$$PVN = -1.5 \times \frac{4.258 - 0.7967 \times \log P - \log V}{0.795 - 0.1858 \times \log P} \tag{2}$$

where *P* denotes the penetration value at 25 °C and *V* signifies the rotational viscosity at 135 °C.

Collectively, this dual approach provides a comprehensive evaluation of the binder’s consistency. Generally, a higher *PVN* signifies reduced temperature susceptibility and enhanced thermal stability within the service temperature window. Consequently, these indices serve as

essential diagnostic tools for quantifying how the thermoplastic nature of the bitumen is modulated by the addition of CLS.

3 Results and Discussion

3.1 Results of Conventional Bitumen Tests

Fig. 1 illustrates that the base bitumen exhibited a penetration value of 55.6 dmm, whereas the incorporation of calcium lignosulfonate resulted in a pronounced and monotonic reduction in penetration depth. Specifically, the 3CLS, 5CLS, 7CLS, and 9CLS samples yielded penetration values of approximately 52.7, 50.9, 49.1, and 47.6 dmm, respectively. These observations indicate that the CLS additive effectively stiffens the bitumen matrix.

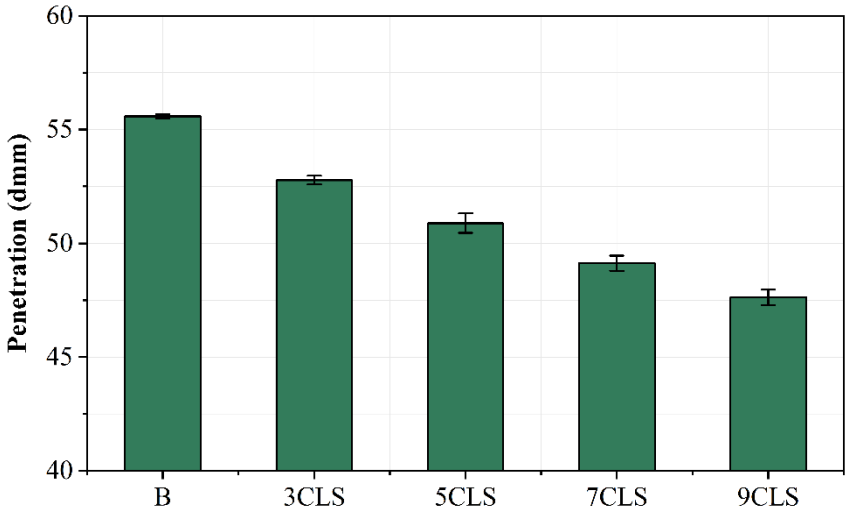

Fig. 1. Penetration test results.

The penetration value decreased by approximately 14.6% at the maximum CLS dosage of 9% compared to the base bitumen. This nearly linear trend suggests a homogeneous dispersion of CLS within the bitumen, underscoring a systematic relationship between additive concentration and binder hardness. Furthermore, this decrease in penetration reflects restricted mobility of the bitumen molecules, likely driven by interactions between the polar functional groups of the lignosulfonate and the asphaltic components [3].

Fig. 2 presents the softening point values of the neat bitumen and the CLS-modified samples. Consistent with the trends observed in the penetration test, the incorporation of CLS led to a monotonic, though modest, upward shift in softening point values. The base bitumen (B) exhibited a softening point of 48.9 °C, while the 3CLS, 5CLS, 7CLS, and 9CLS samples yielded softening points of approximately 49.5, 50.3, 50.3, and 50.4 °C, respectively.

The 9% CLS dosage resulted in a modest increase in the softening point of approximately 1.5 °C compared to the neat binder. This response was significantly more muted in contrast to the penetration test, which demonstrated a 14.6% reduction in penetration depth. This disparity arises because the penetration test is sensitive to near-ambient viscosity, whereas the softening point reflects behavior at elevated temperatures, where the influence of the absorbed maltene fraction is diminished.

Within the tested dosage range, the data reveal two distinct phases. Initially, a moderate increase in the softening point suggests that CLS effectively interacts with asphaltene and resin fractions. Subsequently, this is followed by a plateau phase, which indicates that the stiffening

effect of CLS reaches a saturation point, beyond which additional additive does not significantly alter the binder's flow transition temperature.

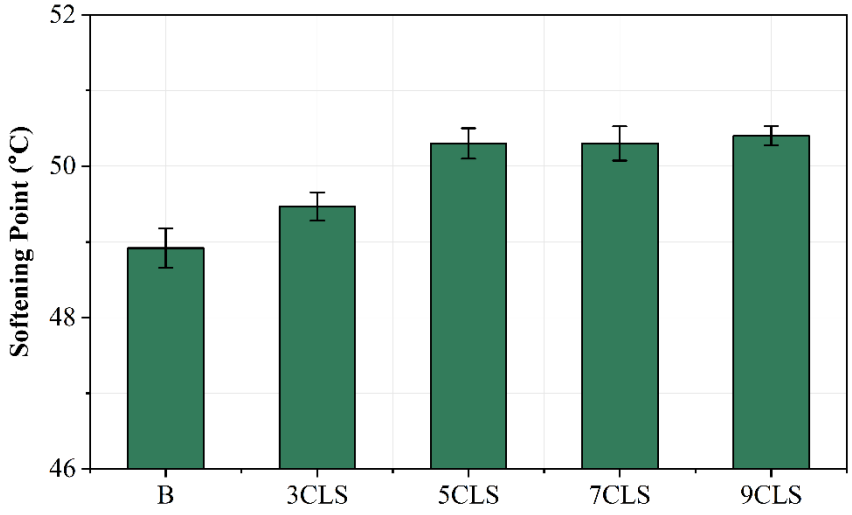

Fig. 2. Softening point test results.

These findings align well with the broader CLS literature. For instance, Fatemi et al. observed a slight upward trend in the softening point of 60/70 penetration-grade bitumen as CLS increased, attributing this limited sensitivity to complex chemical interactions between lignosulfonate and asphaltenes [1]. Furthermore, previous studies indicate that while higher CLS loadings improve high-temperature performance and thermal susceptibility, they offer diminishing returns [1], [5]. Similar trends are reported for kraft lignin modifiers, which can improve softening points but may introduce risks of phase separation and brittleness [10].

Fig. 3 shows the rotational viscosity of the neat and CLS-modified binders. The base bitumen (B) returned an RV of approximately 400 mPa·s, while the 3CLS, 5CLS, 7CLS, and 9CLS samples yielded 440, 463, 490, and 525 mPa·s, respectively. This corresponds to increases of 10%, 15.8%, 22.5%, and 31.3% relative to B.

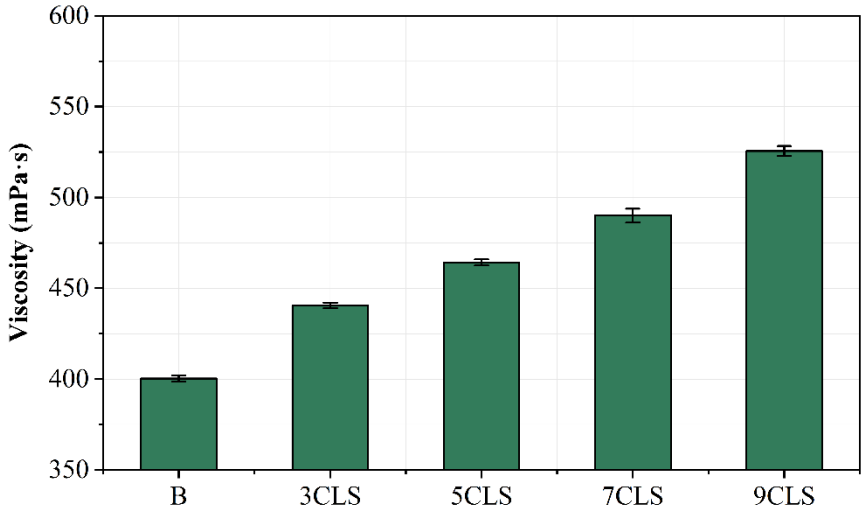

Fig. 3. RV test results at 135 °C.

In contrast to the softening point behavior — where a plateau was observed beyond 5% CLS — RV continued to rise monotonically across the entire dosage range, indicating that CLS

stiffens the binder continuously rather than reaching a saturation threshold. This trend could suggest that CLS acts primarily through maltene absorption, a mechanism that potentially changes the binder's intermediate- and near-ambient viscosity rather than its high-temperature flow onset.

The monotonic RV increase implies a workability penalty: the plant will require higher mixing and compaction temperatures, and the binder becomes more prone to low-temperature cracking [1]. The very small error bars across all samples confirm the repeatability of the measurements.

Taken together, the three conventional tests confirm a consistent picture: CLS acts as a systematic stiffening agent across the 0–9 % dosage window, but the magnitude and shape of the response differ among tests. Penetration decreases monotonically by up to ~14.6 % at 9 % CLS, while softening point rises modestly and plateaus beyond 5 % CLS (~3.1 %), and rotational viscosity climbs more steeply and continuously (~31.3 % at 9 % CLS). This asymmetric response indicates that CLS reinforces the binder predominantly in the intermediate-temperature viscosity regime, consistent with a maltene-absorption mechanism [1], [10]. A practical optimum therefore emerges within the 5–7 % CLS range, where stiffening is largely achieved before the viscosity-related workability penalty becomes dominant [1], [7]. Because the three indices are obtained at different temperatures, they do not yield a single temperature-uniform descriptor of the binder; this motivates the PI and PVN calculations presented in the next section.

3.2 Results of Temperature Susceptibility Indices

The *PI* values calculated from the penetration and softening point results are presented in Fig. 4. All samples exhibited negative *PI* values, ranging from −1.25 to −1.05, which is consistent with conventional paving-grade bitumen and indicates a relatively higher temperature susceptibility compared to oxidized binders.

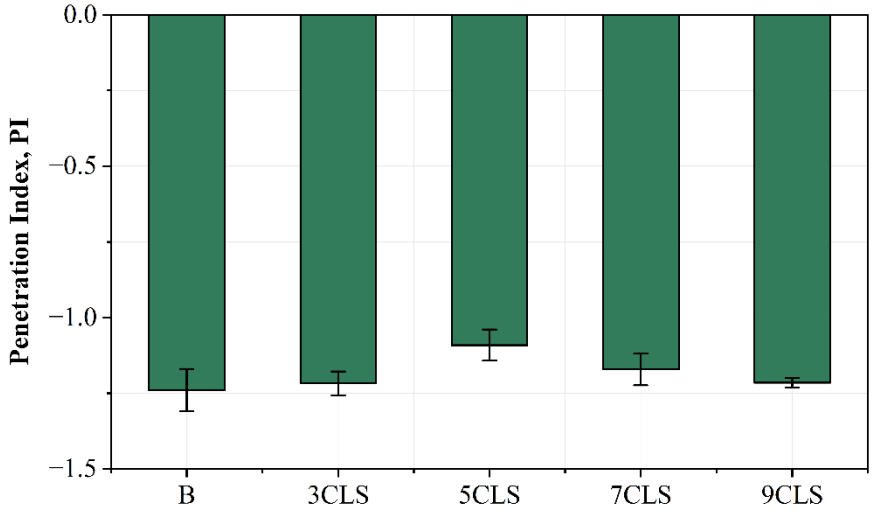

Fig. 4. *PI* values.

The base bitumen (B) yielded the lowest PI value (≈ −1.25), reflecting its higher sensitivity to temperature changes. The incorporation of CLS shifted the PI values towards less negative values, indicating a reduction in temperature susceptibility. Among the modified samples, the 5CLS blend produced the most pronounced improvement, reaching the highest PI value (≈ −1.05) within the tested dosage range. Beyond this optimum, increasing the CLS content to 7% and 9% resulted in a slight reversal of this trend, with PI values decreasing back to

approximately −1.15 and −1.20, respectively. The 3CLS sample (≈ −1.22) showed only a marginal improvement over the base bitumen.

This non-monotonic behavior suggests that 5% represents the optimum CLS dosage for minimizing temperature susceptibility within the investigated range. The narrow error bars across all samples confirm the good repeatability of the measurements. Overall, the PI results indicate that CLS modification enhances the thermal stability of the binder, although the magnitude of improvement remains modest and does not shift the binder outside the range of conventional unmodified bitumen.

The *PVN* values calculated from the penetration, viscosity at 60 °C and viscosity at 135 °C are presented in Figure 5. In line with the *PI* values, all samples yielded negative *PVN* values, indicating that the binders fall within the category of relatively temperature-susceptible bitumens.

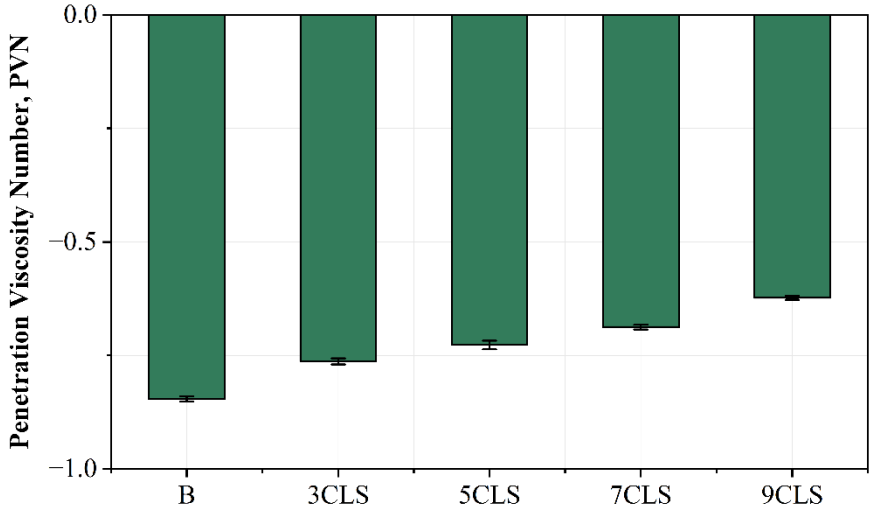

Fig. 5. *PVN* values.

The base bitumen (B) yielded the most negative PVN (≈ −0.85). The addition of CLS shifted *PVN* towards less negative values in a largely monotonic manner as the dosage increased: −0.80 (3CLS), −0.75 (5CLS), −0.70 (7CLS), and the highest value of approximately −0.62 at 9CLS. The narrow error bars again indicate good repeatability of the measurements.

Although both *PI* and *PVN* are derived from the penetration at 25 °C, they incorporate different second parameters: *PI* uses the softening point, whereas *PVN* incorporates the viscosity at 135 °C. This explains the slightly different trends observed for the two indexes. *PI* peaked at 5CLS and then decreased at higher dosages, suggesting that the stiffening effect captured by the softening point does not continue to improve beyond 5% CLS. *PVN*, on the other hand, increased steadily with rising CLS content, indicating that the absolute viscosity at 135 °C, which governs mixing and compaction workability, responds more linearly to CLS addition. In other words, *PI* is more sensitive to high-temperature rheological transitions near the softening point, while *PVN* reflects the progressive increase in viscosity with CLS dosage. Taken together, both indices confirm that CLS reduces the temperature susceptibility of the binder, but *PVN* appears to capture the dosage-dependent improvement more consistently than *PI*.

4 Conclusions

This research investigated the influence of calcium lignosulfonate modification on the conventional properties and temperature susceptibility of bitumen. Bitumen samples modified with 3–9% CLS were subjected to penetration, softening point, and rotational viscosity testing, and the Penetration Index and Penetration Viscosity Number were calculated. Based on these experimental findings, the following conclusions can be drawn:

- CLS acts as a stiffening agent. Adding 3–9 % CLS to a 50/70 penetration grade bitumen produced a monotonic decrease in penetration and a monotonic increase in rotational viscosity at 135 °C, demonstrating a systematic stiffening effect.
- The high-temperature softening response is limited. The softening point increased only modestly and plateaued beyond 5% CLS, indicating that CLS influences the intermediate- and near-ambient viscosity regime more than the high-temperature flow onset.
- The temperature susceptibility is reduced. Both PI and PVN shifted toward less negative values relative to the neat binder, confirming that CLS lowers the binder's sensitivity to temperature variations.
- The two indices show complementary trends. PI peaked at 5CLS and slightly declined at higher dosages. PVN increased monotonically up to 9CLS, reflecting a more linear response of viscosity to CLS dosage.

The conclusions are derived from empirical conventional tests; long-term aging performance and rheological behavior under repeated loading remain to be validated in future studies using RTFOT/PAV aging and DSR-based protocols.

Abstract

Urban transportation policies in Turkey have been planned to be mainly in the center of highway for a long time until recent years. This situation, along with rapid urbanization and population growth, has brought problems in many ways, especially traffic density, accessibility problems and environmental impacts. The development of transportation infrastructure has prevented the sustainable planning of public transportation, especially in medium-sized cities; The flexibility of highway-based systems but their inability to provide high capacity has caused urban mobility to be negatively affected in the long term. In recent years, rail systems have started to gain importance thanks to their high passenger capacity, regular operation, relatively low emission production in terms of environmental impact and opportunities to increase the quality of urban life. In line with this trend, Adapazari - Serdivan Tram Line, stands out as an important project that has the potential to create a fundamental transformation in the city's transportation system. The dense student population in Sakarya City, the commercial and socioeconomic dynamics of the center of Adapazari, the rapid development of the Serdivan region and the increasing demand for travel between these two centers pave the way for the Adapazari - Serdivan Tram Line to be a strategic investment in terms of urban transportation. However, many factors such as the integration of a new rail system line planned in the center of the city with the existing minibus and bus transportation, operating efficiency, critical points in route selection, access distances, possible traffic effects, reflections of the construction process on urban life and long-term demand projections need to be evaluated comprehensively. This study was carried out by continuing the studies with the delphi method in order to analyze the possible effects of the planned tram line on the transportation system in Sakarya with a holistic approach. The opportunities, possible risks, integration requirements and demand potential of the line were evaluated. Pre-construction studies are not only the physical infrastructure for the successful implementation of the project; It reveals the necessity of holistic coordination in public transportation, effective integration with alternative modes of transportation, taking into account the behaviors of the people of Sakarya and a planning approach compatible with urban development dynamics. In this respect, the study opens the place of the tram line planned for Sakarya in the transportation system to discussion on a scientific basis and provides evaluations that guide the decision-making processes for rail system investments in similar medium-sized cities in Turkey.

Keywords: *Transportation; Tram; Feasibility; Planning;*

1 Introduction

Transportation can generally be defined as the transportation (mobilization) of people and goods to where they are needed and when they are needed. According to this definition, the impact of the performance of the transportation system on the economic and social life in the city is quite large [1] [2].

Transportation; It is grouped under five subsystems: rail, road, sea, air and pipeline transportation. Among them, railway and road are two systems that can be substituted for each other [3]. Considering the investment costs of transportation projects, the issue of which of these subsystems will be prioritized is of great importance for the economy. Transportation subsystems; It forms an integrity with infrastructure, vehicles, management and all its elements. Compatible with and supporting social and economic development; The necessary transportation policy should be determined in order to achieve the goal of a cheap, fast, regular, safe, non-polluting transportation that does not pollute the environment, in short, a healthy transportation with the lowest cost to the country. [4].

In terms of planning, transportation is considered as ensuring the necessary harmony between different types of transportation on the one hand, and ensuring an effective integrity between economic development and transportation services on the other. Transportation investments; These are investments that should be evaluated not only according to profitability criteria, but also with criteria such as economic development, social, political, security and public transportation. [3].

In our country, the share of the rail system in both urban and intercity transportation is always It is increasing day by day. With the increase in demand for easy and comfortable transportation Both local and central governments increased their new rail system investments continues. Planning, design, Financing needs Rail that needs programming, field applications and long construction processes The development of the systems is also for the lines that are already in operation and are being taken maintenance is needed. With high investment cost and special Maintenance of rail systems with disciplines Line structure, vehicles, signaling, energy systems, etc. prepared. [5].

Trams use the same road surface as road transportation vehicles and have low floors. A city with a relatively low passenger capacity, where vehicles are controlled by a vatman It is an internal rail system. On rails laid at the same level as the road pavement Transition to moving trams according to road vehicles at crossings and intersections right of way priority is ensured. The distance between the platforms on tram lines is higher than in other urban rail systems.

It is short. Tram systems, which generally have a rail gauge of 1435 mm, are 750 V These are systems that work with energy fed from DC voltage catenary. One way The tram, which has a capacity of 10.000 – 20.000 passengers per hour, has an average of The operating speed is 20 km/h [6].

In this study, it is focused to reveal the possible effects of Sakarya Adapazari - Serdivan Tram Line on Sakarya transportation. The necessity of large-scale projects such as rail system investments, their optimal cost, the location or route where they will be built, the possible damage to the environment and other effects that may arise should be carefully examined. Since the proposed system is an at-grade LRT project, potential traffic congestion has raised significant concerns among the public. In this study, the reality of these concerns was investigated by consulting the opinions of Sakarya Metropolitan Municipality Transportation Department officers, academicians and engineers working in the field of transportation.The positive and negative effects of the projects and investments that are the subject of this study on the city were examined with the Delphi technique. In this technique, two rounds of questionnaires were applied to the officers of the Sakarya Metropolitan Municipality Transportation Department, academicians and engineers who are experts in the field of

transportation working in the project, unaware of each other. The responses given at the end of each round of surveys were evaluated with statistical analyses and it was confirmed whether a consensus was reached on each item. As a result of the survey rounds, the questions on which a common decision could not be reached were redirected to the experts in order to reach a consensus.

2 Sakarya Adapazari – Serdivan Tram Line

The planned Sakarya Adapazari - Serdivan Urban Tram Line has a total route length of 15,4 km and 18 stations, and has been designed as the main public transportation backbone in the urban corridor with high travel demand. In order to overcome the topographic thresholds and narrow land use constraints in the city center, the maximum longitudinal slope was designed as 9.0% in the vertical geometric design of the line. This gradient value is within operationally operable limits thanks to the high traction and drive systems of modern very light rail vehicles.

A total of 2,275 meters long engineering structure was designed in order to keep the line within the slope limits, to maintain the operating speed and to minimize surface traffic intersections. These structures are; It consists of 1,070 meters of open U-section and 1,205 meters of cut and cover tunnel structure. The route mainly proceeds in the Right-of-Way Category B type; TCDD, which provides regional train integration, provides direct service to strategic locations such as Adapazari Station and Cark Street, which is the main pedestrian/commercial axis of the city. Thus, the line establishes a seamless and highly accessible transportation link between the historic city center of Adapazari and the thriving residential and education-oriented areas of Serdivan.

3 Materials and Methods

The 13-question survey detailed in Table 1 was administered to the expert group

Table 1 - Questions

Possible User Effects of Sakarya Adapazarı - Serdivan Tram Line on Sakarya Transportation

A. Please rate each of the statements compiled below regarding Integration and Competition with Existing Public Transportation (Dolmus/Minibus) on a scale from 1 to 5 (1 = Strongly Disagree, 2 = Disagree, 3 = Undecided, 4 = Agree, 5 = Strongly Agree). **Note: If desired, you may write the rationale for your score in the line provided below each item.**	**Rating**
1)Once the Adapazari–Serdivan tramway line becomes operational, existing dolmus and minibus lines along this corridor should be completely phased out and converted exclusively into 'perpendicular feeder lines'.	**-**
Reason:	
2) In order to ensure the financial sustainability of the tramway system, the service frequencies of road-based public transit vehicles on parallel routes should be reduced.	**-**
Reason:	
3) Considering the mobility habits of the residents of Sakarya, if the access distance to tram stops exceeds 500 meters, passengers will continue to prefer the more flexible dolmus instead of the tramway.	**-**
Reason:	
B. Please rate each of the statements compiled below regarding Risk Analysis on a scale from 1 to 5 (1 = Strongly Disagree, 2 = Disagree, 3 = Undecided, 4 = Agree, 5 = Strongly Agree). **Note: If desired, you may write the rationale for your score in the line provided below each item.**	**Rating**
4) The intersection congestion issues observed in the Sakarya Metrobus (BRT) operation are highly likely to occur on the at-grade (street-running) Tramway line as well.	-
Reason:	
C. Please rate each of the statements compiled below regarding Risk Factors and Reflections of the Metrobus Experience on a scale from 1 to 5 (1 = Strongly Disagree, 2 = Disagree, 3 = Undecided, 4 = Agree, 5 = Strongly Agree). **Note: If desired, you may write the rationale for your score in the line provided below each item.**	**Rating**
5) Traffic congestion stemming from lane reductions in the Metrobus project carries a high risk of causing similar or more severe operational chaos on the at-grade Tramway line.	-
Reason:	
6) The failure to fully integrate the tramway system with existing dolmus and minibus routes (i.e., failing to transform them into feeder routes) is the most critical operational risk that will undermine project efficiency.	-
Reason:	
7) The "door-to-door" travel habits (dolmus culture) of Sakarya residents and students, coupled with resistance to walking distances, will keep demand for a station-based tramway system below expectations.	-
Reason:	

8) Long-term disruptions in the city center during construction (particularly along Cark Street and its feeder roads) will lead to a loss of public support before the project is completed.	-
Reason:	
D. Please rate each of the statements compiled below regarding the Impacts and Travel Demand of the Adapazari – Serdivan Line on a scale from 1 to 5 (1 = Strongly Disagree, 2 = Disagree, 3 = Undecided, 4 = Agree, 5 = Strongly Agree). **Note: If desired, you may write the rationale for your score in the line provided below each item.**	**Rating**
9) The tramway line will reduce private vehicle and private shuttle usage by Sakarya University students for campus access by at least 20% within the next 5 years.	-
Reason:	
10) Retail trade volume along Cark Street and Medeniyet Boulevard will be positively influenced by the pedestrianization effect generated by the tramway.	-
Reason:	
11) The tramway line carries the risk of remaining merely a 'campus line' focused solely on student transport; its contribution to overall urban transit will be limited.	-
Reason:	
E. Please rate each of the statements compiled below regarding the Future Vision and System Expansion on a scale from 1 to 5 (1 = Strongly Disagree, 2 = Disagree, 3 = Undecided, 4 = Agree, 5 = Strongly Agree). **Note: If desired, you may write the rationale for your score in the line provided below each item.**	**Rating**
12) In long-term planning, the existing Metrobus route should be decommissioned, converted into a tramway corridor, and integrated into the rail transit network.	-
Reason:	
13) In long-term planning, rather than planning new tramway lines, the Adapazari–Serdivan Tramway Line should be extended.	-
Reason:	

3.1 Delphi Method

The Delphi technique was developed in the 1950s by researchers Olaf Helmer and Norman Dalkey to systematically elicit expert consensus on military-related issues [7]. Delphi is a "method for structuring a group communication process so that the process is effective in allowing a group of individuals, as a whole, to deal with a com plex problem." The belief is that the group's judgment will have more validity, and will be more complete and accurate than individual points of view [10]

Project designers and technical personnel frequently encounter situations where decision-makers approach a problem from different perspectives, leading to conflicting viewpoints. These differences of opinion may arise regarding the necessary features of a product, the viability of a proposed project, the prioritization of objectives, or the required qualifications of personnel. The Delphi technique is utilized as a consensus-building tool in environments

characterized by such divergent views. It is particularly effective when decisions must be made in political or emotionally charged contexts, or where outcomes risk being influenced by dominant individuals or groups. Defined as a consensus-building mechanism, Delphi systematically solicits expert judgments regarding a specific problem domain. By applying the Delphi technique, individuals and groups with varying perspectives aim to achieve consensus without face-to-face interaction [8], [9].

Anonymity in participation is one of the most critical characteristics of the Delphi technique. The identity behind each proposed opinion is kept confidential throughout the research process. Consequently, ideas are emphasized rather than individuals, preventing unconditional agreement with the views of well-known or highly respected figures within the group. The principle of anonymous participation ensures that diverse and novel ideas can be shared freely without hesitation [8].

Statistical analysis of group responses is conducted after the administration of each Delphi survey round. Participants must thoroughly understand the meaning of the statistics used in these analyses [8]. In this context, the researcher(s) must clearly inform participants regarding the interpretation and significance of the applied statistical analysis results [9].

Controlled feedback; In the Delphi technique, successive questionnaires are used. After the statistical analysis of the survey is completed, the results showing the general trend of the participants are communicated to the participants in the next round. In this way, individuals re-evaluate their own thoughts by comparing them with the results, different opinions and approaches conveyed to them [9].

3.2 Application of the Delphi Method

First, the problem should be identified and described in a few words in a way that all participants can understand [8]. There should be a participant group of at least seven experts who have knowledge and perspective thanks to their experience and qualifications in the work done. The ideal group size consists of 10-20 specialists. Expert groups can be formed from university faculty members in related branches and employers in related fields [8]. First, a 13-question questionnaire containing the problems that may be encountered and possible effects on the project was forwarded to the expert team. All items prepared in the first Delphi questionnaire are forwarded to the participants and they are asked to indicate the level of agreement with each item on a 5-point or 7-point Likert scale. After the second round of survey responses are collected, the 1st quartile, median, 3rd quartile, and interquartile range (IQR) values are calculated for each item [8].

The second Delphi survey is the same as the first round of the survey. In this round, each item is accompanied by the participant's response to that item with the 1st, median, 3rd quartile, and IQR values calculated as a result of the first round. In the second round of the survey, participants are asked to review their responses from the first round, taking into account statistical values. The values calculated in the first round are also calculated for the answers at the end of the second round and evaluated by comparing them with each other. If there is a decrease in the IQR values calculated in the first round for any item in the third round, it can be said that there is a tendency towards consensus for that article. [11].

In this study, while preparing the Delphi survey, the relevant project was meticulously examined and what possible pros and cons there may be in the projects were evaluated. Then, the reservations of the public about the projects were investigated and as a result, it was decided to evaluate the positive and negative aspects of the projects under four main headings (integration management, operational performance and risks, accessibility and social acceptance, socio-economic impact). In the next stage, a participant list consisting of designer engineers (Private Sector), Municipal transportation department officers and academicians from Sakarya University (12 people) working in the Sakarya Adapazari - Serdivan Tram Line

project was prepared. Then, 4 questions were prepared under 13 main headings about the Sakarya Adapazari - Serdivan Tram Line. The questionnaire with the questions was forwarded to each expert in the participant group.

13 experts responded to the first round of the survey. The responses of the experts were evaluated and organized into bullet points to adapt to the format of the second survey. The items prepared in the second questionnaire were adapted to the 5-point Likert scale. Participants were asked to rate each item on a scale of 1 to 5 (1 = strongly disagree, 2 = disagree, 3 = undecided, 4 = agree, 5 = strongly agree). 13 respondents responded to the second round of the survey. The responses were compiled and the 1st quartile, median, 3rd quartile and IQR values were calculated for each item. Having a smaller IQR value means reaching a consensus. In this study, it was accepted that the articles with a IQR value below 1.2 were agreed upon [7].

Then, the second and final round of the questionnaire was conducted and sent to the respondents, who were the respondents of the first round. The second round was conducted in a similar way to the first round of the survey. The 1st quartile, median, 3rd quartile, and IQR values calculated at the end of the first round were added to the second round of the survey, and the participants were asked whether they changed their answers in the second round by taking these values into account. 13 participants responded to the second round of surveys. The responses were recompiled and quartile, median, quartile, 3rd, and IQR values were calculated for each item. Agreed and unagreed articles have been identified.

4 Results

In the last round of the Delphi survey, it was seen that consensus was reached on 11 of the 13 questions.

Possible effects of Sakarya Adapazari - Serdivan Tram Line on Sakarya Transportation:
Integration Management it was examined by 3 items and all of those were agreed upon,
operational performance and risks it was examined by 5 items and 4 of those were agreed upon,
accessibility and social acceptance it was examined by 3 items and 2 of those were agreed upon,
Socio-Economic Impact It was examined by 2 items and all of those were agreed upon.

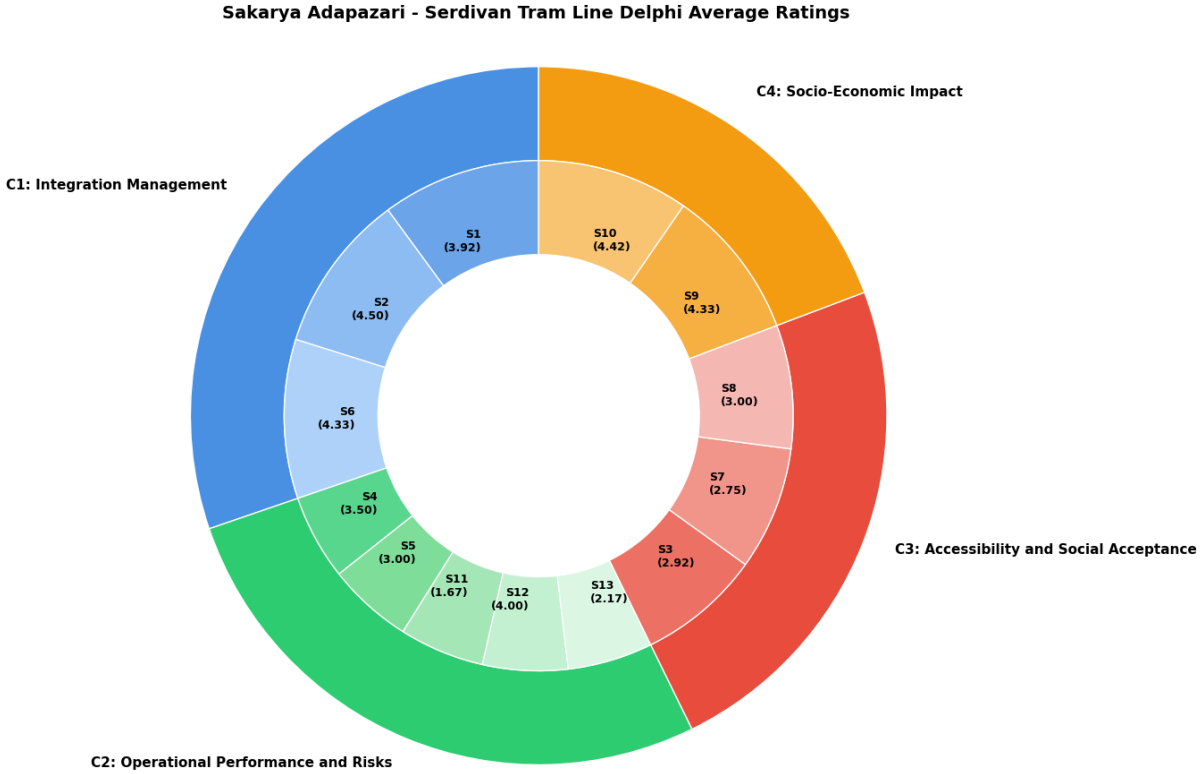

Figure 2 - Average Ratings

In our analyses regarding the detailed examination of the possible effects of the Sakarya Adapazari - Serdivan Tram Line on Sakarya Transportation, it is concluded that a consensus has been reached at the level of "I agree" with the questions about the integration management of the tram line to be made. The decision to organize public transportation vehicles integrated with the tram to be built before the tram is common.

Survey questions on operational performance and risks include the possible effects of the tram line on Sakarya traffic and solutions that can be made to increase tram usage. In the survey responses, it was seen that a consensus was reached in 4 out of 5 questions.

Survey questions were asked about the habits of the people of Sakarya and their adaptation to the use of trams in terms of accessibility and social acceptance. Consensus was reached on 2 of the 3 questions. In the survey responses, it was seen that a consensus was reached at the level of "I am undecided".

Finally, a consensus was reached on 2 questions on socio-economic impact. The possible effects of the tram on the economy of Sakarya and the effects on the places on the route it passes are in the form of the questions conveyed on this subject. The survey responses concluded that a consensus was reached at the level of "agree".

As a result, it is clear that the Sakarya Adapazari - Serdivan Tram Line will be an important part of transportation for Sakarya. However, the issue that has not been agreed upon is the negative effects on Sakarya traffic both during the construction phase and when it becomes operational. The most important issue during the project design phase is that the tram proceeds in traffic at the level and does not increase possible traffic jams. The issues that have been agreed upon are generally their positive effects. There is a common idea that it should revitalize the route it passes, be highly preferred as a use, be designed in a holistic structure with road – based public transit and integrate other public transportation.

Abstract

Cooperative Intelligent Transportation Systems (C-ITS) enable real-time data exchange among vehicles, infrastructure, and road users. However, most existing Intelligent Transportation Systems (ITS) applications remain focused on traffic monitoring, data collection, and operational control rather than creating dynamic and continuously updated digital representations of road infrastructure. Although digital twin technologies have gained increasing attention in transportation research, corridor-scale approaches integrating real-time data synchronization, roadside units (RSUs), edge AI, V2X communication, and traffic management centers remain limited.

This study examines digital twin road corridors from a C-ITS perspective through a conceptual review of recent literature and selected C-ITS and smart-road initiatives. The roles of sensor networks, AI-supported camera systems, IoT-based data collection, edge computing, and V2X communication are examined, while C-Roads, NordicWay, and selected smart-road initiatives are reviewed to identify relevant practices and implementation approaches. Based on this synthesis, the study proposes a five-stage Digital Twin Corridor Maturity Framework describing the transition from conventional infrastructure toward sensor-enabled, cooperative, digital twin, and adaptive corridor systems. In addition, a C-ITS-based implementation framework for Türkiye is proposed, integrating physical road infrastructure, RSUs, AI-supported perception systems, traffic management centers, cloud/edge computing, and the digital twin platform within a unified architecture.

The analysis suggests that digital twin road corridors can extend beyond conventional traffic monitoring by supporting real-time decision-making, predictive traffic management, and adaptive corridor operations. However, standardization, interoperability, data governance, cybersecurity, and infrastructure compatibility remain key challenges. In view of Türkiye's emerging 5G-supported smart road initiatives, the proposed framework provides a conceptual basis for the future development of C-ITS-enabled digital road corridors.

Keywords: C-ITS; Digital Twin Road Corridors; Predictive Traffic Management

1. Introduction

Cooperative Intelligent Transportation Systems (C-ITS) are emerging as a next-generation transportation approach based on real-time data sharing among vehicles, road infrastructure, and traffic management centers. Through Vehicle-to-Everything (V2X) communication technologies, the goal is for the infrastructure to move beyond being merely a physical component of transportation and actively participate in sensing, communication, and decision-

making processes. This transformation offers significant opportunities for improving traffic safety, optimizing traffic flow, and supporting sustainable transportation policies [1].

However, the majority of Intelligent Transportation Systems (ITS) applications currently in use are limited to functions such as traffic monitoring, incident management, and operational traffic control. Although current systems collect information from various data sources, they are unable to create an integrated digital structure that represents the physical road infrastructure in real time and is continuously updated. In particular, the widespread adoption of connected and autonomous vehicles necessitates the transformation of infrastructure into smart systems capable of not only generating data but also perceiving their surroundings, generating predictions, and providing decision support [2].

Against this background, Digital Twin (DT) technology has attracted increasing attention in transportation research. The DT approach integrates monitoring, analysis, simulation, and decision-support processes by creating digital representations of physical systems synchronized with real-time data. Recent studies indicate that DT technology holds significant potential for the management of transportation infrastructure throughout its lifecycle [3].

However, the existing literature largely focuses on DT applications in building management, industrial production systems, smart cities, and individual transportation infrastructure elements such as bridges, tunnels, and pavements [4]. While European-scale C-ITS initiatives such as C-Roads and NordicWay have demonstrated the feasibility of interoperable V2X services, they do not offer an approach that integrates sensor networks, roadside units (RSUs), artificial intelligence, edge computing, cloud data management, and traffic management centers within a corridor-scale DT architecture [2, 5].

In this context, there is a significant gap in the literature regarding an integrated DT Road Corridor reference architecture applicable at the corridor scale, a systematic maturity framework for assessing technological development levels, and an implementation model for adapting the approach to Türkiye's transportation ecosystem. This study addresses this gap with three key contributions. First, a Digital Twin Road Corridor Reference Architecture that addresses C-ITS components in an integrated manner is proposed. Second, a five-level Digital Twin Road Corridor Maturity Framework is developed to assess the technological transformation of road corridors from static infrastructure to adaptable digital twin corridors. Finally, by jointly evaluating international best practices alongside Türkiye's C-ITS vision and 5G-enabled smart road initiatives, a C-ITS-based DT Road Corridor Implementation Framework is proposed for Türkiye.

2. The Digital Twin Road Corridor Approach and Literature Review

In this section, DT approaches in transportation infrastructure are evaluated in conjunction with C-ITS-based smart road applications, and the theoretical foundations of the proposed corridor architecture are presented.

2.1. Digital Twin in Transportation

DT applications in the transportation sector cover various areas of application, including the lifecycle management of infrastructure assets such as bridges, tunnels, pavements, and highways, as well as structural health monitoring, maintenance planning, traffic operations, and decision support systems [4], [6]. Research conducted particularly in recent years demonstrates that DT technology can be effectively utilized in real-time data collection, the evaluation of operational performance, and predictive maintenance processes [7]. In addition, DT architectures for highway infrastructure highlight the importance of sensor networks, data management, and analysis layers that enable a continuous flow of data between the physical infrastructure and the digital platform [3].

2.2. Current Intelligent Road Projects

The field implementation of C-ITS has gained significant momentum in recent years, particularly in Europe and Asia. The projects developed within this framework demonstrate the

feasibility of implementing key C-ITS components—such as V2X communication, roadside units (RSUs), traffic management centers, and real-time data sharing—at various scales. However, the focus areas, technologies used, and scope of implementation vary depending on each country's transportation policies and technological infrastructure.

The C-Roads Platform, implemented in Europe, is one of the most comprehensive initiatives aimed at developing interoperable C-ITS services across different countries. Within the scope of the project, services such as hazardous road conditions, roadwork, traffic congestion, and variable speed management have been tested using common communication standards, with a strong emphasis on cross-border interoperability [2]. Similarly, the NordicWay project has focused particularly on cross-border data sharing and cooperative traffic services by implementing real-time V2X services over cellular communication infrastructure in the Nordic countries [5].

In applications outside Europe, smart road and connected transportation projects being carried out in China and South Korea demonstrate trends toward the integration of components such as advanced sensing systems, AI-powered data processing, 5G-based communication, and autonomous vehicle testing environments into transportation infrastructure. These applications demonstrate that digital road infrastructure is not limited to communication systems alone; rather, it must be viewed as a comprehensive ecosystem encompassing data collection, analysis, decision support, and traffic management processes [6].

2.3. Literature Review

In transportation infrastructure, DT technology goes beyond the traditional reactive management approach to offer a dynamic, proactive, and data-driven approach that encompasses the entire project life cycle—from planning and design through construction, operation, maintenance, and decommissioning. In a comprehensive literature review conducted by Wu et al. (2025), DT systems for transportation infrastructure were categorized based on their functional scope and data integration methods; a "4 Horizontal + 4 Vertical + N"-based urban transportation architectural framework, comprising data, model, service, and application layers, as shown in Figure 1, was proposed. However, the majority of applications in the existing literature focus on independent components such as traffic flow management or structural health monitoring (SHM) of structures like bridges and tunnels; it is emphasized that critical technical challenges—such as the integration of multi-source heterogeneous data, real-time data processing latency, and a lack of interoperability between systems—persist. This situation underscores the need to advance efforts to establish a standardized road corridor architecture that enables data sharing among heterogeneous devices within the C-ITS ecosystem and to design a maturity framework that evaluates the evolutionary development of these systems [7].

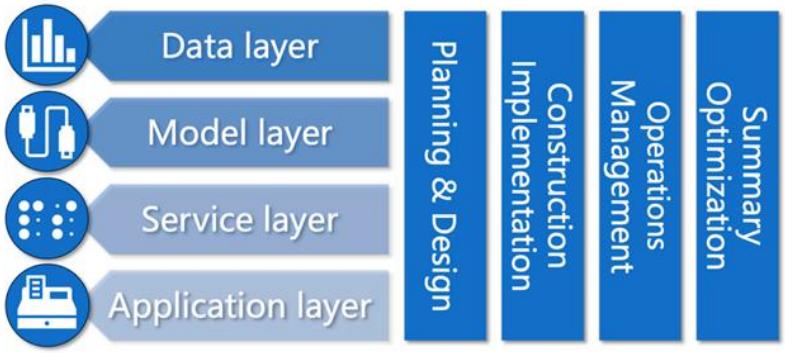

Figure 1. DT framework for urban transportation infrastructure based on the "4 Horizontal + 4 Vertical + N" model [7].

In the literature, theoretical frameworks and general reference architectures for the integration of ITS and DT technologies have begun to be developed. Indeed, Irfan et al. (2024) proposed a hierarchical Transportation DT (TDT) architecture extending from the individual entity level to the network level and comprehensively compiled potential application areas. However, a large portion of existing studies either remain at the conceptual level or are limited to simulation scenarios at the scale of a specific intersection or corridor. In dynamic transportation networks, the real-time synchronization of heterogeneous and large-scale sensor data, the instantaneous estimation of missing information, and the low-latency real-time processing requirements for network-wide proactive optimizations are among the technical challenges on which current research is focusing. Furthermore, the high uncertainty inherent in driver and pedestrian behavior makes it difficult for existing data-driven and physics-based models to generate scalable decisions on their own [8].

Studies on highway infrastructure demonstrate that DT technology must be approached as an integrated framework—encompassing data management, system modeling, and service layers—rather than merely creating a digital representation of the physical infrastructure. In this context, the proposed architectures aim to monitor and manage highway infrastructure throughout its lifecycle via multi-layered structures comprising physical infrastructure, virtual models, data management, connectivity, and service components [3]. Similarly, DT approaches developed for transportation systems focus on enhancing traffic safety, mobility management, and operational decision-support processes by integrating the physical, digital, and communication layers [8].

A comprehensive review of the existing literature reveals that DT technologies are being addressed in an increasingly comprehensive manner within transportation infrastructure. While Wang et al. [3] proposed a multi-layered DT architecture for road infrastructure, Wu et al. [7] comprehensively examined data integration, architectural layers, and decision-support mechanisms in transportation infrastructure. Similarly, Irfan et al. [8] presented a scalable DT reference architecture for transportation systems. Despite these advances, few studies integrate physical road infrastructure, RSUs, V2X communication, sensor networks, AI-based analytics, edge/cloud computing, and Traffic Management Centers (TMCs) within a single corridor-scale operational architecture. Similarly, while existing research focuses on DT architectures or functional layers, maturity models capable of systematically evaluating the technological transformation of corridors are also addressed only to a limited extent. Furthermore, despite international developments, studies on application frameworks that link Türkiye's C-ITS ecosystem, national strategy documents, and 5G-enabled pilot applications to a DT approach are considered an emerging area of research. To address these gaps, an integrated DT Road Corridor Reference Architecture, a five-level maturity framework, and a C-ITS-based implementation framework for Türkiye are proposed.

3. Proposed Digital Twin Corridor Maturity Framework

3.1. Design Approach of the Reference Architecture

Rather than being based on a specific technology or communication infrastructure, the proposed reference architecture is designed as a modular and scalable structure centered on the core functions that a DT-based transportation corridor must fulfill. Three fundamental design principles were adopted in the development of the reference architecture. These design principles align with the physical-digital mapping, continuous data flow, multi-layered architecture, service-oriented usage, and decision-support requirements throughout the lifecycle—all of which are emphasized in the current literature on transportation digital twins. First, the goal is to transfer and update data obtained from the physical road corridor to the digital environment in real time. Second, a flexible architectural structure has been adopted to ensure that different sensing and communication technologies can be integrated into the system in an interoperable manner. Finally, a closed-loop data flow has been established to ensure that

the generated information is used not only for monitoring purposes but also in traffic management and operational decision-support processes. The six-layer reference architecture developed in accordance with these principles is described in the following section.

3.2. Definition of Architectural Layers

The proposed DT Road Corridor Reference Architecture is based on an integrated data lifecycle that enables the sensing, secure transmission, processing, digital representation, and conversion of data generated within the physical road corridor into operational decisions. The architecture consists of six complementary functional layers; while each layer performs a specific task, it also forms part of the data flow that feeds the subsequent layer. Thus, the system transcends the role of a mere data-collecting infrastructure; through a real-time feedback mechanism, it acquires a closed-loop structure that ensures continuous synchronization between the physical corridor and the DT. Figure 2 visualizes the proposed DT road corridor reference architecture and the closed-loop data flow. The architecture also addresses cybersecurity, data governance and privacy, interoperability and standards, and organizational collaboration as cross-cutting enablers that support all six functional layers.

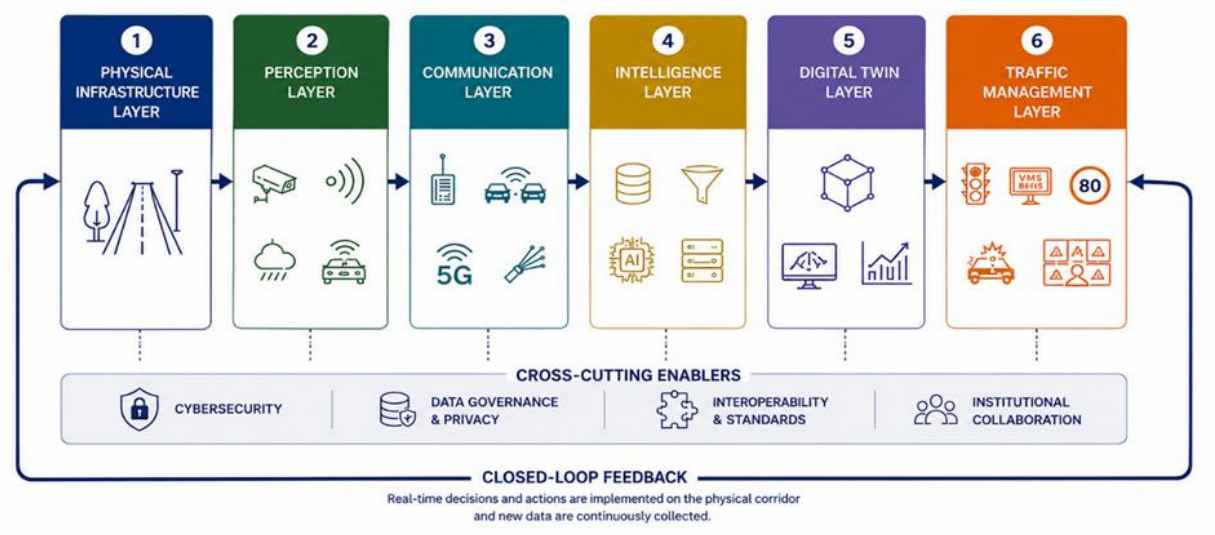

Figure 2. Proposed DT Road Corridor Reference Architecture and Closed-Loop Data Flow

In the proposed architecture, data obtained from the Physical Infrastructure and Perception layers is transmitted to the upper layers via the Communication Layer; it is processed in the Intelligence Layer and used to create a dynamic digital representation of the physical corridor in the Digital Twin Layer. The Traffic Management Layer, in turn, ensures that Digital Twin outputs are converted into operational decisions and fed back to the physical corridor. Thus, the architecture forms a closed-loop structure spanning from perception and data transmission to predictive analysis and operational intervention. The basic functions, components, and data types processed by the layers are summarized in Table 1. In this context, the layers comprising the proposed reference architecture have been defined by considering their basic functions, main components, and the data flow between layers (Table 1). The proposed layers have been designed to seamlessly represent the data, information, and decision lifecycle, extending from the physical system to the generation of operational decisions.

Table 1. Layers of the Proposed DT Road Corridor Reference Architecture

Layer	Basic Function	Main Components	Data Generated/Processed
Physical Infrastructure Layer	Represents the physical route corridor	Roads, intersections, lanes, traffic signals, VMS, vehicles	Physical status information
Perception Layer	Collects data from the physical environment	Cameras, LiDAR, radar, IoT sensors, weather sensors	Raw sensor data
Communication Layer	Transmits data securely and in real time	RSU, OBU, V2X, 5G, fiber-optic network	Communication messages
Intelligence Layer	Analyzes and interprets the data	Edge computing, AI, data fusion, analytics engines	Processed data
Digital Twin Layer	Creates a dynamic digital representation of the physical system	DT platform, simulation, data model	Digital corridor status
Traffic Management Layer	Generates and implements operational decisions	Traffic Management Center (TMC), adaptive signal control, VMS, speed management	Control decisions

3.3. Digital Twin Corridor Maturity Framework

While the DT Corridor Reference Architecture defines the functional structure of the corridor, a systematic assessment approach is needed to compare the levels of digital transformation across different road corridors. The maturity framework developed for this purpose is based not only on the technologies the corridor possesses but also on the operational capability these technologies collectively create. Thus, two different corridors with the same hardware components can be assessed at different maturity levels based on their capabilities in data generation, communication, digital synchronization, and decision-making.

The proposed model consists of five levels (Level 1–Level 5). Each level encompasses all the capabilities of the previous level and progresses by adding new functions. Transition between levels is determined not only by the addition of new technologies to the system but also by advancements in data management, communication infrastructure, DT integration, and operational decision-making capacity. Therefore, for a corridor to be assessed at a specific level, it is expected that the fundamental technical and operational requirements associated with that level are met collectively.

The levels proposed in this study are named Conventional Corridor, Instrumented Corridor, Cooperative Corridor, Digital Twin Corridor, and Adaptive Digital Twin Corridor (Table 2). Each level represents the new capabilities gained by the corridor during its digital transformation process, and the distinct characteristics of the levels are summarized in Table 2. The maturity framework proposed in this study is not an empirical scale statistically validated with direct field data; rather, it is a conceptual assessment tool derived from the literature on transportation digital twins, highway infrastructure, C-ITS communication, and operational decision support. In subsequent phases, the framework must be tested through pilot corridor applications, and measurable performance indicators and threshold values must be determined for each level.

Table 2. DT Road Corridor Maturity Levels

Level	Level Definition	Key Features
Level 1	**Conventional Corridor**	A corridor structure based on physical road infrastructure, where digital data generation is limited and traffic management is largely reactive.
Level 2	**Instrumented Corridor**	A corridor structure capable of generating real-time data using sensors and detection systems, but which uses this data primarily for monitoring purposes.
Level 3	**Cooperative Corridor**	A corridor structure that enables data sharing between vehicles and road infrastructure and facilitates coordinated traffic management through RSU, V2X, and communication infrastructure.
Level 4	**Digital Twin Corridor**	A corridor structure in which continuous synchronization is maintained between the physical corridor and the DT platform, and where simulations and predictive analyses support operational decision-making processes.
Level 5	**Adaptive Digital Twin Corridor**	An adaptive corridor structure in which operational decisions are dynamically optimized through AI-powered analyses and closed-loop feedback mechanisms.

The term "Adaptive Digital Twin Corridor" does not refer to a corridor dedicated to driverless vehicles; rather, it refers to a corridor capable of generating adaptive and largely automated operational decisions by feeding DT outputs into traffic management systems. A conceptual definition of the levels is not sufficient on its own for comparing the maturity levels of corridors. Therefore, the technological and operational capabilities associated with each level must be evaluated together. Table 3 presents a comparative overview of the levels included in the proposed maturity model in terms of technological infrastructure, data processing capacity, communication capabilities, and decision-making capabilities. Thus, the fundamental differences between the levels can be assessed not only based on the technologies used but also based on the functional capabilities these technologies create within the system.

Table 3. Comparative Evaluation of Levels

Evaluation Dimension	L1	L2	L3	L4	L5
Sensor-based data generation	–	✓	✓	✓	✓
Real-time data monitoring	–	✓	✓	✓	✓
RSU and V2X communication	–	–	✓	✓	✓
Multi-source data integration	–	△	✓	✓	✓
DT synchronization	–	–	–	✓	✓
Simulation and scenario analysis	–	–	–	✓	✓
AI-supported decision-making	–	–	△	✓	✓
Closed-loop adaptive management	–	–	–	–	✓

Note: ✓: Fully provided, △: Partially implemented, –: Not available.

While defining and comparing levels within the maturity model helps determine the current status of the corridor, the transition criteria between levels must also be clearly outlined. In this

context, Figure 3 summarizes the fundamental technical and operational requirements that a road corridor must meet in order to reach the next maturity level. Thus, the proposed framework not only provides a conceptual model for classifying the current state but also serves as an assessment tool that defines the development path corridors can follow during their digital transformation process.

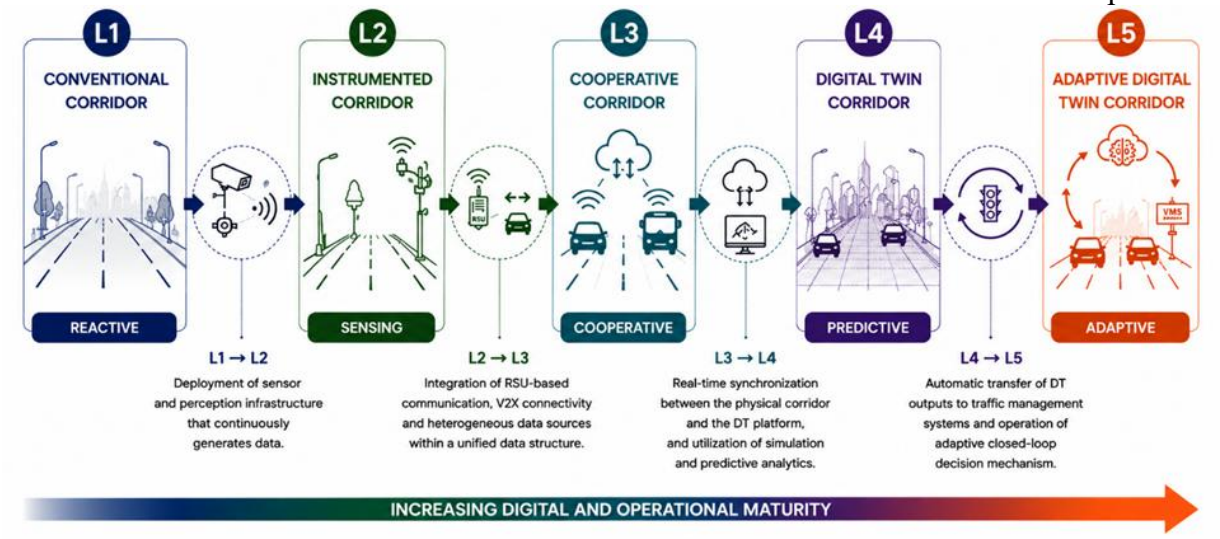

Figure 3. Criteria for Transition Between Levels

This framework makes it possible to compare different road corridors based on common criteria, determine current competency levels, and systematically identify the technical requirements necessary to reach the next level of maturity.

4. Implementation Framework for the Digital Twin Road Corridor in Türkiye

Strategic initiatives carried out in Türkiye in recent years in the field of C-ITS indicate that a significant transformation process has begun for the digitalizing transportation infrastructure. Under the National Intelligent Transportation Systems Strategy Document and the 2024–2030 Action Plan, objectives have been defined for vehicle-to-infrastructure communication, data sharing, standardization, and smart road applications; furthermore, testing of communication- and collaboration-based applications in real-world road environments has begun via a 5G-enabled C-ITS test corridor [9], [10]. However, current efforts are primarily focused on the development of specific technologies and the validation of pilot applications; a systematic implementation approach for evaluating these components within a DT-based integrated corridor management model is still under development.

The reference architecture and five-level maturity framework proposed in this study provide a conceptual implementation framework that enables the evaluation of road corridors at different levels of development in Türkiye using a common methodology. Within this scope, the maturity level of the existing corridor is first determined; then, by identifying gaps in technological and operational capabilities, the transformation steps required to advance to the next level can be planned. Thus, the proposed approach can be used as a decision-support tool not only in the design of new corridors but also in the phased transformation of existing highway infrastructure into DT-based systems.

The proposed framework is compatible with interoperability-focused initiatives such as the C-Roads Platform and NordicWay in Europe, and references the communication and system architecture principles defined in the ETSI TS 103 301 and ISO/TR 7872 standards [1], [11]. However, this study goes beyond these standards by positioning the DT platform as the corridor's central decision-support component and integrating physical infrastructure, communication systems, data processing workflows, and operational management mechanisms under a single evaluation model. In this regard, the proposed implementation framework offers

a common reference approach that can be used for the planning, prioritization, and performance evaluation of future DT road corridors to be established in Türkiye.

5. Conclusion

The analysis indicates that, within the scope of C-ITS, road corridors should be considered not merely as physical infrastructures where traffic data is collected and monitored, but as cyber-physical systems that enable real-time data exchange, digital synchronization, predictive analysis, and operational decision support. A joint evaluation of DT initiatives in transportation infrastructure and C-ITS-based smart road applications has shown that current approaches offer significant contributions in the areas of data collection, communication, infrastructure management, and decision support; however, efforts to address these functions in an integrated manner at the corridor scale remain limited.

Accordingly, as the first contribution of this study, a DT Road Corridor Reference Architecture has been developed that integrates physical infrastructure, sensing, communication, data processing, DT, and traffic management processes under six functional layers. The proposed architecture is based on a closed-loop data flow that enables data obtained from the physical corridor to be processed in upper layers, synchronized within the DT environment, and the resulting decisions to be fed back into the physical system. Thus, DT is positioned not merely as a visualization or monitoring tool, but as a central decision-making and coordination component supporting corridor operations.

The second contribution of this study—the five-level DT Road Corridor Maturity Framework—defines the evolution of corridors from traditional infrastructure levels toward structures equipped with sensors and capable of cooperative, DT-based, and autonomous operation. The levels—named Conventional Corridor, Instrumented Corridor, Cooperative Corridor, Digital Twin Corridor, and Adaptive Digital Twin Corridor—are compared based on technological infrastructure, data processing, communication, and operational decision-making capabilities. The separate definition of transition criteria between levels enables the model to serve not only as a conceptual classification but also as a tool for assessing the current status of different corridors and identifying transformation requirements.

From Türkiye's perspective, national ITS strategies and 5G-supported C-ITS test corridor initiatives provide a significant foundation for implementing the proposed framework. However, validating the reference architecture under field conditions, developing measurable threshold values for maturity levels, and defining data governance, interoperability, cybersecurity, and institutional responsibilities should be key topics for future work. Implementations and performance evaluations conducted in pilot corridors will help test the adaptability of the proposed framework to different road types and operating conditions.

Declaration of Generative AI and AI-assisted technologies in the writing process

During the preparation of this work, the authors used Google NotebookLM, ChatGPT, DeepL and Abacus AI to assist with language editing, structural review, clarity checks, translation, and grammar. Following the use of these tools, the authors carefully reviewed, verified, and edited the content as necessary and take full responsibility for the final manuscript.

Abstract. This review synthesizes current knowledge on the physico-chemical identity and pavement performance of four recycled aggregate streams based on literature published between 1978 and 2023. These four streams include- Recycled Concrete Aggregate (RCA), Reclaimed Asphalt Pavement (RAP), Steel Slag Aggregate (SSA), and Crushed Brick (CB). Each material is classified according to its distinct physical and chemical characteristics. The review then examines how these characteristics affect asphalt and concrete mix design including adjustments to optimum bitumen content, the Equivalent Mortar Volume approach, and binder blending for RAP. Conventional index tests, such as Los Angeles Abrasion and Sulfate Soundness, are compared against performance-based methods including Micro-Deval and Resilient Modulus testing. This is done to evaluate their suitability for heterogeneous recycled materials. Mechanistic-empirical evidence shows a trade-off for RCA base layers. These layers can have higher resilient stiffness. But they also show increased susceptibility to permanent deformation. RAP-containing mixtures show a different trade-off. They may improve rutting resistance. But this can come at the cost of reduced fatigue life. Several key research gaps have been identified in this study. RAP binder blending, better mechanistic-empirical representation, performance-based specifications, and life-cycle assessment all need further study. These include source-dependent material variability and the lack of long-term field validation. Additionally, RAP binder blending, better mechanistic-empirical representation, performance-based specifications, and life-cycle assessment all need further study. These findings support a shift in practice. Pavement engineering should move from index-based acceptance toward performance-oriented characterization of recycled aggregates.

Keywords: Recycled aggregates; Pavement engineering; Mix design; Laboratory performance testing; Mechanistic-empirical evaluation; Sustainability.

1 Introduction

The global pavement industry is undergoing a shift in its approach to construction and demolition waste (CDW). These materials are increasingly being recognized as valuable resources rather than landfill waste [1]. Depleting natural aggregate (NA) resources, rising waste generation, and diminishing landfill capacity have created an urgent need to incorporate recycled materials such as Recycled Concrete Aggregate (RCA), Reclaimed Asphalt Pavement (RAP), Steel Slag Aggregate (SSA), and Crushed Brick (CB) into pavement systems [2,3]. Their incorporation can provide substantial environmental benefits. These include reductions of up to 65% in greenhouse gas emissions and 58% in non-renewable energy consumption

versus conventional NA in concrete [1,4]. However, unlike NA, these materials retain "material memory" inherited from their original sources and processing histories. Thus, additional engineering considerations are required [1,4].

Research as well as adoption on recycled aggregates is growing. But characterization and classification remain inconsistent across standards. Conventional testing protocols developed for homogeneous natural aggregates are often applied to recycled aggregates without change. Recycled aggregates, however, are heterogeneous, porous, and chemically reactive. This mismatch creates uncertainty in material selection, specification, and mix design.

This review addresses these gaps by systematically synthesizing current knowledge on RCA, RAP, SSA, and CB to: (1) classify these materials by physico-chemical characteristics and sources; (2) evaluate how these characteristics influence mix design and engineering performance; (3) examine performance-based laboratory testing as alternatives or complements to index testing; and (4) synthesize mechanistic-empirical (ME) evidence to identify key knowledge gaps and research priorities.

2 Methodology

This study used a systematic literature review framework. The framework followed established practice for recycled aggregate research [1]. It synthesized findings on four materials - RCA, RAP, SSA, and CB focusing on their use in pavement applications. Literature was covered from 1978 to 2023 across Google Scholar.

2.1 Search Strategy and Selection Criteria

Database searches combined material-specific terms ("recycled concrete aggregate", "reclaimed asphalt pavement", "steel slag aggregate", "crushed brick") with pavement-engineering terms ("mix design", "resilient modulus", "Micro-Deval", "mechanistic-empirical", "rutting", "cracking") using Boolean AND/OR operators. Studies were included if they were peer-reviewed, English-language journal articles (1978-2023) that investigated at least one target material for pavement applications and reported quantitative or technically interpretable physico-chemical, mix-design, laboratory, or ME performance data. Conference papers, non-English publications, theses, book chapters, technical reports, and studies unrelated to pavement applications, or lacking sufficient engineering detail, were excluded, along with duplicate records.

2.2 Screening and Selection Process

The literature-selection process followed four sequential stages - identification, screening, eligibility assessment, and inclusion. Searches identified more than 500 records; after removing duplicates and clearly irrelevant results, remaining studies were screened by title and abstract, then assessed in full text against the inclusion criteria, with particular emphasis on whether relevant engineering or performance data for RCA, RAP, SSA, or CB were reported. This process, illustrated in Fig. 1, is summarized as:

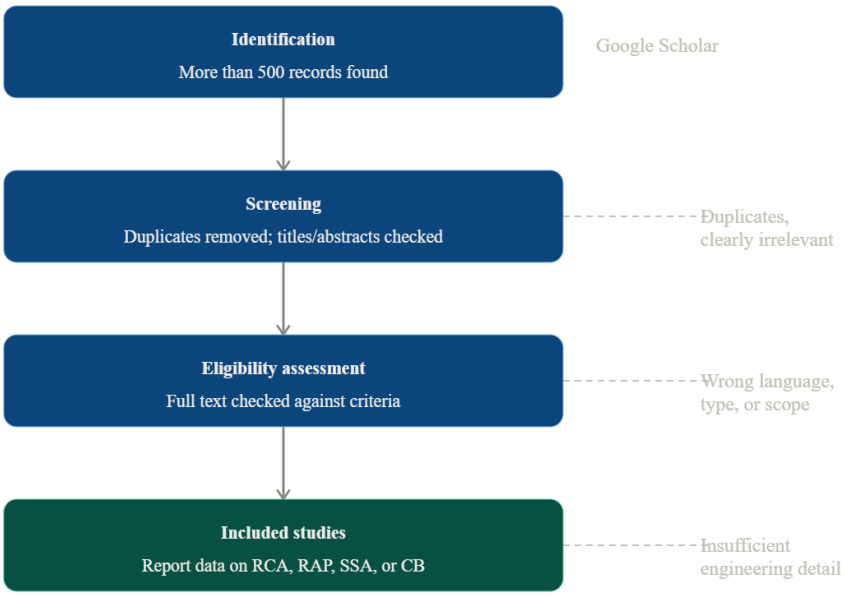

Fig. 1. Systematic literature identification, screening, eligibility assessment, and inclusion process for RCA, RAP, SSA, and CB studies.

2.3 Data Classification and Synthesis

The selected literature was organized by the origin and physico-chemical identity of each material [3], synthesizing source characteristics, physical and mechanical properties, environmental behavior, and pavement-application implications. Conventional index tests were critically compared against performance-based methods such as Resilient Modulus (Mr) and Micro-Deval testing [3], and ME approaches. These tests included tools such as AASHTOWare Pavement ME Design primarily focusing this examination on predicted rutting and cracking outcomes [5]. This synthesis linked three things together – (1) recycled-material characteristics and laboratory-measured properties, (2) laboratory properties and mix-design parameters, and lastly (3) mix-design parameters and pavement performance.

3 Physico-Chemical Properties of Recycled Aggregates

Recycled aggregates exhibit distinct physico-chemical characteristics governed by source material, processing history, contamination, and adhered or residual binder content [3,6]. Unlike relatively homogeneous natural aggregates (NA), recycled aggregates retain characteristics inherited from their parent materials. Properties such as density, porosity, water absorption, surface texture, chemical composition, and binder condition directly influence handling, mix design, and pavement performance. The principal characteristics of RCA, RAP, SSA, and CB are summarized in Table 1.

Recycled Concrete Aggregate (RCA): RCA consists of crushed concrete containing natural aggregate and adhered cement mortar. This mortar is typically porous and alkaline and may constitute 25–35% of RCA mass depending on parent concrete and crushing process [3]. RCA therefore generally shows lower density and substantially higher water absorption than NA (approximately 3–10% versus <1.5% for many conventional aggregates [3]). This directly influences effective water-to-cement ratio and asphalt binder demand, so moisture correction and pre-treatment are important during mix design.

Reclaimed Asphalt Pavement (RAP): RAP consists of mineral aggregate coated with aged, oxidized asphalt binder. This binder is stiffer and less ductile than virgin binder, and

substantially alters mixture rheology [8,9]. Increasing RAP content can increase stiffness and rutting resistance. However, it also increases susceptibility to fatigue or thermal cracking unless the aged binder is balanced by virgin binder or rejuvenators [8,9]. So RAP must be characterized by both aggregate properties and residual binder condition.

Steel Slag Aggregate (SSA): SSA is a dense (3.4–3.5 g/cm³), hard, angular industrial by-product [7]. It offers strong mechanical interlocking, abrasion resistance, and skid resistance, but may contain free CaO and MgO that hydrate and cause volumetric expansion [7]. Thus, SSA requires aging, weathering, or stabilization before use where dimensional stability is critical.

Crushed Brick (CB): CB, from crushed waste masonry, is characterized by high porosity, low density, and high water absorption (approximately 6–19%, well above conventional NA) [10,11]. It contributes to lower mechanical strength and greater degradation susceptibility under loading and environmental exposure. Water-soluble sulfates can create durability concerns in cementitious systems. Besides, capillary action within its porous structure can accelerate soundness-test deterioration [10,11].

Table 1. Physical property comparison of natural and recycled aggregates

Property	NA	RCA	RAP	SSA	CB
Bulk Density (g/cm³)	2.5–2.7	2.1–2.5	~2.4	3.4–3.5	~1.9
Water Absorption (%)	<1.5	3.0–10.0	1.5–2.0	0.7–1.3	6.0–19.0
LA Abrasion Loss (%)	10–30	20–45	~24	10–20	35–40
Porosity (%)	2–3	10–15	~5	4–8	>15

Overall, the four recycled streams exhibit fundamentally different material identities. RCA is primarily governed by adhered mortar and associated porosity; RAP by residual aged asphalt binder; SSA by its dense, angular, and potentially expansive mineral phases; and CB by its highly porous ceramic structure. These differences mean that recycled materials cannot be evaluated solely using the same criteria applied to conventional NA. Their physico-chemical characteristics must instead be explicitly incorporated into material selection, laboratory characterization, and pavement mix design.

4 Mix Design for Pavements

Incorporating recycled aggregates into pavement mixtures requires modifying conventional mix-design procedures. This is because higher absorption, heterogeneous composition, residual binders, and chemical reactivity can substantially alter mixture volumetrics and mechanical behavior [3,8,12]. The necessary adjustments depend on both material and pavement type. For flexible pavements, RCA generally increases optimum bitumen content (OBC). This increase is approximately 0.3–1.7 percentage points versus natural aggregate (NA) mixtures. The reason behind this is the porous adhered mortar because it absorbs part of the binder [3,12]. For this reason, two factors should be explicitly considered. These are aggregate absorption and effective specific gravity. For RAP, aged, oxidized binder is the principal challenge. Higher RAP content can increase stiffness and rutting resistance but reduce low-temperature and fatigue-cracking resistance. Hence, binder selection, blending, and rejuvenators are important for restoring stiffness-ductility balance [8,9].

For rigid pavements, conventional aggregate-volume replacement can overestimate new cement paste needed for RCA concrete. This can be attributed to the fact that adhered mortar already contributes to the mortar phase. Thus, the Equivalent Mortar Volume (EMV) approach accounts for this by proportioning mixtures based on the mortar associated with the recycled aggregate [3]. Treatments such as accelerated CO_2 curing have also been investigated to densify the RCA surface and reduce water absorption via carbonation of alkaline phases. This may

potentially improving early-age performance [13]. But effectiveness depends on RCA characteristics and carbonation degree. This should be verified experimentally rather than assumed universally.

4.1 Asphalt Mix-Design Parameters and Specification Context

Table 2 summarizes representative asphalt mix-design ranges reported for mixtures containing RCA and RAP [8,12]. The values illustrate the changes in mixture properties associated with recycled-material incorporation. They should not be interpreted as universal specification limits, because acceptance criteria depend on the selected mix-design method, nominal maximum aggregate size (NMAS), traffic level, binder grade, and governing agency specification.

Table 2. Representative asphalt mix-design parameters for natural and recycled-aggregate mixtures and their specification context.

Parameter	Natural Mix	RCA Mix (30–60%)	RAP Mix (25–50%)	Relevant specification/interpretation
Optimum Bitumen Content (%)	5.0–5.5	5.3–7.2	4.8–5.4	Project- and material-specific; no universal AASHTO M 323 limit
Marshall Stability (kN)	8–12	10–15	12–18	Marshall-method criterion; commonly ≥8 kN where applicable
Marshall Flow (mm)	2.0–4.0	2.0–3.5	2.5–4.5	Project/agency specific; commonly assessed with stability
Air Voids (%)	3–5	4–6	3–5	Superpave design target is typically 4% at N-design
Specification status	—	Generally compliant except upper-end air voids	Generally within typical ranges	Must be verified against the governing project specification

For Superpave volumetric design, AASHTO M 323 specifies a design air-void target of approximately 4.0% at N-design, with additional requirements for VMA, VFA, and compaction density. Moisture susceptibility is commonly evaluated using AASHTO T 283 with a minimum tensile strength ratio (TSR) of 0.80 [14]. Marshall Stability and Flow, by contrast, are not AASHTO M 323 requirements; where specified (per AASHTO T 245 or ASTM D6927), applicable minimum stability, flow, and air-void limits are set by the relevant agency. This is commonly around 8 kN stability and 3–5% air voids. But these are not universal values. The Asphalt Institute's MS-2 Asphalt Mix Design Methods treats Marshall and Superpave as distinct approaches. Under MS-2, criteria depend on two things. These are the selected design method and the specification framework.

On this basis, the Table 2 values indicate that reported RCA and RAP mixtures generally meet an 8-kN Marshall stability minimum where applicable. RCA mixtures, however, show air-void values up to 6%. This is above the typical 3–5% Marshall range and the 4% Superpave target and requires binder, gradation, or compaction adjustment before being specification-compliant. RAP mixtures (3–5% air voids) generally fall within range. Importantly, improved Marshall stability should not by itself be read as superior pavement performance. Higher stability may reflect increased stiffness. Despite being beneficial for rutting resistance, it is

potentially detrimental to fatigue or thermal-cracking resistance. This is especially true for aged RAP binder. Recycled mixtures should therefore be evaluated using volumetric requirements together with moisture susceptibility, rutting, fatigue, and cracking performance.

5 Laboratory Testing Protocols

Characterizing recycled aggregates requires care because many standardized index tests were developed for relatively homogeneous natural rocks and may not capture the heterogeneous, porous, composite nature of recycled materials [3]. A test result may reflect adhered mortar, residual binder, or pore structure rather than the aggregate skeleton alone. For RCA, the Los Angeles Abrasion test may be dominated by breakdown of the weak adhered mortar rather than the natural aggregate's fragmentation resistance [3]. Again, the Sulfate Soundness test can show comparatively high mass losses for porous materials owing to salt crystallization within interconnected pores [10]. Such results should be interpreted alongside morphology and absorption rather than as direct equivalents of dense natural-aggregate results.

5.1 Performance-Based Testing Framework

A tiered, performance-oriented testing framework is recommended. The first tier establishes fundamental physical and chemical characteristics (particle density, water absorption, gradation, contaminant content, chemical composition) for material classification and mix design. The second tier applies durability and mechanical-performance tests more representative of pavement service conditions. The Micro-Deval test (AASHTO T 327) measures resistance to abrasion and degradation in the presence of water. This is particularly relevant given the moisture-sensitive, porous nature of many recycled materials [3]. The Resilient Modulus (Mr) test (AASHTO T 307) characterizes recoverable deformation under cyclic traffic loading. It provides information more directly relevant to structural and ME design than a single-load index test. It is particularly useful for evaluating whether compositional or moisture differences in recycled base and subbase materials translate into meaningful load-bearing differences.

The resulting testing framework, shown schematically in Fig. 2, can therefore be represented as:

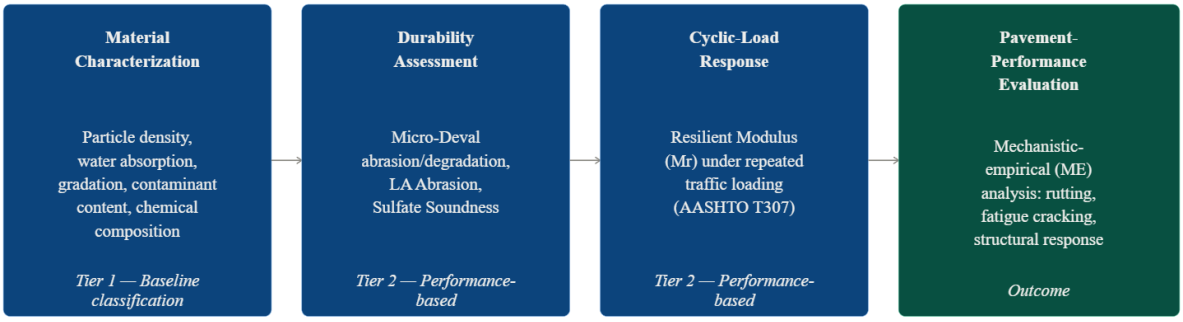

Fig. 2. Tiered, performance-based laboratory testing framework for recycled aggregates

This does not mean conventional index tests should be abandoned. They, however, remain useful for screening, classification, and quality control. But performance-based tests supply the additional evidence needed to establish engineering suitability. This is because two aggregates with similar index properties can behave very differently under repeated traffic loading or environmental exposure.

5.2 Environment and Leaching Assessment

Environmental characterization is a further dimension of assessment. Batch leaching tests provide standardized screening of contaminant release but may not fully reproduce the hydraulic and time-dependent release conditions of pavement systems. This is particularly relevant for materials such as steel slag, which can exhibit high initial alkalinity [5,14]. Column percolation or flow-through leaching tests can complement batch testing by capturing the evolution of contaminant release under controlled, repeated water flow. Thus, it offers a more field-representative assessment of temporal stability [5,14]. Overall, laboratory evaluation should move from isolated index properties toward a multi-level performance-based framework. This framework should combine physical characterization, mechanical durability, cyclic-load response, and environmental stability. Together, these elements would better link laboratory measurement to long-term pavement behavior.

6 Mechanistic-Empirical Performance

Mechanistic-empirical (ME) analysis evaluates whether the laboratory properties of recycled materials translate into acceptable pavement performance under realistic conditions. Pavement structures incorporating RCA in base or subbase layers can achieve performance comparable to natural aggregate (NA). This is only possible under certain conditions. Material quality, gradation, and moisture must be controlled. When they are, RCA's stiffness and particle interlock may permit reduced base-layer thickness. This should not be inferred from laboratory values alone, though. It should instead be confirmed by project-specific ME analysis [3,5]. For flexible pavements, RAP primarily acts as a stiffness modifier. Its aged binder can improve rutting resistance at elevated temperatures. But it may also reduce fatigue and thermal-cracking resistance. This trade-off requires careful control. RAP content, virgin binder grade, and, where necessary, rejuvenation all need attention [9]. RCA asphalt mixtures show a similar pattern. They also show favorable rutting resistance but a greater sensitivity to moisture and compaction. This sensitivity comes from their absorption and porosity [12].

For rigid pavements, recycled aggregate concrete may benefit from residual cementitious activity in the adhered mortar. This can continue hydrating and increase long-term stiffness [1]. However, the magnitude depends strongly on source concrete, carbonation, processing, and replacement level and should not be assumed uniform across RCA sources.

6.1 Mechanistic Performance Indicators

Table 3 summarizes representative mechanistic-performance indicators reported for NA, RCA, and RAP base materials [5]. The values should be interpreted as literature-reported ranges rather than universal design values. This is because resilient modulus, rutting, fatigue life, and permeability are strongly dependent on material gradation, moisture state, compaction, stress conditions, climate, traffic loading, layer thickness, and model calibration.

Table 3. Representative mechanistic-performance indicators for natural- and recycled-aggregate pavement materials.

Performance Metric	NA Base	RCA Base	RAP Base
Resilient Modulus (MPa)	200–350	250–550	300–700
Rutting Depth	Baseline	5–15% higher	10–20% lower
Fatigue Life	Baseline	Similar	15–30% lower
Permeability (cm/s)	(10^{-3})	(10^{-2})–(10^{-4})	(10^{-4})

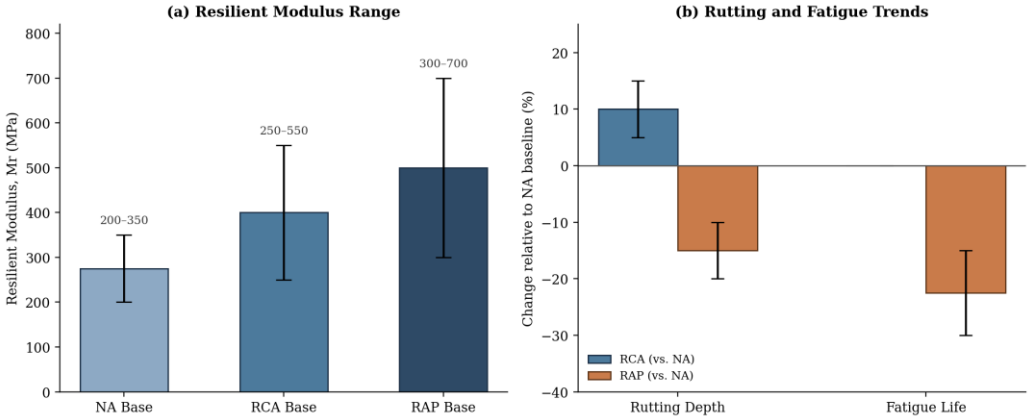

Fig. 3. Schematic comparison of resilient modulus, rutting, fatigue life, and permeability trends for NA, RCA, and RAP base materials.

As summarized schematically in Fig. 3, an important distinction must be made between resilient stiffness and permanent deformation resistance when interpreting Table 3. Although RCA bases may exhibit higher resilient modulus than NA, this recoverable-stiffness gain does not necessarily translate into proportionally lower rutting. Resilient modulus characterizes recoverable deformation under cyclic loading, while rutting reflects accumulated plastic deformation from particle crushing, rearrangement, and moisture-dependent effects. The reported 5-15% increase in RCA rutting is therefore not inconsistent with a higher resilient modulus. The two represent different aspects of pavement response. RCA suitability should be assessed alongside permanent-deformation and moisture-susceptibility indicators, not resilient modulus alone.

The RAP results show a related trade-off: higher stiffness can reduce rutting depth by 10-20%, but the same stiffness may lower fatigue life by approximately 15–30% [9]. Hence, ME evaluation of RAP-containing pavements should weigh rutting and cracking resistance together. It should not treat improvement in one distress as evidence of overall superior performance. Overall, RCA may combine high resilient stiffness with increased permanent-deformation susceptibility. Meanwhile, RAP may trade fatigue-cracking resistance for improved rutting resistance. These trade-offs reinforce the need for ME approaches incorporating multiple distress mechanisms and material-specific behavior.

7 Research Gaps and Recommendations

Despite substantial progress in characterizing and applying recycled aggregates in pavement systems, several limitations continue to restrict their reliable, widespread implementation. The reviewed literature points to five principal gaps: material variability, limited long-term field validation, RAP binder interaction, incomplete representation in mechanistic-empirical (ME) design frameworks, and the absence of performance-based specifications integrated with sustainability assessment.

7.1 Material Variability and Long-Term Field Validation

Recycled-aggregate properties are strongly governed by parent-material characteristics and processing history. For RCA, these are strength, age, and deterioration of the source concrete [6]. Again, for RAP, SSA, and CB, these include binder aging, steelmaking processes, and manufacturing conditions, respectively. This source-dependent variability limits broad material classifications as reliable indicators of performance. Compounding this, most existing evidence derives from laboratory or short-term studies, with comparatively few long-term field observations under realistic traffic and environmental conditions [5]. Future work should

combine two approaches. The first is source-to-performance databases. These link parent-material characteristics to pavement outcomes [1,6]. The second is long-term field monitoring. This monitoring should track resilient modulus, permanent deformation, and degradation. Regional conditions such as freeze–thaw cycling in cold regions and wet–dry and monsoon infiltration in tropical climates should be explicitly accounted for [5].

7.2 RAP Binder Blending and Chemical Interaction

The extent of blending between aged RAP binder and virgin binder remains uncertain. This blending varies with several factors including RAP content, particle size, mixing conditions, and rejuvenator use [9]. Assuming complete blending can be misleading and may misrepresent effective binder properties. Future research addressing this needs to combine three approaches. These are micromechanical characterization, binder rheology, and mixture-level performance testing. This combined approach would quantify RAP–virgin binder interaction and also help establish reliable blending models. Such models could then guide the selection of virgin binder grades and rejuvenator dosages [9].

7.3 Representation of Recycled Materials in ME Design

Current ME pavement design frameworks do not always explicitly represent recycled-material behavior, particularly moisture-dependent response, hydraulic characteristics, and nonlinear stress–strain behavior [5]. Future ME models should incorporate recycled-material-specific parameters such as Soil-Water Characteristic Curves (SWCCs), moisture-dependent resilient modulus, and degradation behavior [5]. This should be done to predict pavement response under changing conditions rather than relying on classifications developed for natural aggregates.

7.4 Performance-Based Specifications and Sustainability Integration

Conventional index tests do not fully capture heterogeneous recycled-material behavior. So, future specifications should combine basic classification with performance indicators such as resilient modulus, permanent deformation, and moisture susceptibility. Acceptance should be allowed based on demonstrated engineering performance rather than similarity to natural aggregates. This effort should be paired with life-cycle assessment (LCA), since additional processing, transport, or treatment can offset environmental savings. Integrating ME performance analysis with LCA would clarify the trade-off between environmental benefit and durability. Overall, future research should progress from isolated laboratory characterization toward source-specific databases, long-term field monitoring, performance-based specifications, and integrated ME–LCA frameworks. The core of this research would be to support the transition of RCA, RAP, SSA, and CB from case-specific use to reliable, scalable components of sustainable pavement infrastructure.

Abstract. Passenger satisfaction is an important indicator of service quality from the perspective of user experience in public transportation systems. At transfer centers where different transportation modes converge, both transfer conditions and vehicle service quality can influence the overall travel experience. This study examines the effects of passenger satisfaction with transfer center and vehicle services on overall satisfaction and compares satisfaction levels across transportation modes at the Konak, Halkapınar, and Bostanlı transfer centers in İzmir. A survey was conducted with 510 passengers, and 443 usable responses were obtained after data cleaning and excluding passengers making their first boarding at the transfer center. Satisfaction was assessed using a 5-point Likert scale. The data were analyzed using descriptive statistics, Pearson correlation, multiple linear regression, and one-way analysis of variance (ANOVA). The results showed that both transfer center and vehicle satisfaction were positively and significantly associated with overall satisfaction. Together, these variables explained 51.4% of the variance in overall satisfaction, with vehicle satisfaction ($\beta = 0.455$) having a stronger effect than transfer center satisfaction ($\beta = 0.340$). Significant differences in satisfaction levels were also found across transportation modes. Ferry users had the highest mean satisfaction scores across all three measures, while lower satisfaction levels were particularly observed among İZBAN and bus users. The findings highlight the importance of addressing transfer center conditions and vehicle services together through a holistic approach to improve passenger satisfaction.

Keywords: Public transportation, transfer center, passenger satisfaction, vehicle satisfaction, transportation mode.

1 Introduction

Public transportation is one of the fundamental components of urban transportation systems in metropolitan cities. In İzmir, approximately 31% of urban trips are made by public transportation, making it the second most widely used transportation mode after walking [1]. As the use of public transportation becomes more widespread, ensuring that the services provided meet user expectations and improve the travel experience has become increasingly important. In particular, transfer centers, which enable passengers to switch from one transportation mode to another, play an important role in the functioning of urban transportation systems, and the characteristics of these centers can directly affect passenger satisfaction.

When evaluating public transportation systems, it is important to consider not only the provision of transportation services but also how passengers perceive and evaluate these services. Previous studies have indicated that service characteristics such as service frequency, punctuality, waiting time, comfort, cleanliness, safety, accessibility, and passenger information

are associated with passengers' perceptions of service quality and satisfaction [2]. Similarly, the EN 13816 standard provides a framework for defining and measuring public transportation service quality based on passenger expectations and perceptions, identifying eight key quality areas, including accessibility, information, time, comfort, and safety [3]. In this context, passenger satisfaction can be considered an important indicator for evaluating public transportation services from the user's perspective. In addition to vehicle-related service characteristics, such as waiting time, punctuality, onboard comfort, cleanliness, safety, and information provision, factors related to transfer centers—including accessibility to the center, pedestrian connections between different transportation modes, the cleanliness and comfort of waiting areas, safety, accessibility for passengers with disabilities, and the quality of signage and information systems—also shape the overall travel experience. Therefore, evaluating transfer center and vehicle services together allows passenger satisfaction to be assessed from a more comprehensive perspective.

The relationship between public transportation service quality and passenger satisfaction has been examined across different transportation modes and cities. Eboli and Mazzulla [4] investigated the effects of various public transportation service attributes on user satisfaction, while Susilo and Cats [5] examined the factors influencing satisfaction in multimodal journeys. Sil et al. [6] focused on user comfort and satisfaction at transfer points and demonstrated the importance of different service attributes in shaping the user experience. Carvalho and El-Geneidy [7] investigated the key factors determining passenger satisfaction at hubs where road, rail, and maritime transportation intersect, as well as changes in satisfaction over time. In Türkiye, most studies have focused on transfer centers in Istanbul, while user perceptions, experiences, and satisfaction levels have not been directly examined [8-9]. Buran [10], on the other hand, found that "safety and security" was the most critical satisfaction dimension for both passengers and station operators, while passengers ranked "comfort and travel time" second.

Overall, although studies on passenger satisfaction are available in the literature, research examining the combined effects of satisfaction with services provided at transfer centers and the vehicles used on overall passenger satisfaction remains limited. Moreover, recent studies indicate that passenger satisfaction should not be evaluated based on a single service attribute but rather in relation to the different components of the overall travel experience.

The aim of this study is to examine the effect of passenger satisfaction with transfer center and vehicle services on overall satisfaction at the Konak, Halkapınar, and Bostanlı transfer centers in İzmir and to compare satisfaction levels among passengers using different transportation modes.

2 Materials and Methods

2.1 Study Area

The study area consists of the Konak, Halkapınar, and Bostanlı transfer centers located in İzmir city center (Figure 1). These centers were selected as the study area because they are important transportation nodes where different public transportation modes are integrated and where passengers frequently make transfers during their daily journeys.

Konak Transfer Center: Konak is an important transportation hub where metro, tram, ferry, and bus services converge. In addition to providing connections between different transportation modes, its central location contributes to high passenger activity.

Halkapınar Transfer Center: Halkapınar is an important transfer point served by metro, İZBAN, tram, and bus services. It has a particularly important role in providing connections between different rail-based transportation systems.

Bostanlı Transfer Center: Bostanlı is a transfer center where tram, ferry, and bus services converge. It is an important transportation node, particularly for connecting road-based and maritime transportation.

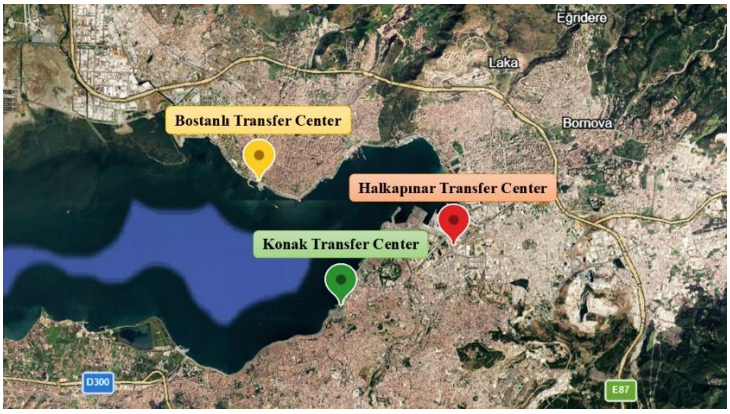

Fig. 1. Study Area and Locations of the Selected Transfer Centers

2.2 Survey Design

A passenger survey was conducted at the Konak, Halkapınar, and Bostanlı transfer centers located in different parts of İzmir, and survey data were collected for use in the study. A total of 510 passengers participated in the survey. After removing incomplete and invalid responses, 497 valid responses remained. Among these, responses from passengers making their first boarding at the transfer center were excluded, resulting in a final sample of 443 survey responses for the analysis.

The questionnaire was developed by adapting items from similar scales in the literature [11-12]. The survey collected the following information:

- Transfer center where the survey was conducted: Konak, Halkapınar, or Bostanlı
- Stage of transfer center use at the time of the survey: first transfer, second transfer, third transfer, or end of journey
- 5-point Likert-scale questions assessing satisfaction levels:
    - Evaluation of the stop/station/ferry terminal being used:
        - Ease of access to the stop at the transfer center
        - Suitability of pedestrian connections between public transportation modes
        - Cleanliness of the waiting area
        - Safety of the waiting area
        - Passenger density and space management
        - Comfort of the waiting area
        - Accessibility for passengers with disabilities
        - Signage and information provision
    - Evaluation of the vehicle most recently used:
        - Service frequency
        - Punctuality
        - Waiting time
        - Onboard cleanliness
        - Onboard safety
        - Onboard comfort
        - Quality of information provided on the vehicle
    - Overall evaluation of the transfer/journey experience.

2.3 Statistical Analysis

All data obtained from the survey were analyzed using IBM SPSS Statistics. To assess the reliability of the scale used in the questionnaire, Cronbach's alpha reliability analysis was performed on the satisfaction items.

Descriptive statistical analyses were conducted on the responses to the satisfaction questions, and the mean and standard deviation values were calculated for each item.

Correlation analysis was performed to examine the relationships between the variables. Pearson correlation analysis was used to assess the linear relationships between the variables and to provide a basis for the subsequent regression analysis. A multiple linear regression analysis was conducted to determine the effects of transfer center satisfaction and vehicle satisfaction on overall satisfaction.

A one-way ANOVA was conducted to examine whether satisfaction levels differed across vehicle types in terms of vehicle satisfaction, transfer center satisfaction, and overall satisfaction. For the analysis, vehicle types were coded as follows:
Bus = 1, Metro = 2, Tram = 3, Ferry = 4, İZBAN = 5.

When statistically significant differences were found between groups, a Tukey post hoc test was performed to determine which specific groups differed significantly from each other.

3 Results

3.1 Reliability Analysis

When the reliability analysis was performed on the 8-item scale assessing the stop/station/ferry terminal at the transfer center, Cronbach's alpha was found to be 0.839. For the 7-item scale assessing the vehicle most recently used at the transfer center, Cronbach's alpha was 0.860. Since both values fall within the range of 0.70–0.90, the scales can be considered reliable and internally consistent (Table 1).

Table 1. Reliability Analysis Results

Scale	Number of Items	Cronbach's α
Transfer Center Satisfaction	8	0.839
Vehicle Satisfaction	7	0.860

3.2 Descriptive Statistics

The analysis of the responses to the satisfaction questions showed that the mean satisfaction score for the transfer center was 3.40, with a standard deviation of 0.86. These values indicate a moderate level of satisfaction, with responses generally concentrated around the mean. Similarly, the mean satisfaction score for the vehicle most recently used at the transfer center was 3.66, with a standard deviation of 0.92. The mean overall satisfaction with the transfer/journey experience was 3.56, with a standard deviation of 0.92 (Table 2).

Table 2. Descriptive Statistics of Satisfaction Measures

Variables	Mean	Std. Deviation
Transfer Center Satisfaction	3.40	0.86
Vehicle Satisfaction	3.66	0.92
Overall Satisfaction	3.56	0.92

Regarding the stop/station/ferry terminal at the transfer center, passengers gave the highest satisfaction score to ease of access to the stop, while the lowest scores were given to accessibility for passengers with disabilities and passenger density and space management.

For the vehicle most recently used at the transfer center, the highest satisfaction score was given to punctuality, while the lowest score was given to onboard comfort.

3.3 Correlation Analysis

The Pearson correlation analysis yielded the results presented in Table 3. The strongest relationship was observed between vehicle satisfaction and overall satisfaction, with a correlation coefficient of 0.666. As passengers' satisfaction with the vehicles they used, including comfort, cleanliness, and overall condition, increased, their overall satisfaction also tended to increase substantially.

The correlation coefficient between transfer center satisfaction and overall satisfaction was 0.623. This indicates that higher satisfaction with transfer center conditions, including waiting areas, signage, and connections between transportation modes, was associated with higher overall satisfaction.

The correlation coefficient between transfer center satisfaction and vehicle satisfaction was 0.622. This suggests that passengers who evaluated the transfer center more positively also tended to evaluate their onboard experience more positively, and vice versa. This may indicate that passengers perceive the quality of the transportation system as a whole rather than as completely separate components.

All correlation coefficients were positive and greater than 0.50, indicating strong positive relationships between the variables. Since the relationships were statistically significant at the 0.01 significance level ($p < 0.01$), the observed associations are statistically significant.

Table 3. Pearson Correlation Analysis Results

Variables	Overall Satisfaction	Transfer Center Satisfaction	Vehicle Satisfaction
Overall Satisfaction	1.000	0.623	0.666
Transfer Center Satisfaction	0.623	1.000	0.622
Vehicle Satisfaction	0.666	0.622	1.000

3.4 Multiple Lineer Regression Analysis

The results presented in Table 4 show that the regression model was statistically significant ($p < 0.001$). This indicates that transfer center satisfaction and vehicle satisfaction have significant effects on overall satisfaction.

The R^2 value was 0.514, indicating that transfer center satisfaction and vehicle satisfaction together explain 51.4% of the variance in overall satisfaction. The remaining 48.6% can be attributed to other factors not included in the model.

The standardized coefficient Beta values were 0.340 for transfer center satisfaction and 0.455 for vehicle satisfaction. Therefore, vehicle satisfaction has a stronger effect on overall satisfaction than transfer center satisfaction.

The regression equation is:

$$OS=0.655+0.363(TCS)+0.457(VS) \quad (1)$$

where *OS* represents overall satisfaction, *TCS* represents transfer center satisfaction, and *VS* represents vehicle satisfaction.

Table 4. Multiple Linear Regression Analysis Results

Variables	Stardardized Coefficients β	t	p value (sig.)
Transfer Center Satisfaction	0.340	8.007	<0.001
Vehicle Satisfaction	0.455	10.717	<0.001

3.5 Comparison of Satisfaction Levels by Transport Mode

When the mean transfer center satisfaction scores were compared across transportation modes, ferry users had the highest satisfaction score, with a mean of 3.68, while bus users had the lowest, with a mean of 3.22.

For vehicle satisfaction, ferry users again had the highest mean satisfaction score (4.03), whereas İZBAN users had the lowest (3.07).

Regarding overall satisfaction, ferry users had the highest mean score (3.87), while İZBAN users had the lowest (3.25) (Figure 2).

Fig. 2. Comparison of Satisfaction Levels Across Transportation Modes

The one-way ANOVA for transfer center satisfaction yielded $F = 3.447$ and $p = 0.009$. Therefore, there was a statistically significant difference in mean transfer center satisfaction across transportation modes. The Tukey post hoc test showed that a statistically significant difference was found only between bus and ferry users.

For vehicle satisfaction, the one-way ANOVA yielded $F = 19.588$ and $p < 0.001$, indicating a statistically significant difference in mean vehicle satisfaction across transportation modes. According to the Tukey post hoc test, significant differences were found between bus and metro, bus and tram, bus and ferry, metro and İZBAN, tram and İZBAN, and ferry and İZBAN users.

For overall satisfaction, the one-way ANOVA yielded $F = 4.592$ and $p = 0.001$, indicating a statistically significant difference in mean overall satisfaction across transportation modes. The Tukey post hoc test showed significant differences between bus and tram users and bus and ferry users (Table 5).

Table 5. One-Way ANOVA Results by Transportation Mode

Variables	**F**	**p**
Transfer Center Satisfaction	3,447	0,009
Vehicle Satisfaction	19,588	<0,001
Overall Satisfaction	4,592	0,001

4 Discussion and Conclusion

This study examined the effects of passenger satisfaction with transfer center and vehicle services on overall journey satisfaction at the Konak, Halkapınar, and Bostanlı transfer centers in İzmir and compared satisfaction levels across different transportation modes. The results showed that satisfaction with both transfer center and vehicle services was positively and significantly associated with overall journey satisfaction. This finding is consistent with studies

indicating that public transportation satisfaction cannot be explained by a single service component and that different dimensions of the travel experience should be considered together [13-14], [10].

The reliability analysis showed that the scales measuring transfer center and vehicle satisfaction were reliable and internally consistent. The descriptive statistics indicated that vehicle satisfaction was higher than transfer center satisfaction. In the evaluation of transfer centers, ease of access to the stop was the most positively rated attribute, whereas accessibility for passengers with disabilities and passenger density and space management emerged as the main areas requiring improvement. Regarding vehicle services, punctuality received the most positive evaluation, while onboard comfort received a comparatively lower rating. These findings are consistent with a systematic review highlighting safety, security, comfort, reliability, and accessibility as key factors shaping public transportation service quality and user satisfaction [14], as well as with the study by Minelgaitė et al. [15], which identified distance to the stop as an important determinant of public transportation use.

The correlation and multiple linear regression results showed that transfer center and vehicle satisfaction together explained 51% of the variance in overall satisfaction. The higher standardized regression coefficient for vehicle satisfaction indicates that this variable has a stronger relationship with overall satisfaction than transfer center satisfaction. This suggests that conditions experienced directly inside the vehicle may play a more influential role in passengers' overall evaluations. This finding is consistent with van Lierop et al. [13], who reported that factors such as onboard cleanliness, comfort, punctuality, and service frequency are associated with overall passenger satisfaction.

The comparison across transportation modes revealed statistically significant differences in satisfaction levels depending on the mode used. Ferry users had the highest mean scores for transfer center, vehicle, and overall satisfaction, whereas bus users had lower transfer center satisfaction and İZBAN users had lower vehicle and overall satisfaction. These differences indicate that mode-specific service conditions should be considered when evaluating public transportation services. Factors such as travel comfort, passenger density, waiting conditions, and service reliability may vary across transportation modes and consequently contribute to differences in satisfaction levels. This finding supports studies emphasizing the importance of considering transportation mode and regional conditions when evaluating public transportation service quality [14], [16]. Therefore, rather than directly generalizing these findings to different transportation systems, the results should be interpreted within the context of the specific service conditions and user profiles of each system.

In conclusion, improving passenger satisfaction requires more than improving only transfer center characteristics or only vehicle-related services. Transfer center attributes, including ease of access to stops, suitability of pedestrian connections, cleanliness, safety and comfort of waiting areas, passenger density and space management, accessibility for passengers with disabilities, and signage and information provision, should be addressed together with vehicle-related factors such as service frequency, punctuality, waiting time, onboard cleanliness, safety, comfort, and the quality of information provided on vehicles. Accordingly, evaluating public transportation service quality through a holistic approach can contribute to improving the overall passenger experience and satisfaction.

Acknowledgments

The authors would like to thank the passengers who participated in the survey and contributed to this study.

Abstract. This study aims to identify the transportation preferences of students and staff at the Muğla Sıtkı Koçman University (MSKU) central campus. Due to their large populations and extensive areas, universities function as small cities and have significant impacts on the surrounding environment. Therefore, transportation is a fundamental component of university sustainability policies. Promoting transportation modes such as carpooling, public transportation, and cycling, reducing the use of private vehicles on campus, and improving pedestrian mobility are among the key objectives within this framework.

On-campus travel, transportation was mostly held by private vehicles, this situation increases traffic congestion and creates environmental problems. In addition, the campus location and local climate conditions limit the use of cycling as a transportation alternative. Therefore, this project aims to support the planning of a new campus shuttle route to reduce on-campus vehicle traffic, encourage the use of public transportation, and improve accessibility, using the data of transportation preferences of campus population that is identified through a questionnaire administered to university students and staff. A binary logistic regression model will be employed to analyze the survey data and determine the factors influencing transportation mode choices and needs while calculating and suggesting improvements for the carbon emission in the campus.

Keywords: Sustainable transportation, Multinominal regression analysis, shuttle route, transportation planning

1 Literature Review

The primary motivation of this research is to establish a stable and optimal transportation profile based on previous empirical studies and methodological frameworks. Accordingly, an extensive body of literature on sustainable transportation and campus shuttle (ring service) planning has been reviewed. Among them, Balsas (2003) emphasized the potential of university campuses to promote sustainable transportation due to their educational environment. The study argued that universities could actively reduce private automobile dependency through educational programs and infrastructure improvements that encourage sustainable mobility alternatives **[1]**. Kaplan (2015) emphasizes that transportation sustainability on university

campuses depends on both the availability of appropriate transportation infrastructure and the travel behavior of campus users. That study empirically evaluated transportation sustainability at a large US university using a mixed-method approach. The author measured pedestrian and bicycle activities during morning and afternoon periods, and conducted surveys involving 668 students. Walking and cycling rates were found to be low, with bicycle usage remaining negligible. Primary barriers included time constraints, lack of convenience, and inadequate infrastructure, showing that existing physical environments heavily constrain active mobility. Furthermore, students' perceptions, together with the campus infrastructure inventory, revealed that the existing transportation environment constituted a significant barrier to sustainable mobility **[2]**.

Whereas more recent studies, analyze the travel mode preferences of students and university personnel through comprehensive survey data and Multinomial Logit (MNL) models. Miralles-Guasch and Domène (2010) examined travel preferences and barriers at the Autonomous University of Barcelona across 5,525 students and staff. Major barriers preventing a shift from private vehicles to walking, cycling, or public transit included insufficient infrastructure, low active travel levels, and prolonged public transport travel times. Owing to its large sample size, this study underscores the necessity of incorporating variables such as "perceived travel time in public transportation" and "adequacy of active transportation infrastructure" into campus survey instruments **[3]**.

Deneke et al. (2024) examined work and school travel choices across seven urban districts in Hawassa, Ethiopia, using the Multinomial Logit (MNL) model. The categorical dependent variable was transportation mode (private car, motorcycle, bus), while independent variables included in-vehicle travel time, out-of-vehicle travel time, travel cost, monthly income, perceived comfort, and socioeconomic factors. Results confirmed that higher income and longer in-vehicle times increased private automobile selection, whereas students preferred public transportation over motorcycles **[4]**. In addition, the study utilized behavioral survey data to estimate future travel demand and modal shares while emphasizing the importance of transportation policy interventions. Similar MNL models could therefore be employed to analyze users' willingness to shift toward the proposed campus shuttle service. The explanatory variables identified in the Hawassa case (such as travel cost, travel time, and income) provide valuable guidance for the development of survey questions and the specification of the analytical model. Given that the present study is conducted within a university campus, the study by Akter and Alam (2024) is particularly relevant, as it examines both campus access and intra-campus mobility at the University of Toledo, Ohio, using descriptive statistics and Multinomial Logit (MNL) modeling. Key determinants included automobile ownership, travel distance, age, gender, academic status, income, perceived safety, travel frequency, and weather conditions. Specific findings demonstrated that; greater travel distance, older age, and staff status increased private car reliance, faculty members walked and cycled more frequently than undergraduate students and higher-income individuals exhibited a higher tendency for intra-campus walking. Which leads us to believe that increased travel frequency promotes car commuting for off-campus trips while increasing walking likelihood for short intra-campus trips **[5]**.

Pun, Zhao, and Liu (2019) proposed a Multiple Linear Regression (MLR) model for traffic flow estimation in Hong Kong. Their study incorporated both topological characteristics

of the road network (e.g., node degree, intersection density, betweenness, closeness, and PageRank indices) and geometric characteristics (road length) to estimate traffic volumes. Three different traffic flow datasets, including vehicle counts, bus routes, and fixed traffic counting stations, were utilized to validate the proposed model. Six explanatory variables, five topological indicators together with road length, were incorporated into the regression analysis to investigate the relationship between road network characteristics and traffic flow **[6]**. Although the methodological framework proposed by Pun et al. does not directly correspond to the objectives of the present study, it provides valuable insights into the application of Multiple Linear Regression for transportation planning. Specifically, the relationship between campus road characteristics (e.g., road length, intersection density, and accessibility) and anticipated shuttle service demand could be investigated using a similar analytical framework. Furthermore, the study demonstrates how heterogeneous transportation datasets can be integrated into a single regression model, providing methodological guidance for estimating campus traffic volumes and expected shuttle passenger demand.

Rybarczyk (2018) analyzed active transportation determinants among residential university students in Michigan using Exploratory Spatial Data Analysis (ESDA), OLS regression, and Geographically Weighted Regression (GWR). Modeling variables included demographics, household automobile ownership, population density, land-use diversity, and network design. Findings revealed that travel distance is not a uniform barrier across geographic space; proximity strongly dictated active travel in certain areas, whereas infrastructural factors dominated in others. This highlights the utility of GWR and GIS spatial visualization for identifying localized demand clusters and accessibility deficiencies on campus **[7].** In some areas, proximity to destinations strongly influenced active transportation, whereas in others, different environmental and infrastructural factors played a more dominant role. These findings emphasize the importance of considering spatial heterogeneity when planning campus shuttle services.

Among the studies conducted in Türkiye, the most relevant examples include Süt, Hamurcu, and Eren (2019) and Keleş, Özgül, and Ulutaş (2024). Süt et al. (2019) applied AHP and TOPSIS methods at Kırıkkale University to select eco-friendly campus shuttle vehicles. Evaluation criteria encompassed engine attributes (fuel type, power, climbing performance), vehicle equipment (capacity, passenger comfort, charging duration), aesthetics, energy efficiency, accessibility, economic cost, and environmental performance **[8]**.

Keleş, Özgül, and Ulutaş (2024) surveyed 60 undergraduate students in Kuşadası, Türkiye, regarding walking, cycling, and shuttle choices. Weather conditions and ambient temperature played critical roles in active travel preferences. Campus shuttles were most frequently preferred during examination periods, whereas walking was restricted to students living near campus. Narrow bicycle lanes were identified across genders as a primary barrier to cycling **[9]**. Although the study was conducted on a relatively small sample, it demonstrates that environmental and infrastructural factors substantially influence transportation behavior even within university campuses such as Kuşadası.

2 Methodology

Based on literature review and preliminary field observations, binary logit regression framework was selected as the primary analytical method for this study. To gather the empirical data required for this framework, a mobile intercept survey comprising 32 questions structured into four distinct sections was developed. The first section gathers demographic and socioeconomic profile data, including gender, age, occupation, and financial status. The second section examines participants' travel habits, covering both off-campus commuting and intra-campus mobility. The third section evaluates user expectations, service requirements, and projected usage rates regarding a potential campus ring shuttle system. The final section incorporates a satisfaction assessment to determine how effectively current municipal bus services fulfill campus transit demand, alongside an open-ended area for participant suggestions and feedback.

Data collection was carried out across the main campus and its immediate surroundings using a mobile survey administration approach, yielding a final sample size of 629 valid respondents. The dataset will be processed, tabulated, and analyzed using IBM SPSS software, followed by binary logit regression modeling to extract behavioral determinants, empirical insights, and policy recommendations. Furthermore, baseline campus-level transportation carbon emissions will be estimated using the survey data. The anticipated environmental improvements resulting from the integration of electric buses and an optimized ring shuttle corridor will be quantified and reported alongside targeted recommendations to reduce the university's carbon emission.

2.1 Survey Results

Regarding the gender distribution of the sample, 51.03% of the participants were male and 48.97% were female. The vast majority of respondents (73.77%) belonged to the age category of 25 and under. The breakdown for the remaining age groups was 7.31% for ages 26–35, 14.47% for ages 36–50, and 4.45% for participants aged 51 and above. Consistent with this age profile, the sample breakdown by institutional status comprised 76.15% students, 12.40% academic personnel, 10.17% administrative staff, and 1.11% private sector employees.

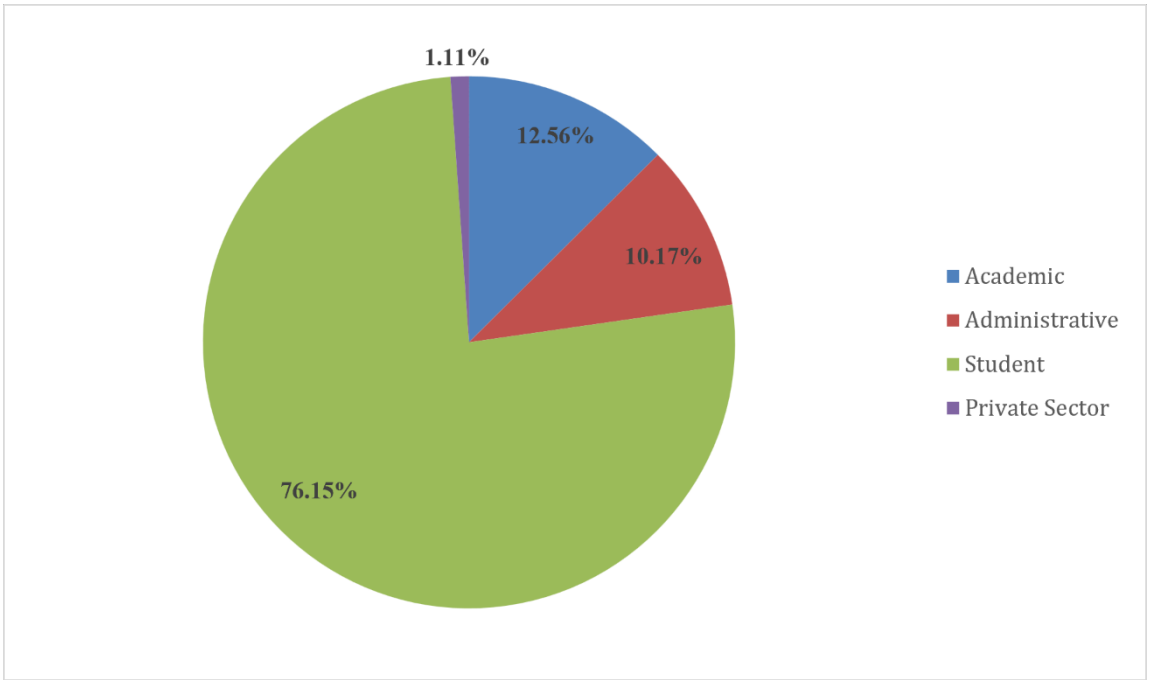

Fig. 1. Pie Chart of Institutional Status of the Campus

Regarding campus entry points, Gate C (which connects the campus to the Kötekli neighborhood area) was identified as the most frequently used entrance, accounting for 54.25% of all access. This was followed by Gate A, leading to the KYK student dormitories, at 29.86%, and Gates B and Gate D, representing 10.43% and 5.46% of campus entries, respectively.

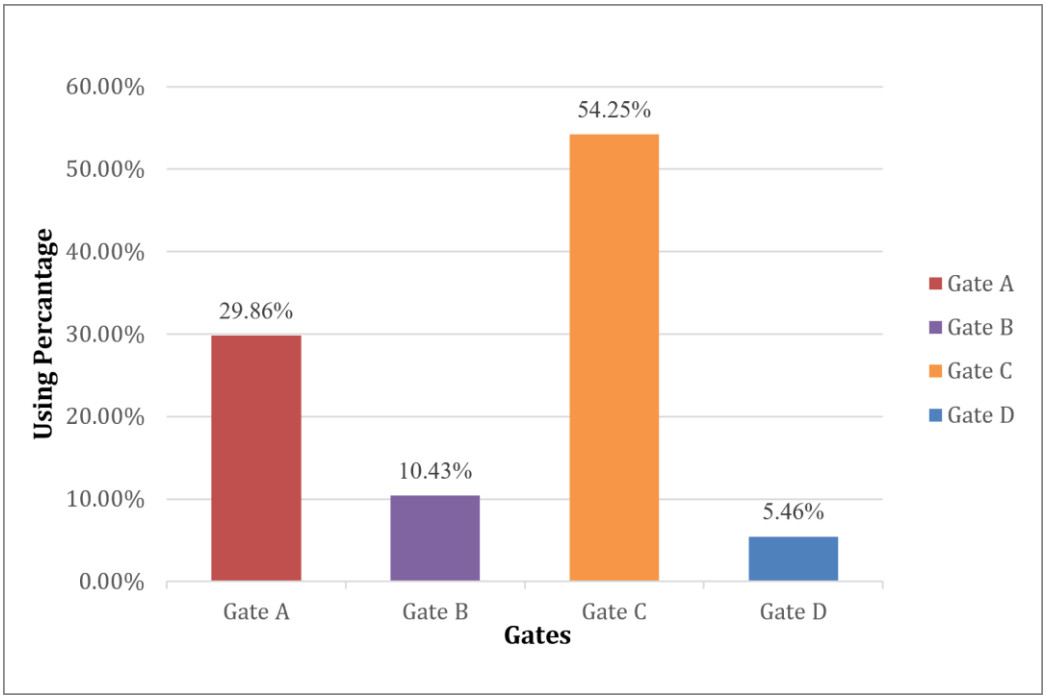

Fig. 2. Chart of Most Used Entrances on MSKU campus

Public transportation was identified as the predominant mode of travel to the campus, accounting for 58.85% of the respondents. Private cars constituted the second preferred mode of transportation, accounting for 26.95% of the respondents. In contrast, bicycle use was remarkably low, representing only 0.16% of all participants. The remaining respondents preferred walking (10.21%) and motorcycles (3.83%) as their primary mode of transportation.

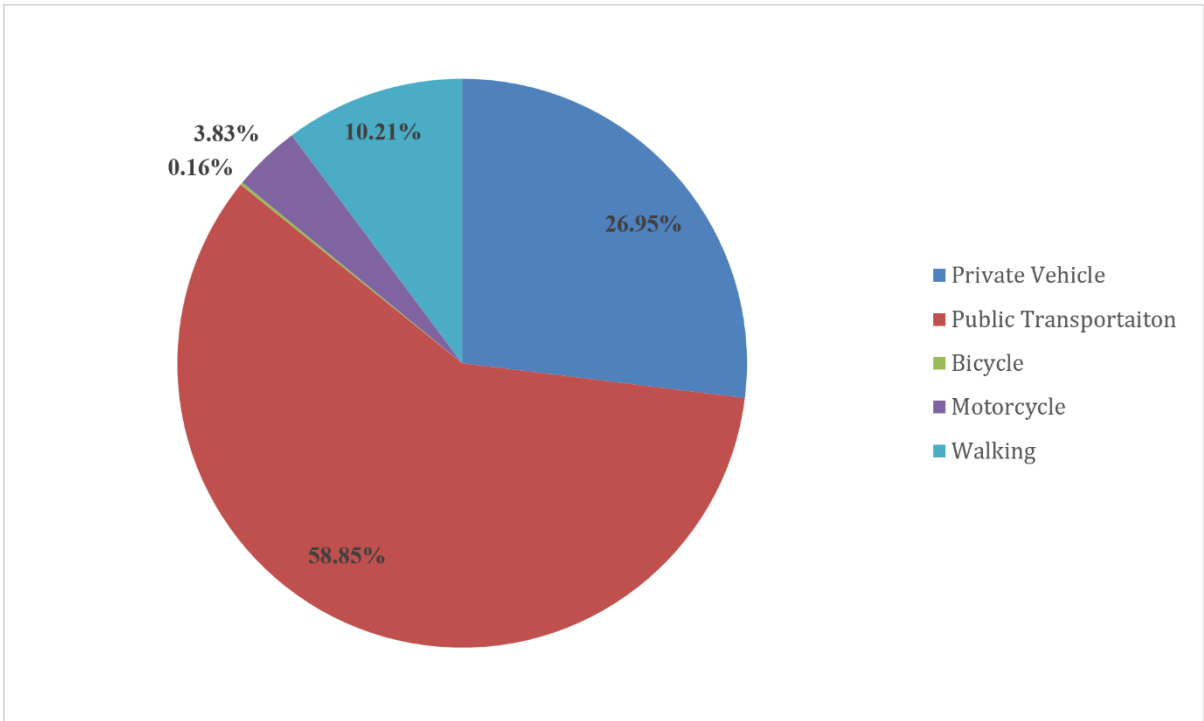

Fig. 3. Preferred Transportation Modes When Coming to the Campus

Private vehicle users prefer 88.21% petrol/diesel, 6.67% hybrid and 5.13% electric vehicles.

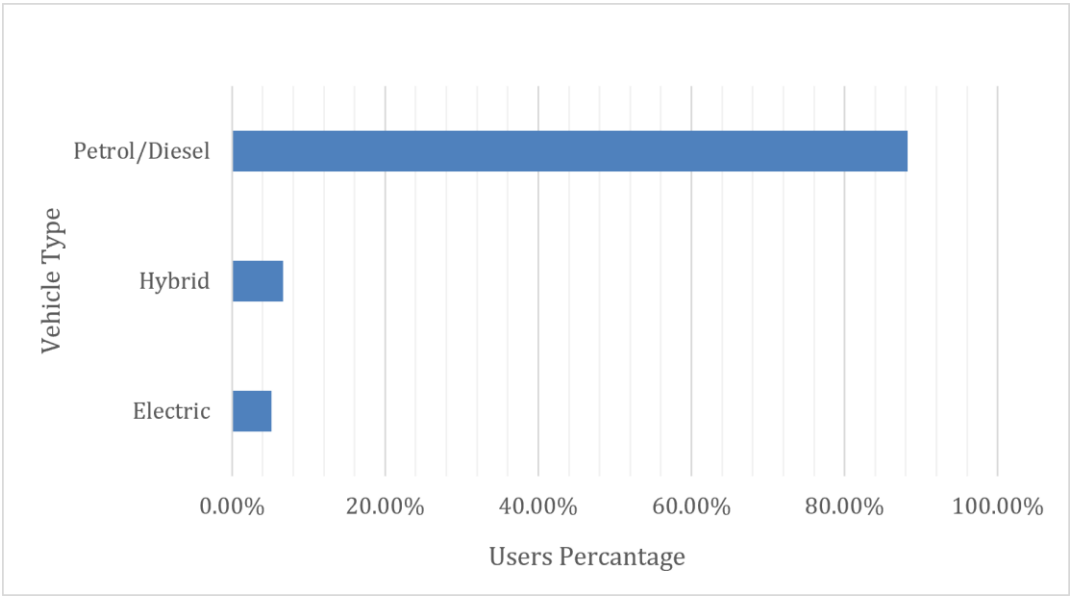

Fig. 4. Chart of Private Vehicle Types Used in the Campus

Compared to travel to the campus from outside, the use of public transportation for on-campus travel decreased slightly to 42.21%. Nevertheless, public transportation remained the dominant

mode of travel within the campus. The proportion of respondents who preferred walking increased substantially, rising from approximately 10% to 39.05%. Meanwhile, the share of private car users declined to 14.71%, whereas the use of bicycles and motorcycles remained at relatively similar levels.

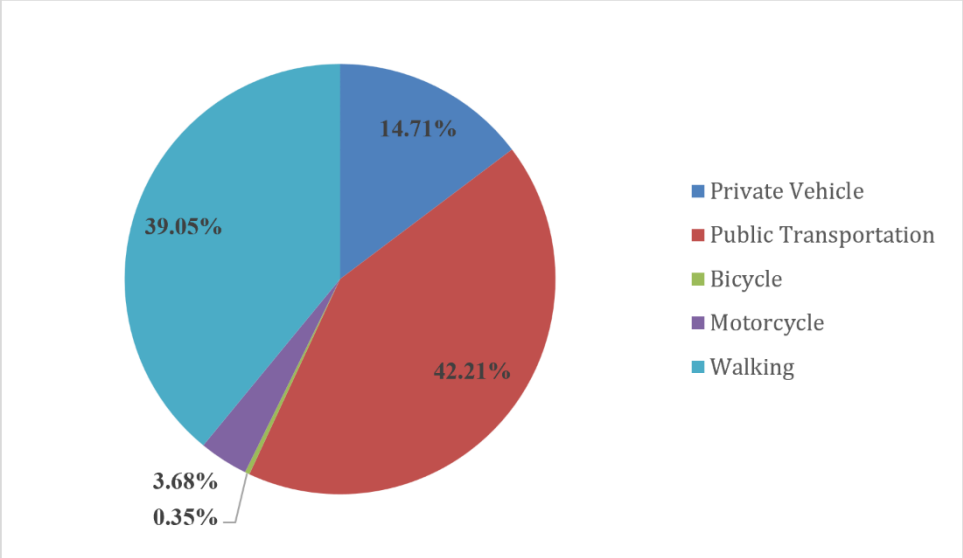

Fig. 5. Preferred Transportation Modes Travelling On-Campus

The findings revealed that 73.44% of the respondents expressed a willingness to use a campus shuttle service if one were provided, while 26.56% reported that they would not utilize such a service. The following table presents the responses to the question of whether the existing municipal bus service (Route 1–48), which currently provides transportation to the campus, adequately meets the transportation needs of the respondents.

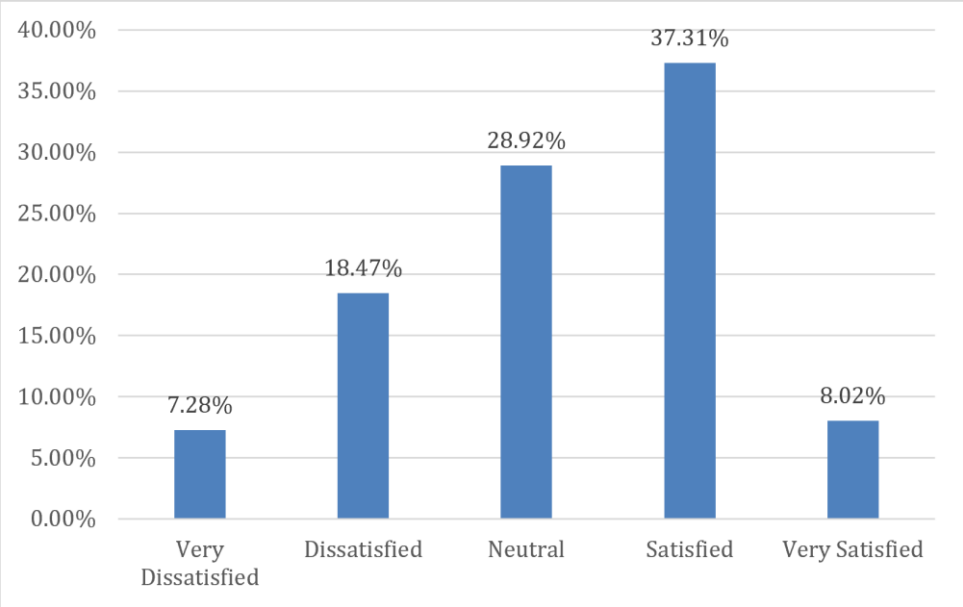

Fig. 6. Thoughts on Current Municipality Public Transportation Route

2.2 Binary Logistic Regression Analysis

A binary logistic regression analysis was conducted to identify the factors associated with participants' intention to use the campus ring shuttle service. The dependent variable was defined based on participants' responses to the question, "Would you use a ring shuttle service if it were available?" Gender, age, occupation, driving licence ownership, income level, preferred campus entrance gate, frequency of travel to the campus, mode of transportation used to access the campus, mode of transportation used within the campus, and awareness of the existing campus ring service were included in the model as independent variables. Due to missing observations, 558 (89.3%) of the 625 valid responses were included in the regression analysis.

The binary logistic regression model provided a statistically significant improvement over the intercept-only model (χ^2 (26) = 81.422, $p < 0.001$). The Cox and Snell pseudo-R^2 and Nagelkerke pseudo-R^2 values were 0.136 and 0.204, respectively. The Hosmer–Lemeshow goodness-of-fit test indicated no statistically significant discrepancy between the observed and model-predicted values (χ^2 (8) = 4.055, $p = 0.852$), suggesting an acceptable fit of the model to the data.

Table 1. Variables in the Equation

	B	S.E.	Wald	df	Sig.	Exp(B)	95% C.I.for EXP(B)	
							Lower	Upper
Driving License	,742	,275	7,288	1	,007	2,099	1,225	3,597
Frequency of travel to campus			9,721	4	,045			
Frequency of travel to campus (1)	1,438	,850	2,858	1	,091	4,212	,795	22,303
Frequency of travel to campus (2)	,623	,427	2,128	1	,145	1,865	,807	4,306
Frequency of travel to campus (3)	,713	,380	3,517	1	,061	2,039	,968	4,294
Frequency of travel to campus (4)	1,050	,360	8,517	1	,004	2,857	1,412	5,783
Awareness of the existing campus ring (1)	-,979	,322	9,246	1	,002	,376	,200	,706
Constant	-1,964	1,408	1,947	1	,163	,140		

An examination of the contributions of the independent variables showed that driving licence ownership ($p = 0.007$), frequency of travel to the campus ($p = 0.045$), and awareness of the existing campus ring service ($p = 0.002$) were significantly associated with the intention to use the ring shuttle service. In contrast, gender ($p = 0.498$), age ($p = 0.927$), occupation ($p = 0.974$), income level ($p = 0.155$), preferred campus entrance gate ($p = 0.713$), mode of transportation used to access the campus ($p = 0.686$), and mode of transportation used within the campus ($p = 0.255$) did not make statistically significant contributions to the model.

Regarding driving licence ownership, participants who held a driving licence had approximately 2.10 times higher odds of reporting that they would not use the ring shuttle service than those without a driving licence ($B = 0.742$, $OR = 2.099$, 95% CI: 1.225–3.597, $p = 0.007$), after controlling for the other variables in the model. This finding indicates that driving licence ownership was associated with a lower intention to use the ring shuttle service.

Frequency of travel to the campus was also significantly associated with the intention to use the ring shuttle service (Wald χ^2 (4) = 9.721, $p = 0.045$). Using participants who travelled to the campus six or more days per week as the reference category, those who travelled to the campus five days per week had approximately 2.86 times higher odds of reporting that they would not use the ring shuttle service ($B = 1.050$, $OR = 2.857$, 95% CI: 1.412–5.783, $p = 0.004$). Differences between the other frequency categories and the reference category were not statistically significant at the 5% significance level.

Awareness of the existing campus ring service was also significantly associated with the intention to use the ring shuttle service. Participants who were aware of the existing ring service had 0.376 times the odds of reporting that they would not use the ring shuttle compared with participants who were unaware of the service ($B = -0.979$, $OR = 0.376$, 95% CI: 0.200–0.706, $p = 0.002$). Expressed in terms of the inverse odds ratio, participants who were aware of the existing ring service had approximately 2.66 times higher odds of intending to use the ring shuttle service than those who were unaware of it. This finding suggests a positive association between awareness of the existing ring service and intention to use the service in the future.

Regarding classification performance, the intercept-only model correctly classified 76.2% of the observations, whereas the all correct classification rate increased to 79.7% after the independent variables were included. The final model correctly classified 95.1% of participants who indicated that they would use the ring shuttle service and 30.8% of those who indicated that they would not use it. Thus, although the inclusion of the independent variables improved the all classification rate, the model showed substantially lower classification performance for participants who did not intend to use the ring shuttle service.

The findings indicate that, rather than most of the demographic characteristics examined, driving licence ownership, frequency of travel to the campus, and awareness of the existing ring service were significantly associated with participants' intention to use the campus ring shuttle service.

Also, a satisfaction score was calculated by averaging the eight items assessing participants' evaluations of the existing campus ring service. The scale demonstrated good internal consistency (Cronbach's $\alpha = .835$), with corrected item-total correlations ranging from .482 to .633. The mean satisfaction score was 3.23 (SD = 0.75) on a five-point scale (N = 532; range = 1–5), indicating a moderate level of satisfaction with the existing campus ring service.

Table 2. Descriptive Statistics

3.CO_2 Emission Assessment under the Proposed Electric Ring Shuttle Scenario

A scenario-based CO_2 emission analysis was conducted to assess the potential environmental implications of introducing a battery-electric ring shuttle service for internal trips within the university campus. Since the proposed service is intended exclusively for intra-campus transportation, the analysis focused on the transportation modes currently used by participants within the campus rather than the modes used to access the campus.

The survey results indicated that 83 participants currently used private cars for intra-campus travel, 241 used public transport, 21 used motorcycles, and 223 used active modes, including walking and cycling. Among these groups, 47 private car users (56.6%) and 12 motorcycle users (57.1%) stated that they would use the proposed ring shuttle service. These potential shifts from individual motorised transport to the ring service were considered the primary source of avoided emissions in the scenario analysis. In contrast, shifts from walking and cycling were not considered to generate avoided operational emissions, since these modes were assumed to have zero direct operational CO_2 emissions.

Because detailed operational characteristics of the proposed service have not yet been determined, several assumptions were introduced to establish a baseline scenario. The length of the proposed ring route was assumed to be 3.35 km, which was also adopted as the average distance of an intra-campus trip. The ring service was assumed to operate 20 trips per day using a battery-electric bus. This corresponds to a total daily vehicle distance of 67 km. An average electricity consumption of 1.5 kWh/km was assumed for the electric bus, resulting in an estimated daily electricity demand of 100.5 kWh. Electricity-related emissions were calculated using the emission factor for electricity consumption from the Turkish distribution grid. Private car and motorcycle emissions were estimated using representative vehicle emission factors. Since the latter factors were not specific to the Turkish vehicle fleet, they were treated as proxy values and should therefore be interpreted within the context of a scenario-based assessment.

Under the assumption that each potential mode-shift participant makes one 3.35-km intra-campus trip per day, the avoided emissions associated with the shift of 47 private car users and 12 motorcycle users to the ring service were estimated at approximately 30.90 kg CO_2e/day. In comparison, operation of the proposed electric ring service was estimated to generate approximately 47.13 kg CO_2e/day of indirect emissions associated with electricity generation. Consequently, under the one-trip-per-day scenario, implementation of the ring service would result in a net increase of approximately 16.23 kg CO_2e/day, corresponding to a 52.5% increase relative to the emissions avoided from private car and motorcycle trips.

Given the uncertainty regarding the actual number of daily intra-campus trips, a sensitivity analysis was conducted using one, two, and three trips per person per day. The results are presented in Table 3.

Daily intra-campus trips per person	Avoided private car and motorcycle emissions (kg CO_2e/day)	Electric ring emissions (kg CO_2e/day)	Net change (kg CO_2e/day)	Relative change
1	30.90	47.13	+16.23	+52.5%
2	61.81	47.13	−14.67	−23.7%
3	92.71	47.13	−45.57	−49.2%

The sensitivity analysis demonstrates that the environmental performance of the proposed electric ring service is strongly dependent on the number of motorised intra-campus trips replaced by the service. While the one-trip-per-day scenario does not produce a net reduction in CO_2 emissions, the results change when two or more daily trips per person are assumed. Under the two-trip scenario, the proposed ring service would reduce emissions by approximately 14.67 kg CO_2e/day (23.7%), whereas the three-trip scenario would result in an estimated reduction of 45.57 kg CO_2e/day (49.2%).

Based on the assumptions adopted in the analysis, the break-even point was estimated at approximately 1.53 intra-campus trips per person per day. Thus, the electric ring service becomes advantageous in terms of CO_2 emissions when the average number of private car and motorcycle trips replaced by the service exceeds approximately 1.53 trips per potential mode-shift user per day. This finding highlights that the environmental benefits of an electric shuttle system depend not only on vehicle technology but also on the extent to which the service substitutes existing individual motorised trips.

An additional consideration arises from the potential shift from active transportation modes to the ring service. Of the participants currently using walking or cycling for intra-campus transportation, 162 (72.6%) indicated that they would use the proposed ring service. Since walking and cycling were assumed to generate no direct operational emissions, replacing these trips with motorised shuttle trips would not generate direct emission savings. Although additional passengers may have little effect on the marginal operational emissions of a scheduled electric bus once the service is already operating, a reduction in active-mode use would be undesirable from a broader sustainable mobility perspective. Therefore, the proposed ring service should primarily be designed to substitute private motorised trips rather than compete it walking and cycling for short intra-campus journeys.

The scenario analysis suggests that the introduction of an electric ring shuttle does not automatically guarantee a reduction in transport-related CO_2 emissions. Its environmental effectiveness depends substantially on service frequency, electricity consumption, route length, and, particularly, the number of private car and motorcycle trips replaced. Accordingly, service planning should aim to maximise the modal shift from individual motorised transportation while preserving active transportation for short-distance campus trips. Under sufficiently high substitution of private motorised travel, the proposed electric ring service has the potential to contribute to reducing transport-related CO_2 emissions within the university campus.

4 Results and Conclusion

The findings demonstrate a substantial potential demand for a campus ring shuttle service at Muğla Sıtkı Koçman University. 73.44% of the respondents indicated that they would use such a service if provided, while public transportation was already the predominant mode for both campus access and intra-campus travel. The binary logistic regression model was statistically significant ($\chi^2(26) = 81.422$, $p < 0.001$) and showed an acceptable fit to the data (Hosmer–Lemeshow $\chi^2(8) = 4.055$, $p = 0.852$; Nagelkerke $R^2 = 0.204$). Driving licence ownership ($p = 0.007$), frequency of travel to campus ($p = 0.045$), and awareness of the existing campus ring service ($p = 0.002$) were significantly associated with willingness to use the proposed service, whereas the other demographic and travel-related variables included in the model were not statistically significant. In particular, participants who were aware of the existing ring service had approximately 2.66 times higher odds of intending to use the proposed service than those who were unaware of it. The satisfaction assessment further indicated a moderate level of satisfaction with the existing service ($M = 3.23$, $SD = 0.75$), with the eight-item scale demonstrating good internal consistency (Cronbach's $\alpha = 0.835$).

The environmental assessment indicates that the potential benefits of an electric ring service depend strongly on its ability to substitute private motorised intra-campus trips. Among current intra-campus users, 56.6% of private car users and 57.1% of motorcycle users stated that they would use the proposed service. Under the assumed 3.35-km route, 20 daily services, and battery-electric bus operation, the shuttle was estimated to generate 47.13 kg CO_2e/day from electricity consumption. Sensitivity analysis showed that replacing only one motorised trip per potential user per day would increase net emissions by 16.23 kg CO_2e/day; however, replacing two and three trips would reduce emissions by 14.67 kg CO_2e/day (23.7%) and 45.57 kg CO_2e/day (49.2%), respectively. The estimated break-even point was 1.53 substituted private car or motorcycle trips per person per day, indicating that electrification alone does not guarantee an environmental benefit; sufficient modal shift away from individual motorised transport is also required.

The results support the introduction of a carefully planned electric ring shuttle as part of MSKU's sustainable campus mobility strategy, provided that its operation is designed primarily to reduce private car and motorcycle use rather than replace active travel. This distinction is particularly important because 72.6% of current walking and cycling users also expressed willingness to use the proposed service, suggesting a potential unintended shift away from zero-emission active modes. Accordingly, route and service planning should prioritise locations and periods with high private motorised travel demand, while walking and cycling should remain

attractive alternatives for short intra-campus trips. The proposed ring system should therefore be regarded not simply as an additional transport service, but as a demand-responsive mobility intervention whose effectiveness depends on service design, user awareness, and its capacity to achieve a measurable shift from individual motorised transport toward collective electric mobility.

Abstract. Hospital location determines who can reach care, how quickly, and at what cost, yet siting decisions in most health systems still rely on land price and cost rather than population accessibility. This paper develops a policy framework linking hospital location decisions to the transportation intelligence that smart city infrastructure already produces. The framework has three components: an information integration protocol that converts routing-API travel-time matrices, GTFS transit schedules, fleet GPS, smart-card records and mobile-network mobility data into a time-dependent multimodal travel-time matrix; a Transportation Accessibility Impact Assessment (TAIA) that scores accessibility with a two-step floating catchment area method and evaluates fairness with a population-weighted Gini index for elderly, low-income and vehicle-less residents; and an institutional coordination mechanism, grounded in the Health-in-All-Policies approach, requiring joint health-transport review before a hospital siting decision is finalised. Türkiye's City Hospitals programme, which has relocated more than twenty major facilities to urban peripheries since 2017 without a documented accessibility review, supplies the context, and Eastern Anatolian cities such as Elazığ, with below-average car ownership, limited transit coverage, hilly terrain and severe winters, illustrate the equity stakes most sharply. A stylised numerical example shows how the TAIA metrics would flag a peripheral relocation that raises average accessibility while widening the gap between vehicle-owning and vehicle-less residents, a pattern a bed-count criterion cannot detect. The technical barrier to evidence-based hospital siting is now smaller than the institutional one, and closing it requires a few governance instruments rather than new data infrastructure.
Keywords: Smart city; Hospital location policy; Intelligent Transportation Systems; Spatial equity.

1 Introduction

Hospital location affects health outcomes through a channel that can be measured directly: travel time. In acute ischaemic stroke, the treatable brain volume shrinks by roughly two million neurons a minute, so every additional minute of pre-hospital travel carries a quantifiable clinical cost [1]. In out-of-hospital cardiac arrest, a cohort study of the Scottish Ambulance Service found that cutting response time to five minutes could nearly double survival to hospital discharge [2]. For patients managing chronic conditions, the same travel-time channel operates over months rather than minutes: a facility that is hard to reach produces missed appointments and weaker control of the underlying disease. Distance is therefore not an incidental feature of hospital location; it is a determinant of the outcomes that the facility exists to protect.

Despite this evidence, hospital siting is rarely subjected to a formal accessibility test. Decisions are shaped by land availability, construction cost and political negotiation, and the population-level consequence, who can reach the new facility and who cannot, is treated as a byproduct rather than a design criterion. This omission is not a data problem in the way it would have been two decades ago. Contemporary cities operate dense networks of traffic sensors, GPS-tracked transit and emergency fleets, electronic fare systems, navigation platforms and mobile-network infrastructure that jointly constitute what the smart-city literature calls a merger of information and communication technology with traditional urban infrastructure [3]. These systems already expose peak-hour congestion, transit coverage gaps and the neighbourhoods where a short geographic distance translates into a long travel time. The intelligence exists; it simply does not reach the desks where hospital location decisions are made.

This paper argues that the gap between smart-city transportation intelligence and health facility planning is an institutional failure rather than a technical one, and it proposes a framework to close it. The framework couples three components: a protocol for integrating existing smart-city data streams into a usable travel-time input, a quantitative accessibility and equity assessment that health authorities can require before a siting decision is finalised, and a coordination mechanism that gives the assessment institutional force. The remainder of the paper is organised as follows. Section 2 reviews the facility-location, accessibility-measurement and smart-city-data literatures and situates Türkiye's City Hospitals programme within them. Section 3 develops the three-component framework, including a formal accessibility-equity model. Section 4 illustrates the model with a stylised numerical example set in Elazığ. Section 5 discusses implementation barriers, generalisability and limitations, and Section 6 concludes.

2 Background and Related Work

2.1 Hospital location and spatial equity

Facility location research offers a mature toolkit for siting public services. The maximal covering location problem seeks facility positions that maximise the demand served within a coverage radius [4], and a substantial body of covering, median and hierarchical models has since been applied to hospitals, ambulance stations and other health facilities [5]. These models are formally rigorous, but nearly all of them take a distance or travel-time matrix as an exogenous input. They optimise facility positions conditional on that matrix being accurate; they do not address where the matrix comes from or how often it is refreshed. When the underlying travel-time data are static, outdated or based on straight-line distance, the resulting siting recommendation inherits that weakness regardless of how sophisticated the optimisation is.

A parallel literature measures accessibility rather than optimising it. The two-step floating catchment area (2SFCA) method estimates a supply-to-demand ratio around each facility and then sums the ratios reachable from each population zone within a travel-time threshold, combining a floating-catchment logic with a gravity-type distance decay [6]. Subsequent reviews have catalogued the method's sensitivity to threshold choice, zone size and decay-function specification, while confirming its practical advantage of separating the supply side (facility capacity) from the demand side (population distribution) in a single interpretable score [7]. This measurement tradition, rather than the covering-location tradition, is the natural basis for a policy-facing accessibility assessment, because its output is a score that can be mapped, compared across population subgroups and reported to a non-technical decision body.

2.2 Smart-city data infrastructure and transportation intelligence

The travel-time input that both traditions require is exactly what smart-city systems now generate as a byproduct of unrelated operational functions. General Transit Feed Specification (GTFS) schedules make it possible to compute transit accessibility at fine temporal resolution; using GTFS data for Cincinnati, one study showed that accessibility to supermarkets by transit

varies enough across the day that a single representative time-of-day estimate can misstate which residents are actually underserved [8], a finding that applies with at least equal force to hospital access during peak congestion. Automated fare-collection (smart-card) systems, originally deployed for revenue collection, generate detailed records of realised boarding and alighting patterns that a literature review identifies as useful for strategic, tactical and operational transit planning alike [9], making them a source of validated, as opposed to merely scheduled, travel behaviour.

Mobile-network mobility records add a demand-side layer. Analysis of six months of anonymised trajectories from 100,000 mobile-phone users showed that individual mobility is far more regular and predictable than the random-walk models once used to describe it [10], which is precisely the property that allows aggregated, privacy-protected mobile records to approximate where a population actually lives and moves at a spatial and temporal resolution that census data cannot match. Routing platforms complete the picture by supplying time-dependent, multimodal origin-destination travel times on demand. None of these four data streams was designed with hospital planning in mind, and that is the point: the infrastructure investment has already been made for other purposes, so the marginal cost of repurposing it for health facility accessibility is administrative rather than technological [3].

2.3 Institutional context: Türkiye's City Hospitals programme

Türkiye has built more than twenty large City Hospitals through build-lease-transfer public-private partnerships since 2017, consolidating services previously spread across smaller inner-city hospitals into large peripheral campuses. A stakeholder survey of health personnel working in three City Hospitals reported broadly positive views on capacity, service quality and technology, alongside explicit concerns about cost, transparency and management, but access was assessed only qualitatively, through staff perception rather than a measured travel-time distribution across the served population [11]. A separate qualitative study of stakeholders across integrated health campuses reached a similar conclusion: the model was judged on efficiency, quality and financing grounds, with access treated as one perception item among several rather than as a quantitative planning criterion [12].

Neither study, nor the underlying siting process, incorporated a formal transportation accessibility analysis. This is the specific gap the present framework addresses. The facility-location literature supplies models that need accurate travel-time inputs but is silent on how to obtain them at scale; the smart-city literature documents that the required data streams already exist but stops short of connecting them to a health-sector decision procedure; and the Turkish City Hospitals literature documents stakeholder sentiment about an already-built programme without measuring the population-level accessibility change that peripheral relocation produced. Section 3 proposes a framework that closes this three-way gap by turning existing data streams into a standard, auditable input to hospital siting decisions.

3 Proposed Transportation Equity Framework

The framework couples three components, each addressing a distinct point of failure identified in Section 2: an information integration protocol that supplies the travel-time input the facility-location and accessibility literatures require (Component I), a Transportation Accessibility Impact Assessment that turns that input into a decision-relevant accessibility and equity score (Component II), and an institutional coordination mechanism that gives the assessment procedural force (Component III). Figure 1 shows how the three components connect data to decision.

3.1 Component I: information integration protocol

The protocol harmonises four data streams that most municipalities and health authorities already have some access to, either directly or through a commercial or open license. Routing-API queries (for example, Google Maps or HERE) return time-dependent origin-destination travel times for private vehicle, walking and mixed-mode trips and can be sampled at several

representative times of day, including the morning and evening peaks that most affect emergency response and staff commuting. GTFS feeds convert published transit schedules into routable origin-destination transit travel times, which the temporal-variability evidence in Section 2.2 shows should not be collapsed into a single daily average [8]. Fleet GPS and automated fare-collection records validate the schedule-based estimate against realised operating conditions [9], and aggregated mobile-network mobility records supply a demand-side population distribution at a spatial resolution finer than a typical census tract [10]. The integration layer resolves these four streams to a common zonal system and produces a single harmonised, time-dependent multimodal travel-time matrix, refreshed on a fixed cadence, that feeds directly into Component II.

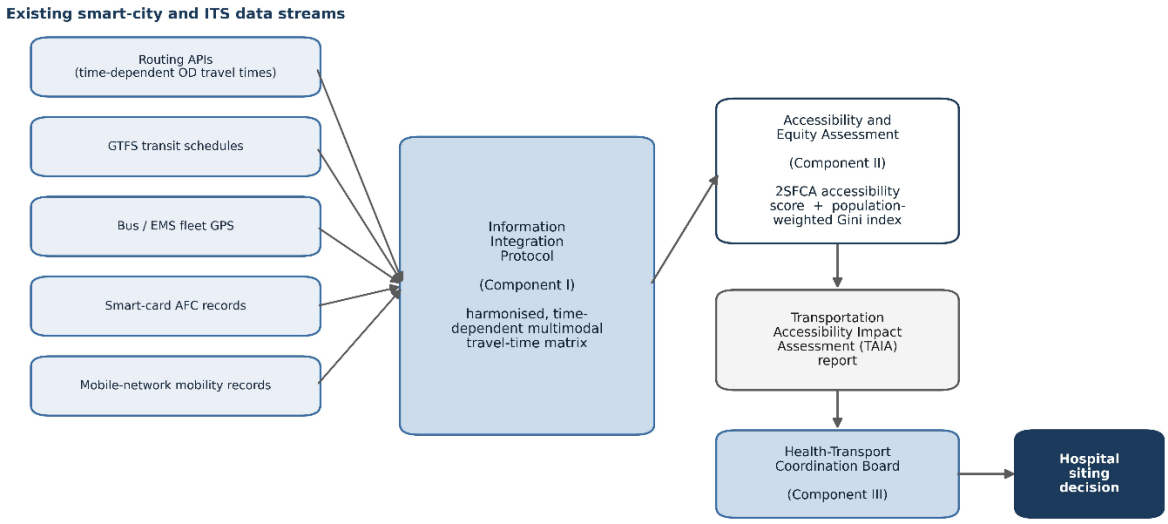

Fig. 1. The three components of the proposed framework, from existing smart-city data streams to a hospital siting decision.

A single data custodian, typically the metropolitan transport authority given its existing ownership of GTFS and fleet data, should be designated to operate the integration layer and to publish the resulting travel-time matrix in a documented, versioned format so that Component II can be audited and reproduced by an independent reviewer.

3.2 Component II: Transportation Accessibility Impact Assessment

The Transportation Accessibility Impact Assessment (TAIA) converts the travel-time matrix from Component I into two decision-relevant quantities for each population subgroup: an accessibility score at each zone and a summary measure of how equally that score is distributed. The model extends the 2SFCA formulation [6] and follows the concept-and-method guidance summarised in [7]. Four assumptions underlie the formulation and are stated explicitly because each has a direct bearing on how the assessment should be interpreted. First, a travel-time matrix built from a small number of representative times of day is taken as an adequate input for comparing siting alternatives at the planning horizon, even though instantaneous travel times fluctuate continuously. Second, licensed bed count, or an equivalent capacity-weighted service unit, is used as a proxy for hospital service availability; this proxy does not capture differences in case mix or medical specialty across facilities. Third, the distance-decay function is assumed to take a negative exponential form, consistent with common 2SFCA practice, with

the decay parameter and catchment threshold calibrated locally rather than imported from another study area. Fourth, population subgroup counts are assumed available at the same zonal resolution as the travel-time matrix, which in practice requires the mobile-network and census inputs from Component I to be reconciled to a common zoning system. Table 1 lists the indicators used in the TAIA model.

Table 1. Notation used in the Transportation Accessibility Impact Assessment model.

Symbol	Definition
I, i	Set and index of population (demand) zones
J, j	Set and index of hospital locations (existing or proposed)
G, g	Set and index of population subgroups (e.g., general, elderly, low-income, vehicle-less)
P_i^g	Population of subgroup g resident in zone i [persons]
P_i	Total population of zone i, Pi = Σg Pi_g [persons]
S_j	Service capacity of hospital j [beds or weighted service units]
t_{ij}	Travel time between zone i and hospital j for a representative time of day [minutes]
d_0	Catchment travel-time threshold [minutes]
β (beta)	Distance-decay (impedance) parameter [1/minute]
W(t)	Distance-decay weight, W(t) = exp(-βt) for t ≤ d0, else 0 [dimensionless, in (0,1]]
R_j	Population-adjusted supply ratio at hospital j [service units per person]
A_i	Spatial accessibility score of zone i, common to all residents of i [service units per person]
$Gini^g$	Gini coefficient of the accessibility scores Ai across zones I, weighted by subgroup g's population [dimensionless, 0-1]
DR^g	Disparity ratio: mean Ai in the top decile of subgroup g's population over the bottom decile, zones ranked by Ai

Equation (1) computes the population-adjusted supply ratio for each hospital by dividing its capacity by the distance-weighted population that falls within its catchment. Equation (2) then sums, for each zone and subgroup, the supply ratios of every hospital reachable from that zone, each discounted by the same distance-decay weight.

$$R_j = S_j / \Sigma_{k \in I} P_k \cdot W(t_{kj}) \qquad (1)$$

$$A_i = \Sigma_{j \in J:\ tij \le d0} R_j \cdot W(t_{ij}) \qquad (2)$$

In Equation (1), Pk is the total population of zone k, summed over subgroups; the denominator therefore represents the effective, distance-discounted population competing for hospital j, so a low value of Rj signals a facility that is either under-capacity or surrounded by dense demand. Equation (2) then aggregates the supply ratios of every hospital within the threshold travel time of zone i into a single accessibility score, Ai, which is a property of the zone itself and is therefore common to every resident of that zone regardless of subgroup: two residents of the same zone face the same geographic accessibility to hospital services. Because Rj and W(t) are both non-negative, Ai is bounded below by zero and increases whenever a new, better-connected or larger facility becomes reachable from zone i, which gives the score the correct sign for use as a planning criterion: higher is better.

Accessibility alone does not reveal whether it is shared or concentrated across population subgroups. Subgroup differentiation enters through the weights used to summarise the distribution of Ai across zones, not through the accessibility score itself. Equation (3) reports the Gini coefficient of Ai across zones I, weighted by the population of subgroup g in each

zone, the same weighted-inequality construction used to assess the equity of public transport supply [13], applied here to ask whether subgroup g's population is disproportionately concentrated in low-accessibility zones.

$$\text{Gini}^{g} = \Sigma_{i\in I} \Sigma_{i'\in I} P_i^{g} P_{i'}^{g} |A_i - A_{i'}| / (2 (\Sigma_{i\in I} P_i^{g})^2 \bar{A}^{g}) \quad (3)$$

where $\bar{A}^{g} = \Sigma_{i\in I} P_i^{g} A_i / \Sigma_{i\in I} P_i^{g}$ is the mean accessibility experienced by subgroup g, weighting each zone's score by how much of subgroup g lives there. Gini^{g} equals zero when subgroup g's population is distributed across zones in exact proportion to accessibility and approaches one as that population concentrates in low-accessibility zones; a companion disparity ratio, DR^{g}, reports the more directly interpretable ratio between the mean accessibility experienced by the best-served and worst-served population deciles of subgroup g. Reporting Gini^{g} and DR^{g} separately for the general population and for the elderly, low-income and vehicle-less subgroups is what allows a Health-Transport Coordination Board to detect a relocation that raises average accessibility while widening subgroup-specific gaps, which Section 4 illustrates numerically.

The formulation inherits two well-documented limitations of the 2SFCA family that any application must manage rather than assume away. Boundary zones near the edge of the study area can appear falsely under-served if hospitals just outside the study boundary are excluded from the catchment search, and the zonal system used to define I is itself a modelling choice that can shift results, the modifiable areal unit problem familiar from the accessibility-measurement literature [7]. Both issues are managed procedurally rather than analytically: the assessment protocol requires the study area to extend at least one catchment radius beyond the municipal boundary, and it requires a documented sensitivity analysis over at least two zonal resolutions and two decay-parameter values before the TAIA report is submitted to Component III.

3.3 Component III: institutional coordination mechanism

A technically sound assessment has no policy effect unless an institutional process requires it to be produced and consulted before a decision is made. The mechanism proposed here adapts the six generic components of the Health-in-All-Policies approach, establishing need and priorities, framing the planned action, identifying supportive structures, facilitating assessment and engagement, ensuring monitoring and reporting, and building capacity [14], to the specific decision point of hospital siting. A Health-Transport Coordination Board, jointly staffed by the health ministry's investment planning unit and the metropolitan transport authority, is convened whenever a proposed hospital investment exceeds a defined capacity or cost threshold, or whenever an inner-city facility is proposed for closure. The Board's sole formal requirement is procedural rather than discretionary: no siting concession may be finalised without a submitted TAIA report, and if the report shows a subgroup-specific Gini or disparity-ratio deterioration relative to the status quo, the responsible health authority must publish a mitigation plan, for example, a dedicated shuttle service or a satellite outpatient clinic, before final approval.

This design deliberately stops short of granting the transport authority a veto over health investment decisions, which would raise the political cost of adoption sharply. It instead makes the accessibility evidence visible and auditable at the point where it can still influence site selection, and it places the burden of response, not the burden of proof, on the health authority when the evidence points to a deterioration in equity.

4 Illustrative Application: A Stylised Scenario for Elazığ

Eastern Anatolian cities such as Elazığ combine below-national-average car ownership, limited public transit coverage, hilly terrain and severe winters, a combination that makes peripheral hospital placement carry a larger accessibility penalty for vehicle-less residents than the same relocation would carry in a flatter, better-motorised city. This section illustrates how the TAIA metrics of Section 3.2 would be read by a Health-Transport Coordination Board facing such a decision. The travel-time matrix, hospital capacities and zonal populations required by

Component I have not yet been assembled for Elazığ as part of this study, so the figures below are explicitly hypothetical (Table 2): they are constructed to be internally consistent with the model of Section 3.2 and to demonstrate how its outputs should be interpreted, not to report a measured outcome of any real siting decision. Assembling and validating the underlying data streams for a real Elazığ catchment is identified as future work in Section 5.4.

Table 2. Illustrative, hypothetical TAIA output comparing a central and a peripheral single-hospital scenario across five stylised zones.

Zone	Vehicle-less population share	Ai, central hospital (illustrative)	Ai, peripheral hospital (illustrative)
Z1 – inner city	38%	1.00	0.55
Z2 – inner-mid ring	29%	0.85	0.70
Z3 – mid ring	22%	0.60	0.80
Z4 – outer ring	17%	0.35	1.05
Z5 – periphery	12%	0.20	1.20
Population-weighted mean	—	0.62	0.83
Gini coefficient (general population)	—	0.29	0.31
Gini coefficient (vehicle-less subgroup)	—	0.24	0.41

The illustrative figures reproduce a pattern that a bed-count-only planning criterion cannot detect. The population-weighted mean accessibility rises from 0.62 to 0.83 after relocation, because the peripheral scenario is built with a larger facility that improves access for the outer, currently under-served zones. The general-population Gini coefficient barely moves, from 0.29 to 0.31, which on its own would read as an acceptable, even a favourable, outcome. The subgroup-specific figure tells a different story: the Gini coefficient for the vehicle-less subgroup rises from 0.24 to 0.41, because the inner-city zones with the highest share of vehicle-less residents, Z1 and Z2, are exactly the zones that lose accessibility under relocation. A TAIA report built only around the general-population average would have cleared this scenario; the subgroup-disaggregated report flags it for the mitigation requirement described in Section 3.3.

5 Discussion

5.1 Policy implications and institutional barriers

Implementing the framework does not require new sensors, new legislation in most jurisdictions, or a new data-collection budget, since Section 2.2 established that the four underlying data streams are already produced for other purposes. The binding constraint is administrative: routing a TAIA through the Health-Transport Coordination Board before a siting concession is signed. In Türkiye, City Hospital concessions are typically negotiated years before a facility opens, and land assembly and financing are locked in early, so the coordination mechanism must intervene at the pre-feasibility stage rather than as a commissioning-stage inspection if it is to have any influence on the final site.

5.2 Generalisability and limitations

The three-component architecture is not specific to Türkiye; it applies to any health system that relies on capital-intensive, centralised hospital campuses and operates in a city with routing-API or GTFS coverage, a condition met by most cities in middle- and high-income countries today. The Turkish City Hospitals programme supplies the motivating and illustrative context because its scale and its peripheral siting pattern make the accessibility question unusually

visible, not because the framework depends on any feature unique to the Turkish institutional setting.

Four limitations qualify these claims. The framework has not yet been validated against a real travel-time matrix and real facility-level outcome data; Section 4 is explicitly illustrative rather than empirical. Mobile-network mobility records raise data-governance and privacy questions, requiring aggregation thresholds and legal agreements with network operators that this paper does not work out in detail. The accessibility score, like any member of the 2SFCA family, is sensitive to zone definition and parameter choice, which is why Section 3.2 requires a documented sensitivity analysis rather than treating a single parameterisation as authoritative. Finally, the framework measures geographic and travel-time access; it does not capture the affordability or clinical-quality dimensions of access, which require complementary assessment instruments outside its scope.

5.3 Future work

Three extensions follow directly from these limitations: a pilot computation of the TAIA model for an existing Turkish City Hospital catchment using open GTFS and routing-API data, an evaluation of institutional uptake through a real pilot of the Health-Transport Coordination Board, and an extension of the accessibility score to incorporate multimodal transfer penalties and the seasonal, winter-specific travel-time degradation that is particularly relevant to Eastern Anatolian cities such as Elazığ.

6 Conclusion

Hospital siting decisions continue to be made without reference to the transportation intelligence that smart-city infrastructure already generates. This paper has proposed a three-component framework, an information integration protocol, a Transportation Accessibility Impact Assessment built on a 2SFCA accessibility score and a population-weighted Gini equity index, and an institutional coordination mechanism, that closes this gap at a low marginal cost, since the underlying data infrastructure is already in place in most cities. Türkiye's City Hospitals programme provided the motivating and illustrative context, and a stylised numerical example showed how the framework would surface a subgroup-specific equity deterioration that an average-accessibility or bed-count criterion would miss. The immediate priority for future research is a pilot application to a real hospital catchment, to establish whether the framework performs as intended once it is exposed to the noise and incompleteness of operational data.

Appendices

Appendix A. Minimum Reporting Fields for a Transportation Accessibility Impact Assessment (TAIA) Report

Table A1 lists the minimum fields a TAIA report must contain before it can be submitted to the Health-Transport Coordination Board described in Section 3.3.

Table A1. Minimum reporting fields for a TAIA report.

Field	Requirement
Study area and zonal system	Boundary definition, zone count and rationale for zone size
Population subgroups covered	At minimum: general population, elderly, low-income, vehicle-less
Travel-time matrix source and date	Data source(s) per Component I, sampling times of day, refresh date
Decay parameters and threshold	Value and justification for β and d0, with source of calibration
Accessibility scores	Ai reported by zone, status quo and proposed scenario
Equity indicators	Gini and DR reported by subgroup, status quo and proposed scenario
Sensitivity analysis	Results under at least two zonal resolutions and two decay parameters
Mitigation plan	Required if any subgroup Gini or DR indicator deteriorates versus status quo
Public disclosure statement	Confirmation that the report has been published prior to Board decision

Conflict of interest: The authors declare no conflict of interest. **Funding:** This research received no dedicated external funding. **Data availability:** This paper presents a conceptual policy framework; the figures reported in Table 2 are hypothetical and illustrative, and no empirical dataset was generated or analysed for a real hospital catchment. **Ethical approval:** Not applicable, as the study involves neither human participants nor personal data.

Note: Following the conference, this Publication Note will be added to each paper; therefore, authors are kindly requested not to remove the note below and to complete the author(s) and paper title information.

Abstract. Micromobility has become an increasingly important component of urban transportation systems, particularly for short-distance trips, first-mile/last-mile connectivity, and flexible daily mobility. While micromobility systems offer several benefits in terms of accessibility, modal integration, and efficient use of urban space, their planning should not be limited to the provision of vehicles alone. The location, design, and management of micromobility stations, parking areas, and mobility hubs directly affect how public space is used and who can benefit from these systems. Therefore, micromobility planning should be considered not only as a transportation issue, but also as a placemaking and fairness in urban mobility issue. This study discusses micromobility through the lens of placemaking, accessibility, and urban transformation. It focuses on how micromobility infrastructure can be integrated into public spaces in a way that supports local needs, improves place quality, and avoids reinforcing existing inequalities. In this context, the study also considers broader fairness-related questions, including gentrification, unequal access, and "accessibility for whom?" Based on a literature-oriented discussion, the paper examines how placemaking can contribute to more inclusive micromobility planning and how station location decisions can shape everyday urban experiences. Finally, the study presents policy implications for Turkey, emphasizing the need to integrate micromobility planning with public space design, pedestrian accessibility, public transport connections, local participation, and context-sensitive urban mobility policies.

Keywords: Micromobility; Placemaking; Fairness in Urban Mobility; Mobility Hubs.

1 Introduction

In recent years, micromobility, which includes lightweight and low-powered personal transport modes often used in shared systems, has rapidly expanded in cities and is expected to continue growing in the coming years [1]. As its use becomes more widespread, micromobility has become an increasingly visible component of urban transportation, particularly for short-distance trips and first-mile/last-mile connections. Micromobility modes, ranging from conventional bicycles to e-scooters, e-bikes, and other small electric vehicles, are increasingly used worldwide and may help address urban transport challenges by encouraging a shift away from private motorized vehicles [2]. As cities seek more sustainable transportation solutions, micromobility is expected to play a growing role in urban mobility.

Dockless micromobility services, particularly bike- and e-scooter-sharing systems, have rapidly expanded worldwide by providing flexible and nearly seamless connections between users and urban activities [3]. Unlike conventional station-based systems, dockless services

allow vehicles to be accessed and left at various locations across the urban environment, providing users with greater flexibility. At the same time, this operational model introduces new spatial challenges, particularly regarding vehicle distribution, parking behavior, pedestrian circulation, and the allocation of public space. A substantial share of conflicts between pedestrians and micromobility users can be attributed to the limited road space allocated to active transport, as most urban road space remains dedicated to motor vehicles [4]. Consequently, the growing presence of micromobility has made its relationship with urban space an increasingly important aspect of transportation planning.

This relationship extends beyond the vehicles themselves to the infrastructure and spaces that support their use. The location and design of stations, parking zones, docking areas, and shared micromobility hubs influence how urban space is used and experienced. Decisions regarding where these facilities are located may determine which users can conveniently access micromobility services while also affecting pedestrian movement and the use of public space. Without designated parking areas, micromobility vehicles may be parked in an uncontrolled manner, potentially blocking sidewalks and reducing the visual quality of public spaces [5]. Beyond their location, the amount of public space allocated to micromobility facilities and the users prioritized in this allocation are equally important, as these decisions may shape who benefits from such interventions and who experiences additional spatial constraints.

Accordingly, micromobility infrastructure should be understood not merely as a transport facility, but as an urban intervention that can reshape the distribution, function, and experience of public space. In this context, placemaking provides a broader perspective for micromobility planning. Rather than considering infrastructure only in terms of transportation efficiency, placemaking emphasizes public space quality, accessibility, social inclusion, and local user needs. Such interventions can also raise questions related to gentrification, unequal access, and "accessibility for whom?" Therefore, integrating placemaking principles into micromobility planning may contribute to transportation systems that are not only efficient but also more inclusive and responsive to their urban context.

2 Literature Review

2.1 Placemaking and Urban Mobility

Placemaking has increasingly emerged as an approach for enhancing the quality of places within neighborhoods, with broader benefits extending to the surrounding community and region, and can be classified into four main types [6]:

- *Standard Placemaking:* Focuses on improving the quality and livability of places through long-term, incremental projects and broad community participation.
- *Strategic Placemaking:* Uses targeted interventions in selected locations to achieve specific objectives, particularly by attracting people, businesses, and economic activity.
- *Creative Placemaking:* Uses arts, culture, and creative activities to shape the physical and social character of places and enhance their vitality.
- *Tactical Placemaking:* Applies low-cost, short-term, and experimental interventions to test potential improvements before committing to larger and more permanent investments.

Beyond these placemaking categories, urbanism can take different forms depending on the level of formality, the degree of design and planning, and the involvement of experts or local communities [7]:

- *Guerrilla Urbanism:* Informal, spontaneous, bottom-up interventions carried out by individuals or local communities, often without formal planning or design procedures.
- *Everyday Urbanism:* Small-scale actions and routines embedded in everyday life that gradually reshape how public spaces are used.
- *Tactical Urbanism:* More deliberate and experimental interventions that may involve temporary design elements and participation by experts or municipalities.

- *Participatory Design / Formal Placemaking:* Structured processes in which professionals and local communities collaborate in planning and designing urban spaces.
- *New Urbanism / Expert Placemaking:* Formally planned and professionally designed interventions led mainly by experts and planning authorities.

Within this broader perspective, space, with its physical characteristics and social features, is a key element of urban development, particularly in its transformation into a meaningful place; therefore, placemaking plays an important role in the planning, management, and experience of urban spaces [8]. Furthermore, as urban neighborhoods are inhabited, their physical and social spaces may gradually transform into meaningful places through everyday interactions, changing residents, and collective actions within the community [9].

Over time, the understanding of placemaking has also evolved. Earlier approaches to placemaking were largely product-oriented, focusing on physical and spatial changes created by designers, whereas more recent perspectives position planners as facilitators and emphasize the involvement of communities and other non-professional actors in the process of shaping places [10].

In addition to these spatial and social dimensions, mobility is also closely connected to how urban places are experienced and transformed. Mobility is neither a new nor a neutral concept, as it has long been intertwined with travel, cultural interaction, globalization, and broader social and political processes [11]. As an integral part of urban life, mobility plays an important role in how people collectively experience and engage with the city [12]. Accordingly, the relationship between mobility and placemaking extends to the infrastructure that supports urban movement. Urban transportation infrastructure can contribute to placemaking not only through its physical presence, but also by generating cultural meanings, shared social interactions, and collective identity within urban space [13].

2.2 Fairness, Gentrification, and "Accessibility for Whom?"

A study investigating residents of traditionally underserved and low-income neighborhoods found that minority respondents faced greater barriers to bikeshare use, particularly regarding membership costs, indicating that spatial access alone may not ensure equitable use [14]. Similarly, in a study on fairness in public transport, autonomous taxis, and bicycle sharing, it is found that simply providing bicycle-sharing infrastructure does not guarantee fair access, since membership procedures, subscription costs, payment requirements, safety concerns, and suitability for different users can continue to exclude women and disadvantaged groups even when stations are spatially accessible [15].

Beyond these user-specific barriers, transportation fairness also requires a clear understanding of what constitutes a fair distribution. In a systematic review of 165 transportation fairness studies, it was shown that assessments of transport fairness often identify disparities without clearly explaining why a particular distribution should be considered fair or unfair, and proposed the 5WH framework to explicitly connect affected groups, benefits and burdens, spatial and temporal context, and fairness standards [16].

Accordingly, fair mobility policies may require differentiated rather than uniform interventions. In a study using European mobility survey data, researchers developed a framework in which socioeconomic characteristics and individual attitudes are used to estimate resistance to sustainable mobility and allocate differentiated incentives to individuals, rather than applying the same incentive to everyone, to maximize adoption while reducing both policy costs and inequalities between groups [17]. Similarly, In a working paper developed within the MyFairShare project, author proposed mobility budgets as a way of distributing limited carbon and street-space resources while accounting for differences in mobility needs, and emphasized that fair allocation may require additional consideration for groups constrained by income, disability, residential location, gender, care responsibilities, or occupational travel needs rather

than assigning identical mobility allowances to everyone [18]. Furthermore, in a paper on fairness and transport sufficiency, it is argued that limited urban street space and carbon-emission capacity should be treated as finite mobility resources, with minimum levels of accessibility guaranteed for users while maximum limits are placed on resource-intensive mobility such as excessive car use [19].

However, fairness concerns in urban mobility extend beyond access to transport services and the allocation of mobility resources, as urban improvements may also influence who is able to remain in and benefit from transformed areas. It is noted that urban regeneration may turn into gentrification when reinvestment leads to displacement or exclusion, including situations in which existing residents are not directly displaced but gradually lose the ability to remain in or access the transformed area [20]. Moreover, it is argued that gentrification should be understood in relation to its geographical and temporal context, since similar regeneration strategies may produce different outcomes depending on the social, economic, and spatial characteristics of cities and neighborhoods [21].

This concern is particularly relevant to transportation investments, which can alter both accessibility and the attractiveness of surrounding areas. It is noted that improvements in transit accessibility can increase land values and attract higher-income residents, potentially displacing lower-income populations and preventing them from benefiting from the new mobility infrastructure [22]. To mitigate such effects, complementary housing policies may therefore be necessary. It is found through an integrated land-use and transportation simulation model in the Washington, DC metropolitan area that affordability requirements targeted at new housing near transit are more effective than housing vouchers or unrestricted increases in housing supply in maintaining low-income households' access to transit and reducing transit-induced gentrification [23].

Nevertheless, the relationship between transportation investment and gentrification is not uniform across different urban contexts. It is found through a systematic review of 35 quantitative studies that, although transit proximity may contribute to gentrification, the relationship is highly context-dependent and is strongly influenced by existing local dynamics, built-environment characteristics, and accompanying policies rather than by transit-oriented development alone [24]. More recently, it is highlighted that transportation investments, including rail, pedestrianization, and improvements in public transport and walking accessibility, can reshape housing markets and neighborhood composition by increasing land values and attracting higher-income groups, while the extent and direction of these effects depend on project design, local socioeconomic conditions, spatial characteristics, and institutional arrangements [25].

2.3 Academic and Real-World Applications of Mobility-Oriented Urban Transformations

A growing number of urban mobility interventions demonstrate how transportation infrastructure and public space transformation can be considered together. Shared micromobility hubs, mobility hubs, tactical urbanism projects, pedestrianization schemes, bicycle-sharing stations, designated e-scooter parking zones, and transit-oriented public space improvements represent different examples of this relationship.

In Brazil, placemaking initiatives have increasingly focused on reclaiming car-oriented urban spaces and transforming them into safer, more inclusive, and people-centered environments that support active mobility and social interaction [26].

- *Eixão de Lazer – Brasília:* The Eixão, originally designed as a high-speed traffic corridor, is closed to vehicles on Sundays and holidays and transformed into a public leisure space for walking, skateboarding, dancing, music, relaxation, and social activities.

- *Paulista Aberta – São Paulo:* Avenida Paulista is closed to motor vehicles on Sundays and holidays, allowing pedestrians and cyclists to use the avenue for recreational, cultural, and sports activities.
- *Minhocão – São Paulo:* The Elevado Presidente João Goulart, originally built to improve traffic flow, has gradually been repurposed for public use and developed toward a park function following concerns over noise, crashes, and community demands.
- *Calçada Viva / Barão do Rio Branco Street – Fortaleza:* Traffic space was reclaimed for pedestrians through wider sidewalks, raised crosswalks, redesigned intersections, kiosks, benches, and outdoor dining areas, increasing pedestrian space from 33% to 60% of the area between façades.
- *João Alfredo Street – Porto Alegre:* The street was redesigned according to Complete Street principles through changes in vehicle-pedestrian flows and the addition of parklets, benches, bike racks, lighting, and green spaces to support active mobility and public-space use.

In the USA, several examples demonstrate how active mobility infrastructure can also contribute to the transformation and improvement of urban public spaces [27].

- *Atlanta BeltLine – Atlanta, USA:* The Atlanta BeltLine combines multi-use trails for walking and cycling with green spaces, public art, transit connections, and community activities, contributing to improved mobility, neighborhood revitalization, and community engagement.
- *Portland Neighborhood Greenways – Portland, USA:* Portland's neighborhood greenways and civic corridors provide safe routes for cyclists and pedestrians while connecting neighborhoods with major transport hubs and key urban functions, improving accessibility and supporting people-oriented streets.
- *Orlando Urban Trail – Orlando, USA:* The Orlando Urban Trail connects parks, cultural sites, and neighborhoods through a multi-use path that supports pedestrian and cyclist mobility while encouraging community engagement and active lifestyles.

In their neighboring continent, Canada, a similar example can be found in Vancouver [27]:

- *Comox–Helmcken Greenway – Vancouver, Canada:* The greenway connects neighborhoods through walking and cycling paths while incorporating landscaped areas and public spaces, contributing to sustainable transportation, improved active mobility infrastructure, community well-being, and environmental sustainability.

3 Discussion

The relationship between placemaking and micromobility becomes particularly important when decisions regarding station and hub locations are considered. Conventional planning approaches may prioritize demand density, expected trip generation, operational efficiency, or technical suitability. Although these factors are necessary, they may not sufficiently explain how micromobility infrastructure interacts with the surrounding public space.

Micromobility infrastructure can either strengthen place quality or create new spatial conflicts. Well-planned stations and hubs can improve connections to public transportation, facilitate short-distance trips, encourage more active street environments, and support more human-oriented mobility networks. In this sense, micromobility facilities may become complementary elements of public space rather than isolated pieces of transportation infrastructure.

In contrast, poorly planned facilities may create sidewalk obstruction, conflicts with pedestrians, or unequal access to mobility opportunities. It is known that, if poorly implemented, micromobility can create additional barriers to public-space access, particularly for people with disabilities whose access is already constrained [28]. Services concentrated

primarily in touristic, central, or high-income areas may also leave peripheral and lower-income neighborhoods relatively underserved. Therefore, the success of micromobility should not be measured only by ridership or vehicle utilization. How the system affects surrounding places, responds to local needs, and distributes accessibility benefits should also be considered.

4 Policy Implications

Placemaking principles can provide practical guidance for integrating micromobility into urban transportation planning. Station and parking locations should therefore not be determined solely by population density, travel demand, and operational data. Public space quality, pedestrian movement, connections with public transportation, social vulnerability, neighborhood characteristics, and local user preferences should also be incorporated into the planning process.

This perspective is particularly relevant for Türkiye, where sidewalk conditions, irregular parking, pedestrian safety, public transportation integration, and municipal access to mobility data can significantly affect the implementation of micromobility systems. Micromobility planning should therefore be coordinated with existing bicycle networks, public transportation transfer points, municipal transportation plans, and local decision-making processes.

Although national regulations establish the broader framework, urban authorities generally hold substantial regulatory influence over local and regional transport through implementation, land-use planning, public transport coordination, and infrastructure provision [29]. In this sense, institutional mechanisms such as UKOME decisions can also be considered together with neighborhood-scale participation and public space planning. Local governments can use participation processes to identify how different groups experience existing micromobility services and whether proposed station locations respond to local mobility needs. In contrast to command planning, which remains widely used, planners should engage directly with neighborhood residents and establish a relationship that recognizes their "right to the city," including their right to participate as local citizens in decisions affecting their communities [30]. Accordingly, micromobility planning in Türkiye should move beyond questions of vehicle numbers and operational permits and incorporate principles of public space fairness and accessibility.

5 Conclusion

Micromobility is likely to become an increasingly important component of urban transportation systems, particularly as cities seek more flexible and sustainable solutions for short-distance mobility. However, its contribution to urban mobility cannot be understood solely through technological development, vehicle availability, or operational performance.

The location and design of micromobility stations and parking areas influence who can access these services, how public space is used, and how transportation benefits are distributed across the city. Placemaking therefore provides a useful framework for connecting micromobility planning with broader questions of accessibility, public space quality, and local needs.

Integrating placemaking into micromobility planning can help cities develop systems that are more accessible, inclusive, and sensitive to their local context. Rather than treating micromobility infrastructure as an independent element of the transportation system, future planning approaches should consider it as part of the wider relationship between mobility, people, and urban space.

Abstract. Urban traffic congestion has become one of the most challenging problems of daily urban life, affecting travel time, service reliability, accessibility, and overall quality of mobility. One of the key approaches to addressing this problem is the improvement of public transportation systems, which can reduce dependency on private vehicles and support more efficient use of limited urban road space. In this context, the integration of autonomous vehicle technologies into public transportation has introduced the concept of Autonomous Public Transport, particularly through autonomous buses and shuttles. While these systems are often discussed as innovative public transport solutions, their potential role in traffic management also deserves attention. Autonomous Public Transport vehicles may not only operate as mobility service providers but may also contribute to the regulation, coordination, and optimization of traffic flow under certain operational and technological conditions. Therefore, this study reviews the existing literature to examine how Autonomous Public Transport is discussed in relation to traffic management. The review focuses on studies addressing autonomous public transport applications, mixed traffic interactions, traffic flow impacts, and management-oriented approaches associated with autonomous and connected mobility systems. Based on the reviewed literature, the study discusses whether Autonomous Public Transport can be considered applicable and feasible as a traffic management element in urban mobility systems. The findings provide a literature-based understanding of the possible roles, limitations, and future research directions of Autonomous Public Transport in traffic management.

Keywords: Autonomous Public Transport; Autonomous Buses; Traffic Management

1 Introduction

Traffic congestion has become a major challenge in many metropolitan areas, leading cities to implement various measures to reduce its impacts [1]. As travel demand increases, cities need more efficient ways to manage existing transportation systems. It is argued that reducing road congestion requires improving alternatives to private car travel [2]. Public transportation is one of the main alternatives because it can reduce private vehicle use and make better use of urban road capacity.

Recent developments in autonomous vehicle technologies have also created new opportunities for public transportation. Autonomous buses and shuttles are increasingly considered as a part of future public transport systems [3]. These vehicles may improve public transport operations through automation, connectivity, and better coordination with transportation infrastructure.

However, autonomous public transport (APT) may have a role beyond carrying passengers. Autonomous and connected public transport vehicles can interact with traffic signals, infrastructure, and other vehicles. Therefore, they may also contribute to traffic flow and traffic management.

Existing studies mainly focus on the technological, operational, safety, and social aspects of autonomous public transport. Its possible use as a traffic management element has received less attention. Therefore, this study reviews the existing literature to examine the relationship between autonomous public transport and traffic management. It also discusses its potential applications, limitations, and future research needs in urban transportation systems.

2 Literature Review

Recent developments in intelligent transportation systems have expanded the possibilities for traffic management beyond conventional infrastructure-based control. Mulay et al. [4] proposed an urban ITS framework that combines GPS-based public transport tracking, CCTV-based congestion detection, and adaptive traffic signal control, showing how real-time information can be used to support both public transport operations and traffic regulation. El Hamdani & Benamar [5] further discussed autonomous traffic management through V2V and V2I communication, particularly for intersection and road traffic control, and highlighted the potential of cooperative autonomous systems to reduce delay and congestion. Similarly, [Mancino [6] discussed the use of AI for real-time monitoring, dynamic signal control, incident detection, and route optimization, while also emphasizing its potential use in public transport scheduling and routing. Traffic prediction also represents an important part of this development. Manne et al. [7] proposed a traffic-flow prediction model based on Bi-LSTM and reported an average prediction accuracy of 0.951, outperforming SVM, random tree, random forest, and conventional LSTM models. In addition, Ud Din et al. [8] examined AIoT-supported autonomous driving technologies and showed that adaptive cruise control and collision-avoidance systems can improve vehicle-level performance under different traffic environments. Together, these studies indicate that connectivity, automation, real-time data, and intelligent decision-making provide a technological basis for more dynamic forms of traffic management.

Based on these technological developments, several studies have focused on controlling autonomous vehicles at the trajectory and conflict-management level. Lu et al. [9] proposed a trajectory-based traffic management model for an exclusive autonomous vehicle zone. The model uses mixed-integer programming to optimize the trajectories of multiple AVs while resolving inter-vehicle conflicts, together with a rolling-horizon algorithm to improve computational efficiency. Their model was developed for a multi-lane single-link AV environment and was later extended to include scheduling and equity considerations. Martin-Gasulla & Elefteriadou [10] applied a similar vehicle-coordination perspective to single-lane roundabouts. Their centralized Roundabout Manager uses seven priority strategies, including a Shortest-Remaining-Time-First approach, to coordinate CAV trajectories under oversaturated conditions. The simulations showed that a fully CAV traffic environment could increase roundabout capacity by 58–73% and reduce average control delay by 80–97% compared with conventional vehicle operations. Naeem et al. [11] also examined vehicle-level coordination at intersections by applying preemptive and non-preemptive scheduling to autonomous, conventional, and emergency autonomous vehicles in SUMO. Their results showed different delay levels across four tested road networks, with the Washington network producing delays of 4.02 s for AVs, 3.62 s for emergency AVs, and 4.33 s for conventional vehicles in the 50-vehicle scenario.

The coordination of multiple autonomous vehicles has also been examined outside conventional road transportation. Draganjac et al. [12] developed a decentralized traffic management method using state-lattice path planning and local conflict negotiation for

autonomous guided vehicles, demonstrating efficient coordination of fleets with up to 50 vehicles in shared industrial environments.

However, the transition toward autonomous mobility is expected to occur under mixed traffic conditions rather than in fully autonomous environments. Therefore, another group of studies has examined how AVs and CAVs can be integrated into networks shared with human-driven vehicles. Amirgholy et al. [13] developed an optimal lane-management framework for heterogeneous traffic consisting of human-driven vehicles, AVs, and CAVs. Using a macroscopic network fundamental diagram and an optimization model for the San Francisco network, the study dynamically adjusted lane allocation and CAV platoon sizes. The results showed that optimal lane management could reduce corridor delays by up to 78%, while the increase in travel time in the downtown network could be limited to approximately 5%. Yıldırım & Özuysal [14] examined mixed traffic conditions using SUMO simulations based on both the Sioux Falls test network and the İzmir urban transportation network. More than 300 simulations were conducted under different AV penetration rates. Their results showed that dedicated lanes could reduce local density, occupancy, and time loss by 5–35% and improve travel time reliability by 15–25%. In contrast, transitions of control at lower AV penetration levels could reduce traffic performance by up to 10%, showing that the benefits of automation depend strongly on traffic composition and operational conditions.

Beyond managing AVs as part of the traffic stream, recent research has also considered the possibility of using CAVs themselves as active traffic management elements. Gokasar et al. [15] developed the SWSCAV approach, in which CAVs are instructed to reduce their speeds according to the speed of a detected shockwave caused by an incident. The method uses Fused Lasso for smoothing traffic data and Fast Fourier Transform for data upsampling before controlling the speed and acceleration of CAVs. The system was tested in 4800 SUMO scenarios on a three-lane tunnel road network by changing CAV penetration rates, incident characteristics, and control distances. The results showed reductions of 12.68% and 8.15% in the occurrence of density levels above 38 and 28 veh/km/lane, respectively, and the method reduced traffic density more effectively than the tested lane control system even at low CAV penetration rates. Gokasar et al. [16] extended this concept by examining whether traffic could be managed with only a limited number of CAVs rather than relying on a specific penetration rate. A total of 189 SUMO scenarios were tested with a maximum of 12 CAVs. The results showed that the proposed approach could increase mean speed by up to 20.35% and flow by up to 2.45%, while reducing mean density by up to 32.54%. These findings are particularly important because they show that autonomous vehicles can function not only as road users affected by traffic management, but also as actuators that actively influence surrounding traffic flow.

While these studies mainly focus on general AVs and CAVs, autonomous technologies are also increasingly being examined in public transportation. Iclodean et al. [17] reviewed autonomous shuttle bus technologies and reported that current applications are generally more suitable for controlled or low-traffic environments. Autonomous shuttles are typically operated on fixed routes at relatively low speeds, and current applications are concentrated in areas such as airports, industrial parks, commercial areas, and low-traffic night routes. [Fielbaum [18] examined how autonomous vehicle technology could change the design of public transport by developing an autonomous feeder–trunk model. The study showed that automation favors larger fleets of smaller vehicles and more direct routes. Traditional public transport technology was estimated to cost approximately 50% more than autonomous alternatives, although the resulting increase in vehicle numbers could lead to a marginal increase in congestion. Trubia et al. [19], reviewing different autonomous public transport scenarios, similarly emphasized the potential of high-frequency and lower-capacity autonomous services. The reviewed evidence included a MATSim-based Berlin scenario in which at least 50,000 shared autonomous vehicles

would be required to replace the existing public transport system of approximately 1,500 buses and 600 trams, illustrating the possible network-scale implications of replacing conventional public transport with smaller autonomous vehicles.

Autonomous public transport has also been studied from an operational control perspective. Hasebe et al. [20] proposed a last-mile public transportation system based on fleets consisting of manually driven lead vehicles and driverless trailing vehicles. Passenger requests are collected in real time by a central management server, which dynamically determines vehicle schedules and reorganizes vehicle fleets according to demand. The study also proposed provisional routing to maintain transport services in the event of central-server failure, although quantitative traffic-flow improvements were not evaluated. Cao et al. [21] focused more directly on real-time operational control of autonomous public transport vehicles. They developed a simulation-based approach combining discrete-event modeling and a time–space matrix with holding and speed-changing strategies. The method was tested on a 13-km, seven-stop bus route in Auckland, where APTVs were assumed to operate on an exclusive public transport lane without external traffic disturbances. The proposed control strategies eliminated schedule deviations by 100% and improved the overall objective function by approximately 31–33%, demonstrating that APT vehicles can respond dynamically to real-time operational conditions.

Table 1. Literature Review Summary Table

Author(s) / Year	**Traffic Management Role**	**Main Result**
Mulay et al. (2013)	Supporting ITS and congestion management	Integrates real-time public transport information, congestion detection, and congestion-responsive signal timing; no quantitative result reported.
El Hamdani & Benamar (2018)	General autonomous traffic management	Identifies cooperative AVs as potential traffic-management agents through V2V/V2I communication, while highlighting challenges related to complex networks, communication, and mixed road users.
Mancino (2022)	Supporting intelligent traffic management	AI can support dynamic signal control, incident detection, congestion prediction, and route optimization; no quantitative validation was reported.
Manne et al. (2021)	Traffic-flow prediction	The Bi-LSTM model achieved an average prediction accuracy of 0.951, outperforming SVM, RT, RF, and conventional LSTM models.
Din et al. (2024)	Vehicle-level control supporting traffic efficiency	Collision-avoidance accuracy increased from 75% to 90% in urban environments, 80% to 95% on highways, and 65% to 85% under low visibility.
Lu et al. (2019)	Trajectory-based traffic management	The proposed framework successfully coordinated multiple AV trajectories, while the rolling-horizon approach provided computationally efficient approximate solutions.
Martin-Gasulla & Elefteriadou (2021)	Roundabout trajectory and conflict management	Fully CAV traffic increased roundabout capacity by 58–73% and reduced average control delay by 80–97% compared with conventional traffic.
Naeem et al. (2023)	Intersection and priority management	In the best-performing Washington network, average delays were 4.02 s for AVs, 3.62 s for VIP AVs, and 4.33 s for conventional vehicles.

Draganjac et al. (2020)	Decentralized multi-vehicle traffic management	The method demonstrated scalable autonomous fleet coordination, reaching a maximum throughput of 953 missions/h with 30 vehicles.
Amirgholy et al. (2020)	Mixed-traffic lane and network management	Optimal lane management reduced corridor delay by up to 78%, while limiting the downtown travel-time increase to approximately 5%.
Yıldırım & Özuysal (2024)	Mixed-traffic AV integration and lane management	Dedicated lanes reduced density, occupancy, and time loss by 5–35% and improved travel-time reliability by 15–25%, while ToC caused up to a 10% performance decline at low AV penetration.
Gokasar et al. (2023)	CAVs as active traffic-management actuators	SWSCAV reduced occurrences of density above 38 and 28 veh/km/lane by 12.68% and 8.15%, respectively, and remained effective at low CAV penetration rates.
Gokasar et al. (2024)	Limited CAVs as active traffic-management actuators	Using a maximum of 12 CAVs increased mean speed by up to 20.35% and flow by 2.45%, while reducing mean density by up to 32.54%.
Iclodean et al. (2020)	APT deployment and operational feasibility	Current autonomous shuttles are mainly suitable for controlled or low-traffic environments because of their low capacity and operating speed.
Fielbaum (2019)	APT network and service design	Autonomous technology favors larger fleets of smaller vehicles and more direct routes; traditional technology was approximately 50% more costly, although a marginal congestion increase was expected.
Trubia et al. (2021)	APT system-level impacts	Reviewed studies indicate benefits from higher-frequency, lower-capacity autonomous services; a Berlin scenario required at least 50,000 SAVs to replace approximately 1,500 buses and 600 trams.
Hasebe et al. (2017)	Dynamic APT fleet and operational management	The proposed system enables dynamic fleet reorganization and continuation of service through provisional routing after central-server failure; no quantitative traffic-flow result was reported.
Cao et al. (2019)	Real-time APT operational control	Real-time holding and speed-changing reduced schedule deviations from 33 min and 13 min to 0 min under low- and high-demand scenarios, with approximately 31–33% improvement in the objective function.

3 Discussion

The reviewed literature shows that autonomous vehicles can be used not only as road users but also as active elements of traffic management. Existing approaches demonstrate that vehicle speed, trajectory, lane use, and interactions with surrounding traffic can be controlled to influence traffic flow. At the same time, studies on Autonomous Public Transport mainly focus on system design, trajectory control, scheduling, and operational management. Some applications also consider APT vehicles operating on exclusive or dedicated routes. When these two research directions are considered together, a broader role for APT in urban traffic management becomes possible.

Public transportation has an important position in urban mobility because its routes, stops, and operational patterns are generally predefined. This creates a more predictable structure than private vehicle traffic. In conventional traffic, other road users are already expected to follow specific rules around public transport operations, such as respecting bus stops, giving space for buses to enter or leave traffic, or avoiding restricted areas. Autonomous public transport could potentially make these interactions more systematic. Since the location of stops and the movement of APT vehicles are known in advance, these vehicles could interact with surrounding vehicles and infrastructure to support traffic regulation around these locations.

This role could be applied in different traffic environments. In an exclusive or dedicated corridor, APT vehicles could coordinate their trajectories, speeds, and headways to manage traffic within their own operating space. In mixed traffic, their role could extend beyond their own movement. For example, an autonomous bus approaching or leaving a stop could influence the speed or positioning of nearby connected vehicles, support lane organization, or create controlled gaps in traffic. In this sense, APT vehicles could act as mobile traffic management elements while continuing to provide passenger transport.

The fixed nature of public transport routes may also make this approach more feasible than applying the same concept randomly across private AVs. APT vehicles repeatedly travel through the same corridors, intersections, and stops. Therefore, traffic management strategies could be designed specifically for these locations and repeated under similar operational conditions. This could allow APT to contribute to traffic management both through its own controlled operation and through its interaction with surrounding traffic.

However, this concept would require a balance between public transport service objectives and traffic management objectives. An APT vehicle should not significantly delay its passengers simply to improve general traffic conditions. Therefore, its traffic management role would need to operate within predefined limits related to schedule reliability, passenger comfort, and service performance. From this perspective, the applicability of APT as a traffic management element appears possible, particularly in locations where public transport already has a defined operational priority. Its feasibility would depend on how effectively traffic-control functions can be integrated with the primary function of providing reliable public transportation.

4 Conclusion

Urban traffic congestion continues to increase the need for more efficient transportation and traffic management approaches. Public transportation already plays an important role in urban mobility, and autonomous technologies may further expand this role.

The reviewed literature shows that autonomous vehicles can support traffic management through coordinated movement, speed control, and trajectory management. At the same time, APT systems allow more dynamic and controlled operations. Therefore, APT may contribute to traffic management in both dedicated and mixed traffic environments, particularly due to its predefined routes and fixed stops.

Overall, using APT as a traffic management element appears promising. However, its implementation should remain compatible with passenger travel time, service reliability, and public transport performance. Further research is needed to examine its applicability and operational feasibility under different traffic conditions.

Abstract. Urban transportation systems in developing areas experience increasing pressure due to congestion, unreliable service, and operational inefficiencies, creating what several studies describe as a mobility crisis. As cities seek sustainable and long-term solutions, autonomous buses have emerged as a promising alternative, supported by their ability to sense the environment, communicate in real time, and operate with consistent, accurate decision-making. These capabilities offer the potential to improve public transportation efficiency, enhance safety, and strengthen pedestrian connectivity, ultimately contributing to a more accessible and livable urban environment. To better understand the feasibility of autonomous bus deployment in terms of social acceptance, this study conducts a SWOT analysis. The analysis highlights substantial strengths, including operational consistency and long-term cost efficiency, as well as opportunities related to smart city integration and environmental benefits. At the same time, weaknesses such as high initial investment and technical limitations, along with external threats like regulatory uncertainty and cybersecurity risks, underscore the complexity of implementation. Altogether, these factors could explain why social acceptance remains uneven across different socioeconomic and cultural groups. The study further discusses how policymakers interpret these conditions differently from the public, viewing autonomous buses as a strategic long-term investment capable of improving welfare, comfort, and overall mobility performance. Finally, the findings emphasize that awareness campaigns, transparent communication, and user-centered engagement strategies will be essential to improving public trust.

Keywords: Autonomous Buses; Social Acceptance; SWOT Analysis; Urban Mobility

1 Introduction

Public transportation is an essential component of urban mobility, and buses remain one of the most widely used modes of public transport in cities. To support this, the EU transport strategy promotes public passenger transport over individual transport to improve road safety and reduce pressure on road infrastructure [1]. However, conventional bus systems face several operational challenges, particularly in rapidly growing urban areas. In this context, the integration of autonomous buses into public transport systems can provide substantial benefits by reducing traffic accidents, congestion, fuel use, and operating costs, while also improving service quality and environmental sustainability [2].

Autonomous buses combine the conventional role of public transportation with the capabilities of autonomous vehicle technologies. Technology companies, vehicle manufacturers, transit operators, and governments have introduced various AV-based mobility services [3]. A fully autonomous vehicle can be defined as a vehicle that uses sensors,

processors, and mapping data to perceive its surroundings, communicate in real time, make rapid decisions, plan its route, and perform driving tasks with limited or no human intervention [4]. Such capabilities can contribute to more consistent vehicle operations, more reliable public transport services, and improved interaction with the surrounding traffic environment. Therefore, their implementation has the potential to influence not only bus operations but also the overall performance of the urban mobility system. The main reason behind it is the lower operational cost of autonomous buses, which can enable more frequent services [5].

Despite the technological development of autonomous vehicles, the successful implementation of autonomous buses cannot be evaluated solely from an operational perspective. Since passengers are the direct users of public transportation services, social acceptance has an important role in determining whether autonomous buses can become a part of everyday urban mobility. Social acceptability is considered a reciprocal and context-dependent process rather than an isolated phenomenon, particularly because the use of public transportation, including autonomous buses, inherently involves participation in a shared social environment [6]. People's perceptions of autonomous technologies may vary according to socioeconomic, cultural, and individual characteristics. Consequently, users may evaluate the same technology differently in terms of its safety, reliability, usefulness, and potential benefits. This makes public trust an important component of autonomous bus implementation.

Safety is closely related to this issue of trust. In addition to the expected safety benefits of autonomous driving technologies, safety continues to be a major concern, particularly regarding public trust, considering that 316 accidents involving autonomous vehicles were reported in the United States between 2015 and 2020 [7]. Technical uncertainties, possible system failures, cybersecurity risks, and unfamiliarity with automated driving may therefore influence how passengers perceive autonomous buses. As a result, technological improvements alone may not be sufficient to ensure widespread adoption if the public remains uncertain about the reliability and safety of these systems.

Accordingly, this study evaluates autonomous buses through a SWOT analysis from the perspective of policymakers and urban planners. Rather than considering social acceptance as an isolated factor, the study examines how the strengths, weaknesses, opportunities, and threats associated with autonomous buses can collectively influence public perception and acceptance. By evaluating these factors together, the study aims to identify the main issues that policymakers should consider when developing strategies for the successful integration of autonomous buses into urban public transportation systems.

2 Evaluation and SWOT Analysis

The implementation of autonomous buses involves a combination of internal technological characteristics and external conditions. A SWOT analysis provides a useful framework for evaluating these factors by separating them into strengths, weaknesses, opportunities, and threats. In this study, the analysis is conducted primarily from the perspective of policymakers and urban planners, as these actors are responsible for developing regulations, allocating resources, planning infrastructure, and guiding the introduction of autonomous transportation systems.

2.1 Strengths

- *Operational consistency:* Autonomous buses can reduce variations caused by human factors and provide more standardized acceleration, braking, and vehicle operation, supporting regular service intervals and more reliable public transportation [8].
- *Enhanced safety:* Sensors, real-time environmental perception, and automated braking systems can continuously monitor surrounding traffic conditions and reduce some of the risks associated with human error [9].

- *Long-term cost efficiency:* Although autonomous buses require considerable initial investment, reductions in driver-related operational costs and improvements in fuel or energy efficiency may provide economic benefits over the long term [10].
- *Data-driven optimization:* Continuous communication between vehicles and transportation management systems can support improvements in route planning, fleet allocation, capacity management, and service scheduling [11].
- *Accessibility improvements:* More predictable and reliable autonomous bus services may contribute to more inclusive public transportation, particularly for passengers who depend strongly on public transit for daily mobility [12].

2.2 Weaknesses

- *High initial investment requirement:* Autonomous buses require advanced sensors, software, communication systems, digital infrastructure, and possible modifications to existing transportation infrastructure, creating substantial implementation costs.
- *Limited performance in complex urban environments:* Dense traffic, unpredictable pedestrian movements, interactions with conventional vehicles, and complicated intersections can create challenging operating conditions for autonomous buses [13].
- *High maintenance and technical expertise requirements:* Autonomous buses depend on advanced sensors, software, and electronic systems that require specialized maintenance, continuous system updates, and highly trained technical personnel.
- *Dependence on reliable connectivity and infrastructure:* Communication failures and infrastructure disruptions may reduce system performance and limit the potential benefits of automation [14].

2.3 Opportunities

- *Urban mobility transformation:* More reliable and efficient bus operations may increase the attractiveness of public transportation and contribute to reducing dependence on private vehicles [15].
- *Integration with smart city systems:* Smart cities aim to involve all stakeholders in the target area, and autonomous buses can directly support the smart city concept due to their structure, which enables high interaction with the road and communication network [16].
- *Environmental benefits:* When combined with electric propulsion, autonomous buses may support more energy-efficient transportation and contribute to broader sustainability objectives [17].

2.4 Threats

- *Regulatory and legal uncertainty:* The absence of a thorough legal structure to handle liability concerns related to autonomous vehicles is one major worry [18]. Delays in developing operational standards, certification procedures, and liability frameworks may slow or prevent large-scale autonomous bus deployment.
- *High-cost project cancellations:* Economic downturns, changing political priorities, and budget restrictions may lead to the postponement or cancellation of autonomous bus projects.
- *Cybersecurity attacks:* Cyberattacks on automotive systems have increased dramatically as cars become more interconnected, posing a serious threat to data privacy and safety [19]. Unauthorized access to vehicle control systems or transportation data may create significant risks for operational safety and system reliability.

2.5 Evaluation of the SWOT Findings and Social Acceptance

The SWOT analysis indicates that social acceptance cannot be explained by a single characteristic of autonomous buses. Instead, public perceptions are likely to emerge from the interaction between technological benefits, perceived limitations, future opportunities, and external risks.

From the perspective of passengers, several weaknesses and threats may naturally create uncertainty. Potential system malfunctions, cybersecurity risks, complex interactions in urban traffic, and unresolved legal questions may make autonomous buses appear less predictable than conventional buses operated by human drivers. The considerable cost of the technology and the continuing development of regulatory frameworks may further reinforce the perception that autonomous buses are still an emerging rather than fully mature transportation solution. Consequently, it is understandable that some members of the public may perceive autonomous buses as a potential risk or threat despite their expected benefits.

The perspective of policymakers and urban planners, however, is likely to differ because implementation decisions are generally evaluated over a longer time horizon. Autonomous buses may provide economic advantages through lower operational costs and improved resource utilization. At the same time, more reliable and predictable public transportation can enhance accessibility, reduce congestion, and improve the mobility of the wider urban population. Potential improvements in safety, accessibility, and service reliability can also contribute to passenger welfare and comfort.

Therefore, from a policymaker perspective, autonomous buses can be considered not merely as a new vehicle technology but as a long-term strategic investment in the urban transportation system. Their potential benefits extend beyond the operation of individual bus services and may contribute to broader objectives related to mobility, sustainability, efficiency, accessibility, and quality of life.

This difference between short-term public concerns and long-term policy expectations creates an important challenge. The technological and operational advantages of autonomous buses may be significant, but these advantages cannot produce their full societal value if passengers remain unwilling to use the service. Social acceptance therefore acts as a bridge between the technical feasibility of autonomous buses and their actual contribution to urban mobility.

3 Policy Implications

The results of the SWOT analysis suggest that policymakers should consider social acceptance as an integral component of autonomous bus implementation rather than as an issue to be addressed after technological deployment. Policies should therefore aim not only to regulate autonomous bus operations but also to reduce the information and experience gap between policymakers, technology providers, and the public.

One important instrument is the use of awareness campaigns. Many public concerns may originate from limited knowledge about how autonomous buses operate and how their safety systems respond to surrounding traffic conditions. Public information campaigns can explain the basic functioning of the technology, its safety mechanisms, its limitations, and the expected benefits for urban mobility. In addition to that, social media can significantly contribute to the wider acceptance of autonomous vehicles by promoting their advantages through interactive campaigns and engaging content [20].

A second policy option involves the use of incentive mechanisms during the early stages of deployment. Generally, free trial periods, discounted fares, or easier access to pilot services may encourage passengers who would otherwise be hesitant to experience autonomous bus transportation. In order to achieve a more successful outcome, different individual groups should be treated differently, as they could be offered specialized incentives [21]. Direct

experience can help users evaluate the technology based on actual service rather than assumptions or unfamiliarity.

Similarly, hands-on public engagement can be incorporated into pilot projects. Test rides, public demonstrations, informational events, and passenger feedback sessions can create direct interaction between users and the technology. Such activities can also provide policymakers with information about passenger concerns that may not be visible through purely technical evaluations. To evaluate such experiments, questionnaires before, during, and after the trip could be a handful and assist decision-makers in determining key performance indicators [22]. As a result, public engagement can operate in both directions: it can familiarize citizens with autonomous buses while simultaneously helping authorities improve implementation strategies.

Finally, and most importantly, transparent communication and regulatory clarity are essential. Policymakers should clearly communicate safety requirements, monitoring procedures, cybersecurity measures, emergency protocols, and responsibility mechanisms. Transparency may be particularly important following technical failures or incidents, since attempts to minimize or obscure risks can have long-term consequences for public trust. Together, these approaches can help narrow the gap between the long-term benefits identified by policymakers and the uncertainties perceived by passengers.

4 Conclusion

Autonomous buses have the potential to become an important component of future urban public transportation systems. Their technological characteristics may improve safety, operational efficiency, accessibility, and service reliability, while their integration with smart transportation systems may create additional opportunities for urban mobility.

At the same time, their successful implementation depends on more than technological capability. The SWOT analysis demonstrates that weaknesses and external threats can significantly influence how the technology is perceived by the public. Policymakers therefore need to consider the difference between the long-term strategic benefits of autonomous buses and the short-term uncertainties experienced by potential users.

In this context, social acceptance should be treated as a central consideration in autonomous bus implementation. Further research supported by empirical data, passenger surveys, real-world pilot projects, and comparisons between different socioeconomic and cultural groups will be necessary to determine which factors most strongly influence acceptance and which policy interventions are most effective.

Evaluating Pedestrian Safety and Crossing Preferences Along Urban Arterial Corridors

Beyhan Ipekyuz[1,*] and Funda Ture Kibar[2]

Abstract. Pedestrian safety is a critical concern on high-speed urban arterials where cross-corridor pedestrian demand conflicts with vehicle-oriented road design. This preliminary study investigates reported crossing behaviour, safety perception and infrastructure preferences along the approximately 4-km Mahabad–Seyrantepe section of Elazığ Boulevard in Diyarbakır, Türkiye. The corridor has an 82 km/h posted speed limit, intensive vehicular and pedestrian activity, two pedestrian overpasses, two signalised at-grade crossings and repeated unauthorised openings in the median fencing. Following the required ethical and administrative approvals, a face-to-face questionnaire was administered to 50 corridor users in late July 2026. Among the 47 valid single-choice responses, 25.5% identified a median-barrier opening as their primary crossing method. In addition, 48.0% of all participants reported crossing at road level at least sometimes despite the availability of a designated facility. Although 92.0% considered this behaviour dangerous or dangerous but sometimes understandable, 75.5% of valid respondents perceived vehicle speed as high or very high and 89.8% felt unsafe or only slightly safe while crossing. Existing overpasses were considered difficult to reach by 69.4%, while excessive distance was the most frequently reported reason for avoidance. A safe signalised crossing and an improved, accessible overpass would be used by 71.4% and 69.4% of valid respondents, respectively. The findings suggest that barrier repair alone may be insufficient where formal crossing facilities are poorly aligned with pedestrian movement demand. The results support the consideration of measured speed management, demand-responsive crossing provision and accessible grade separation where warranted.

Keywords: pedestrian crossing behaviour; road safety; pedestrian overpass; urban arterial; risk perception.

1 Introduction

Pedestrians are among the most vulnerable users of the urban transport system because they have little physical protection in the event of a collision. Road traffic injuries therefore remain a major public-health and mobility problem. Approximately 1.19 million people die in road traffic crashes worldwide each year, and pedestrians, cyclists and users of powered two- and three-wheelers together account for more than half of these deaths [1]. In response, the Global Plan for the Decade of Action for Road Safety 2021–2030 calls for at least a 50% reduction in road traffic deaths and injuries by 2030. Its Safe System approach recognises that human error is inevitable and that road infrastructure, speed management and vehicle operation should prevent such errors from resulting in death or serious injury [2].

Pedestrian safety is also an important concern in Türkiye. Official statistics for 2025 recorded 6,035 fatalities and 403,937 injuries in road traffic crashes. Of all fatalities, 57.2% occurred in

crashes within settlements. Crashes classified under the ‘hitting a pedestrian’ category were associated with 1,190 fatalities, corresponding to approximately 19.7% of all road traffic deaths [3]. These national statistics establish the scale of pedestrian-related road trauma but do not explain why unsafe crossing behaviour becomes concentrated at particular road sections. Identification of the underlying behavioural and infrastructure-related factors therefore requires corridor-specific investigation.

Divided urban arterials present a particularly challenging environment for pedestrians because high vehicle speeds, wide cross-sections, central medians and limited crossing opportunities increase both crossing distance and exposure. At the same time, adjacent residential areas, schools, shopping centres, public institutions, commercial frontage and public transport stops generate frequent pedestrian movements between the two sides of the road. Although overpasses, underpasses and median fencing are intended to reduce uncontrolled pedestrian–vehicle interaction, their presence does not necessarily ensure use. When formal facilities impose substantial detour, physical effort or accessibility constraints, pedestrians may prefer shorter at-grade routes. Repeated use of openings in median fencing may therefore indicate not only non-compliance but also a mismatch between formal crossing provision and actual pedestrian desire lines.

The present study examines this problem along Elazığ Boulevard (D885) in Diyarbakır, Türkiye. Preliminary field reconnaissance identified repeated pedestrian crossings through unauthorised openings in the median fencing despite the presence of two pedestrian overpasses and two signalised at-grade crossings within the approximately 4-km section between Mahabad Intersection and the Seyrantepe grade-separated junction. The corridor has a posted speed limit of 82 km/h [4] and accommodates intensive vehicular traffic together with pedestrian demand generated by schools, residential neighbourhoods, commercial and industrial activities, public institutions, public transport stops and a major shopping centre.

Accordingly, the study examines: (i) the crossing methods reported by corridor users; (ii) the traffic, situational and infrastructure-related factors associated with crossing-location choice; (iii) perceptions of vehicle speed, crossing safety, driver attentiveness, lighting and overpass accessibility; and (iv) stated preferences for alternative pedestrian-safety interventions. Particular attention is given to the apparent discrepancy between the recognition of crossing risk and the continued use of informal at-grade crossing locations.

2 Literature Review

Pedestrian crossing behaviour is influenced by the interaction of traffic conditions, road geometry, infrastructure provision and individual decision-making. Vehicle speed, traffic volume, available gaps, crossing distance, waiting time and the number of traffic lanes directly affect pedestrian exposure and gap-acceptance decisions. At the same time, pedestrians evaluate whether the safety benefit of a designated facility compensates for its additional distance, travel time and physical effort. Crossing behaviour should therefore be understood as a balance between perceived risk and the perceived cost of using the formal alternative [5–15].

The location of a crossing facility relative to pedestrian origins and destinations is one of the principal determinants of its use. Pedestrians are less likely to use a designated facility when it requires a substantial deviation from their intended route [5]. The acceptability of signalised crossings, pedestrian overpasses and underpasses is similarly affected by additional walking time, accessibility, convenience and personal security [6]. Accordingly, the spacing and placement of formal crossing facilities should be evaluated in relation to observed pedestrian demand and acceptable detour distances [7].

Studies conducted on wide, multi-lane arterials demonstrate the importance of route directness. Illegal mid-block crossing decisions have been associated with available gap duration, vehicle speed, waiting time, lane position and the walking-distance savings achieved

by selecting a direct route [8]. On high-speed divided arterials, vehicle presence, pedestrian group behaviour, physical obstructions and the pursuit of the shortest route also affect the decision to cross outside designated facilities [9]. Evidence from unmarked road segments further indicates that road-environment characteristics, individual attributes and the behaviour of surrounding pedestrians jointly influence informal crossing [10]. Collectively, these findings indicate that non-designated crossing cannot be attributed solely to deliberate non-compliance [8–10].

Risk perception does not always translate into safe crossing behaviour. Pedestrians may recognise a crossing manoeuvre as hazardous but still accept the risk when the designated alternative is perceived as distant, inconvenient or difficult to access. In addition to observable traffic conditions, route optimisation, individual risk-taking tendencies, detour distance, waiting time, personal security, habitual behaviour and social influence may contribute to crossing decisions [11–15]. Formal facilities should therefore be evaluated not only according to their physical presence but also according to their accessibility, location and correspondence with pedestrian desire lines.

Comparatively limited attention has been given to informal crossings facilitated by unauthorised openings in continuous median fencing, particularly where pedestrian overpasses and signalised crossings are already available. The present study addresses this specific configuration by examining reported crossing behaviour, perceived traffic risk, overpass accessibility and intervention preferences within the same corridor-level framework. This approach enables the study to evaluate whether continued informal crossing is associated primarily with limited risk awareness or with a mismatch between formal infrastructure and actual pedestrian movement demand.

3 Methodology

3.1 Research design and area

A cross-sectional questionnaire study supported by preliminary field reconnaissance was conducted along Elazığ Boulevard in Diyarbakır, Türkiye. The investigated corridor extends approximately 4 km between Mahabad Intersection in the west and the Seyrantepe grade-separated junction in the east. The inbound direction runs from Mahabad towards Seyrantepe and continues towards the city centre and the historic Sur district, while the outbound direction runs from Seyrantepe towards Mahabad. Seyrantepe is a multi-level junction connecting Elazığ Boulevard with Şanlıurfa Boulevard (E99), whereas Ahmed Arif Intersection constitutes an important intermediate connection within the study corridor (see *Fig. 1*).

Elazığ Boulevard is a divided urban arterial carrying intensive vehicular traffic and serving considerable pedestrian activity. The surrounding land uses include residential neighbourhoods, a school zone, Forum Diyarbakır Shopping Centre, industrial and commercial establishments, restaurants, public institutions and public transport stops. The main carriageways generally comprise two through lanes in each direction, while parallel two-lane frontage or service carriageways are present along substantial parts of the corridor. These service carriageways accommodate public transport operations, local traffic and direct property access. The cross-section varies near intersections, access points and merging or diverging areas. At some pedestrian desire lines, the total crossing distance exceeds 40 m when the main carriageways, central median and service roads are considered together. The posted speed limit was 82 km/h [4]. Two pedestrian overpasses and two signalised at-grade crossings are located within the study section. One overpass serves the Forum Diyarbakır Shopping Mall area, while the other is near the State Hydraulic Works (*DSİ*) frontage before the Ahmed Arif Street connection. Median fencing restricts uncontrolled crossings; however, preliminary field reconnaissance identified missing or displaced sections enabling informal pedestrian access to the median.

Fig. 1. Study corridor, principal junctions, surrounding activity areas and formal pedestrian crossing facilities (Google Earth, 2026).

Fig. 2 illustrates representative corridor conditions, including the main and service carriageways, a signalised pedestrian crossing, the Forum pedestrian overpass and an opening in the median fence. *Fig. 2(b)* shows a pedestrian in the crossing area during a vehicular green phase; since the pedestrian signal is not visible, the image is presented as contextual evidence of potential exposure rather than a verified pedestrian signal violation.

Fig. 2. Representative corridor conditions: (a) divided roadway and adjoining service carriageway; (b) signalised pedestrian crossing; (c) Forum pedestrian overpass; and (d) an opening in the median fence used as an informal access point (Google Maps Street View, 2026)

3.2 Questionnaire design and administration

The questionnaire was developed to examine pedestrian crossing behaviour and perceived safety conditions specific to the study corridor. The complete instrument comprised 38 numbered items covering participant characteristics, corridor use, crossing behaviour, perceived traffic conditions, pedestrian-overpass accessibility, risk-related and situational factors, intervention preferences and additional recommendations. It included single-choice categorical questions, multiple-response items, five-point ordinal and Likert-type scales, and one open-ended question. Of the 38 questionnaire items, 29 were included in the present analysis. These items were grouped into six analytical domains, as summarised in *Table 1*.

Following completion of the ethical and administrative approval processes, the questionnaire was administered intermittently at selected locations along the study corridor in late July 2026 using a non-probability intercept sampling approach. Individuals were eligible to participate if they used and were familiar with the study corridor. The questionnaire was administered face-to-face and required approximately 10–12 min to complete. The preliminary analytical sample comprised 50 completed questionnaires.

Ethical approval was granted by the Dicle University Science and Engineering Ethics Committee. The approved research protocol covered both the face-to-face questionnaire and the observational field study. Participation was voluntary, and participants were informed about the purpose and procedures of the research, as well as their right to withdraw at any time without providing a reason. Personal data were kept confidential, and questionnaire responses were anonymised and used exclusively for scientific purposes. For participants below the legal age for independent consent, age-appropriate information and assent procedures were applied, and consent was obtained from a parent or legal guardian in accordance with the approved research protocol. The required administrative permissions for field implementation were obtained separately from the Diyarbakır Governorate, Diyarbakır Provincial Police Department, and other competent public authorities.

Table 1. Questionnaire structure used in the present analysis

Code	Analytical domain	Variables included	Measurement format
A	Participant and travel characteristics	Gender, age, education, corridor-use frequency and usual travel mode	Categorical
B	Crossing behaviour and decision factors	Primary crossing method, informal crossing frequency, crossing considerations, appraisal of informal crossing and reasons for avoiding overpasses	Categorical, ordinal and multiple response
C	Traffic-safety and risk perception	Perceived speed and crossing safety, signage, driver attentiveness, lighting, hazardous-event exposure, median-opening danger, safety problems and crash likelihood	Five-point ordinal, categorical and multiple response
D	Overpass accessibility and personal security	Suitability of overpass location, ease of access and night-time personal security	Five-point Likert-type
E	Preferred pedestrian-safety interventions	Overpass improvements, crossing alternatives, speed-management measures and willingness to use safer facilities	Multiple response and five-point willingness
F	Additional recommendations	Pedestrian-safety and infrastructure recommendations	Open-ended

Note: The complete questionnaire comprised 38 numbered items; 29 items directly related to the objectives of the present study were included in the analysis.

3.3 Data analysis

Questionnaire responses were analysed using descriptive statistics. Categorical variables were summarised using frequencies and item-specific valid percentages. Five-point ordinal and Likert-type responses were retained in their original order and combined only for selected figures. For multiple-response items, each option was coded separately and percentages were based on respondents answering the relevant item; thus, totals could exceed 100%. Multiple selections for single-choice items were excluded only from that item's analysis, and missing responses were not imputed. Open-ended recommendations were coded into non-exclusive descriptive themes. Given the preliminary non-probability sample, no inferential tests or multivariable models were applied.

4 Results

4.1 Participant and travel characteristics

The sample included 45 male participants (90.0%), three female participants (6.0%) and two participants who preferred not to report their gender (4.0%). Twenty-two participants (44.0%) were aged 10–17 years, 13 (26.0%) were aged 18–29 years, 12 (24.0%) were aged 30–44 years and three (6.0%) were aged 45 years or older. High-school education was reported by 30 participants (60.0%). Corridor use was frequent: 24 participants (48.0%) used it every day, seven (14.0%) every weekday and six (12.0%) several times per week. Thus, 74.0% used the corridor at least several times per week. Among the 47 valid single-choice responses for usual travel mode, walking was the most frequently reported mode (40.4%), followed by private car (29.8%) and municipal bus (17.0%).

4.2 Crossing behaviour and perceived causes

Among 47 valid single-choice responses for primary crossing method, 15 (31.9%) reported using an overpass or underpass, 12 (25.5%) reported using an opening in the median barrier, and 11 (23.4%) stated that their choice depended on prevailing conditions. Other marked or unmarked crossing locations accounted for 10.6%, while 8.5% reported primarily using a signalised crossing (*Fig. 3a*). When asked about crossing at road level despite the availability of a designated facility, 16 participants (32.0%) responded "never," 10 (20.0%) "rarely," 10 (20.0%) "sometimes," 9 (18.0%) "often," and 5 (10.0%) "always." Overall, 24 participants (48.0%) reported engaging in this behaviour at least sometimes (*Fig. 3b*).

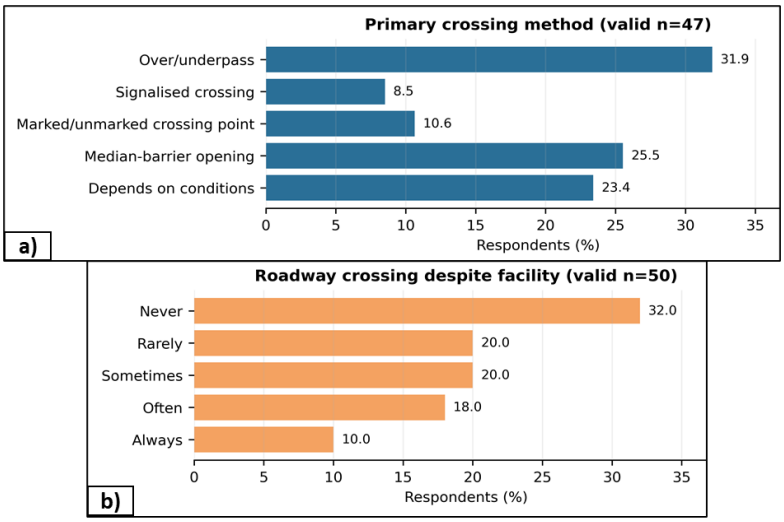

Fig. 3. (a) Reported primary crossing method among unambiguous responses (valid n=47) and (b) frequency of crossing at road level despite an available designated facility (N=50).

Vehicle speed was the most frequently selected factor affecting crossing-location choice (66.0%), followed by traffic volume (18.0%), the availability of a junction or pedestrian overpass (16.0%), signs and markings (12.0%), route directness (10.0%) and the availability of an opening in the median barrier (6.0%). Among the 48 participants who answered the question concerning overpass avoidance, excessive distance to the overpass was the most frequently selected reason (43.8%). Mismatch between crossing demand and facility location and habitual behaviour were each selected by 18.8%, followed by shorter travel time and overpass-design problems (14.6% each) and physical effort (12.5%).

Risk awareness was nevertheless high. 33 participants characterised road-level crossing as definitely wrong and dangerous, and 13 as dangerous but understandable in some circumstances; together these categories represented 92.0% of the sample. Only 3 regarded it as normal and one had no opinion. The coexistence of strong danger recognition and continued informal crossing suggests constrained choice rather than simple risk ignorance.

4.3 Safety perception and overpass evaluation

Of 49 valid responses, 37 (75.5%) rated vehicle speed as high or very high, while 44 (89.8%) felt unsafe or only slightly safe when crossing; none selected “safe” or “very safe”. 32 (65.3%) disagreed that warning signs and markings were adequate, and 42 (85.7%) that drivers were attentive to pedestrians. 41 respondents reported experiencing or witnessing a crash, near miss or hazardous event; 4 answered no, 4 did not remember and one response was missing.

Lighting and access were also evaluated negatively. 34 of 49 respondents (69.4%) considered lighting inadequate, 31 (63.3%) disagreed that overpasses were appropriately located, and 34 (69.4%) that they were easy to reach. Night-time personal security was viewed negatively by 30 of 47 (63.8%). By contrast, only 10 of 49 (20.4%) agreed that overpasses caused excessive time loss and 18 (36.7%) that they were physically tiring, reinforcing the relative importance of access and location.

Crossing risk was rated high or very high by 36 of 47 valid respondents (76.6%), and pedestrian-crash likelihood by 31 (66.0%). Median-fence openings were described as very dangerous by 24 participants (51.1%), dangerous by eight (17.0%) and dangerous but used because pedestrians felt compelled to do so by 14 (29.8%). None considered their use normal. Selected response distributions are presented.

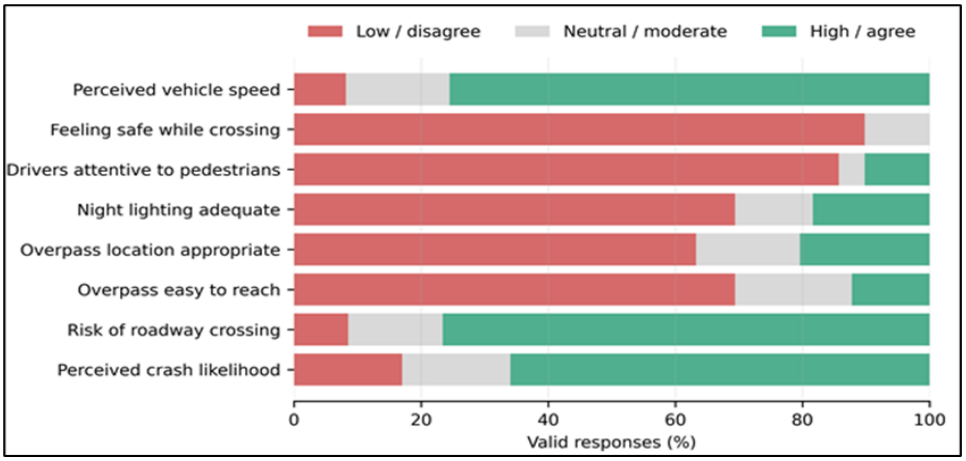

Fig. 4. Distribution of selected responses concerning perceived vehicle speed, crossing safety, driver attentiveness, lighting, overpass location and accessibility, crossing risk and crash likelihood. Percentages are based on the valid responses to each item.

4.4 Preferred pedestrian-safety interventions

Participants selected interventions addressing both overpass conditions and road-level crossing provision. Among the 49 participants answering the overpass-improvement item, escalators were selected by 40.8%, relocation of the overpass by 34.7%, shorter access distance by 28.6%, lifts by 24.5%, and improved lighting and security measures by 20.4% each. Regarding crossing provision, 46.9% selected a new pedestrian overpass, 32.7% a signalised pedestrian crossing, 30.6% an underpass and 22.4% improvement of the existing overpasses. Because these were multiple-response items, the percentages represent endorsement of each measure rather than mutually exclusive preferences.

The most frequently selected traffic-management measure was a reduction in the speed limit (53.1%). Radar-based speed control and speed humps were each selected by 46.9%, followed by electronic enforcement systems (36.7%), pedestrian-priority signalisation (34.7%) and revised signal timing (32.7%). A safe signalised at-grade crossing would be used or definitely used by 35 of the 49 respondents (71.4%), while 34 (69.4%) stated that they would use an improved and accessible pedestrian overpass.

33 participants supplied an open comment. Non-exclusive coding identified requests for more or better-located overpasses in 21 comments, at-grade crossings in 7, lift/escalator provision in 3, speed reduction in 2, enforcement/cameras in 2 and signalisation/lighting. As the thematic categories were non-exclusive, an individual response could be assigned to more than one category. Selected intervention preferences are presented in Fig. 5.

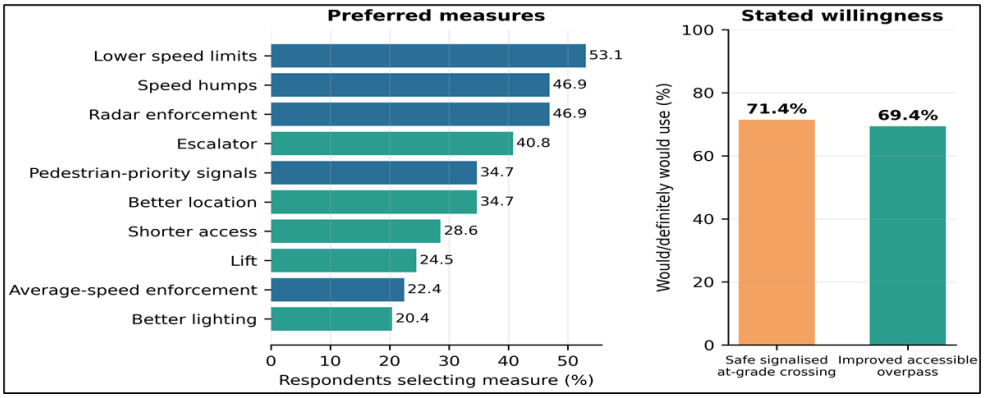

Fig. 5. Preferred overpass improvements, crossing-facility treatments and speed-management measures, together with stated willingness to use safer crossing facilities. Multiple responses were permitted for improvement measures.

5 Discussion

The principal finding was the discrepancy between risk appraisal and reported crossing behaviour. Although 92.0% of participants recognised informal road-level crossing as dangerous or sometimes understandable despite the danger, 48.0% reported doing so at least sometimes. Among those recognising the danger, 47.8% nevertheless crossed informally at least sometimes, indicating that risk awareness alone did not ensure consistent use of designated facilities.

Distance and spatial alignment were the most frequently reported reasons for overpass avoidance. Excessive distance was the leading reason for non-use, while the location and accessibility of existing overpasses were evaluated negatively by most respondents. These findings are consistent with evidence that facility use depends strongly on origin–destination alignment and acceptable detour distance [5–7], and that pedestrians may accept greater traffic exposure for a more direct route [8,9]. Informal crossing may therefore persist or shift if median fencing is restored without addressing pedestrian desire lines.

Most respondents perceived vehicle speeds as high and felt unsafe while crossing. These perceptions should be considered in relation to the corridor's wide cross-section and posted speed limit, although operating speeds were not measured. Direct speed measurements, pedestrian and vehicle counts, trajectory observations, signal compliance and pedestrian–vehicle conflict analysis are needed to establish operational safety conditions.

Similar proportions of respondents stated that they would use a safe signalised crossing or an improved, accessible overpass. The findings therefore do not support a single treatment for the entire corridor. A signalised at-grade crossing could be considered where speed, pedestrian-demand and geometric assessments demonstrate safe operation; otherwise, grade separation may remain necessary if accessible and aligned with pedestrian desire lines. Public transport stops, lighting, maintenance, personal security and approach continuity should also be integrated into crossing-facility planning.

This study has several limitations. First, it used a preliminary non-probability sample of 50 corridor users; the high proportions of male and 10–17-year-old participants limit representativeness and prevent generalisation to all pedestrians in Diyarbakır. Second, crossing behaviour and traffic conditions were self-reported and may be affected by recall and social-desirability bias. Third, some items contained multiple selections despite single-choice wording and were handled using item-specific validity rules. Finally, the study lacked operating-speed measurements, pedestrian and vehicle volumes, accepted gaps, conflict observations and georeferenced crash records. The findings therefore identify reported perceptions and behavioural patterns but do not establish causal relationships or engineering warrants.

6 Conclusions

This study examined reported pedestrian crossing behaviour, perceived safety and crossing-facility preferences along the Mahabad–Seyrantepe section of Elazığ Boulevard. Although most participants recognised the danger of informal road-level crossing, almost half reported engaging in this behaviour at least sometimes. Overpass distance, location and accessibility emerged as the principal infrastructure-related concerns, while perceived vehicle speed and crossing safety were evaluated negatively.

The findings suggest that restoring median fencing alone may be insufficient where formal facilities remain poorly aligned with pedestrian movement demand. Before selecting an intervention, operating-speed measurements, pedestrian and vehicle counts, desire-line mapping, signal-phase observations and accessibility audits of existing overpasses and signalised crossings should be undertaken. These measurements would support location-specific combinations of speed management, formal crossing provision and accessible grade separation where warranted.

Declarations

Ethics approval and consent to participate: Ethical approval was granted by the Dicle University Science and Engineering Ethics Committee on 23 July 2026 (decision item no. 3) and officially communicated by the Dicle University Graduate School of Natural and Applied Sciences on 28 July 2026 (document no. E-56760607-663.05-1191694). Participation was voluntary, and all responses were anonymised. For participants below the legal age for independent consent, age-appropriate information and assent procedures were applied, and consent was obtained from a parent or legal guardian in accordance with the approved research protocol.

Funding: This research received no external funding.

Conflict of interest: The authors declare no conflict of interest.

Abstract. Highway alignment selection involves many interacting criteria spanning technical, environmental, economic, and social dimensions. Most existing methods apply a fixed criteria set regardless of context, and many commit to one optimization algorithm without a clear basis. This study proposes a two-stage decision framework: Stage 1 filters alignment factors against project conditions, and Stage 2 guides algorithm choice through a structured comparison. The filtering stage groups route-selection criteria under seven domains, investor needs, topography and geology, engineering and logistics, traffic demand, economic feasibility, land-use compatibility, and environmental and social constraints, and excludes factors that are not critical in a given context, reducing complexity and focusing the model. The algorithm-selection stage compares genetic algorithms, particle swarm optimization, multi-criteria decision analysis, and GIS-heuristic hybrids on efficiency, multi-objective adaptability, GIS integration, and planning applicability. Fuzzy inference, using Mamdani and Takagi-Sugeno models, drives the decision logic in both stages, with decision-tree and ensemble models tuning the rule bases while keeping them readable. A step-by-step workflow shows how practitioners apply the framework, and implementation challenges and limitations are identified. A case study is planned to validate the framework on a real corridor.

Keywords: Highway Alignment; Multi-Criteria Optimization; Factor Filtering; Fuzzy Inference System.

1 Introduction

Choosing a highway alignment is one of the earliest and most consequential decisions in road planning, since it fixes much of the project's cost, environmental footprint, and service quality; a poor choice is expensive to correct later, and the problem is hard because it involves many criteria that often conflict.

The search space is also vast: an alignment is a continuous path in three dimensions, subject to geometric, geological, and right-of-way constraints. Manual design explores only a few alternatives, while computer-based optimization can explore far more; since the work of Jha and Schonfeld [1], a large body of research has applied search algorithms to this problem.

Two gaps remain. First, most studies use a fixed set of criteria regardless of project context, wasting effort on factors that do not matter locally. Second, most studies commit to a single algorithm, often a genetic algorithm, without a structured reason for that choice [2-3]; the algorithm is treated as given, not selected. This paper addresses both gaps with a two-stage framework: the first stage filters factors to those that matter in a given context, and the second selects an algorithm through a structured comparison. The paper is conceptual, defining the method and decision logic that a planned case study will apply.

Section 2 reviews prior work. Section 3 presents the proposed framework, its decision engine, and its algorithm comparison. Section 4 sets out an application workflow. Section 5 covers the planned case study, challenges, and limitations. Section 6 concludes.

2 Background

2.1 Alignment Optimization Methods

Early alignment optimization minimised total cost as a single objective [1]. Jha and Schonfeld [1] integrated a genetic algorithm with a geographic information system (GIS); this pairing became the dominant approach for a decade. Maji and Jha [2] proposed a multi-objective genetic algorithm returning Pareto-optimal alignments rather than one solution, and Yang et al. [3] extended this with a hybrid algorithm incorporating designer preferences.

Particle swarm optimization (PSO) has also been applied: Shafahi and Bagherian [4] developed a customised PSO for the alignment problem, and Bosurgi et al. [5] added environmental constraints to a PSO-based model. Ant colony optimization has been used mainly for vertical alignment, against earthwork cost [6].

Recent work uses GIS more actively: Al-Hadad et al. [7] used a GIS-derived least-cost path to confine the search to a narrow corridor before the genetic algorithm runs, cutting computation, and Kim et al. [8] used a stepwise strategy to similar effect.

2.2 Multi-Criteria and Fuzzy Methods

Not all alignment decisions reduce to a cost function; many criteria are qualitative, and multi-criteria decision analysis (MCDA) handles these. Liu et al. [9] combined an objective and subjective weighting method with TOPSIS to rank highway route schemes across technical, ecological, social, and economic factors.

Fuzzy inference suits imprecise criteria, representing judgments such as high slope or moderate traffic as fuzzy sets. Mamdani systems produce fuzzy output sets and are easy to interpret [10]; Takagi-Sugeno systems use linear output functions that integrate well with optimization [11], and the two perform similarly on accuracy [12-13]. Machine learning has begun to inform such models: decision trees and ensemble regressors can learn rule bases or output functions from data, and neuro-fuzzy methods combine neural-network learning with fuzzy-system interpretability [14].

3 Proposed Framework

3.1 Two-Stage Decision Process

The framework operates in two sequential stages. Stage 1 filters the candidate factor set against the project context and returns a reduced, context-specific factor set. Stage 2 takes that reduced set, together with the same project priorities, and selects the optimization algorithm best suited to it. Both stages draw on a single fuzzy-inference and machine-learning engine, described in Section 3.2, so one auditable logic governs both what enters the optimization problem and how that problem is solved.

Stage 1: Factor Filtering. Alignment criteria fall into seven domains: investor requirements, topography and geology, engineering and logistics, traffic demand, economic feasibility, land-use compatibility, and environmental and social constraints. Table 1 gives, for each domain, a representative indicator and the project condition that would normally retain or drop it, so every screening decision traces to a named indicator.

Table 1. Taxonomy of route-selection criteria, indicators, and screening conditions.

Domain	Representative factors	Example indicator	Screening condition
Investor requirements	Service level, staged construction, budget ceiling	Target design speed; phasing plan	Retain when funding or schedule constrains the design
Topography and geology	Slope, landslide risk, soil bearing, faulting	Ground slope (%); hazard class	Drop in flat, geotechnically uniform terrain
Engineering and logistics	Earthwork, structures, access, constructability	Cut-and-fill volume; bridge count	Retain where structures or earthwork dominate cost
Traffic demand	Forecast volume, level of service, connectivity	AADT forecast; v/c ratio	Retain on routes serving variable or growing demand
Economic feasibility	Construction cost, life-cycle cost, benefit-cost	Unit cost per km; BCR	Almost always retained as a global objective
Land-use compatibility	Acquisition, severance, zoning conflict	Parcels affected; land-use class	Drop on remote routes far from settlement
Environmental and social	Habitat, noise, emissions, community impact	Protected area overlap; exposed population	Retain near protected or inhabited areas

Table 2 gives examples: for a flat coastal route, steep-grade and landslide factors carry little weight and can be dropped; for a route far from settlements, land-use factors fall away. Filtering cuts the dimensionality of the optimization and focuses the model on the factors that drive alignment performance in the region.

Table 2. Examples of context-based factor exclusion.

Project context	Likely critical factors	Likely excluded factors
Flat coastal corridor	Land use, drainage, traffic demand	Landslide risk, steep grade
Mountain crossing	Slope, geology, earthwork cost	Wide right-of-way acquisition
Peri-urban bypass	Land acquisition, noise, access	Deep cut and fill, tunnelling
Remote rural link	Construction cost, terrain	Dense land-use conflict

Formally, let F be the full factor set and I_j the importance score of factor j, computed by the fuzzy engine of Section 3.2 from the Table 1 indicators and the project priorities. The retained set F* is

$$F^* = \{ j \in F : I_j \geq \tau \} \quad (1)$$

where τ is a retention threshold set by the planning team. A factor tied to a hard regulatory limit is never dropped, and borderline factors are flagged for expert review.

Stage 2: Algorithm Selection. The second stage compares candidate methods, genetic algorithms, particle swarm optimization, MCDA approaches, and GIS-heuristic hybrids, and selects the most suitable one. Each method k receives a suitability score

$$S_k = \Sigma\, v_c\, r_{kc}\,, \quad k^* = arg\ max\ S_k \tag{2}$$

where r_{kc} is the score of method k on criterion c (computational efficiency, multi-objective adaptability, GIS integration, or planning applicability), v_c the weight of that criterion from the project priorities, and k* the selected method; the weights come from the same fuzzy engine, so both stages share one logic. Section 3.3 details the comparison.

3.2 Fuzzy Inference and Machine-Learning Engine

Both stages share a decision engine that turns crisp criterion values into a single score, a factor-importance score in Stage 1 or an algorithm-suitability score in Stage 2, by fuzzification, rule-based inference, and defuzzification. The framework supports Mamdani inference, used where interpretability matters most, such as explaining why a factor was excluded [10], and Takagi-Sugeno inference, used where the output feeds a numerical step, since its linear output functions integrate cleanly [11].

Each retained criterion is mapped to membership grades over linguistic terms, for example low, moderate, and steep for slope, using triangular and trapezoidal membership functions whose breakpoints are easy to set and justify. A triangular function is fixed by three points and returns a grade between zero and one:

$$\mu(x) = max(\ min(\ (x - a)/(b - a),\ (c - x)/(c - b)\ ),\ 0\ ) \tag{3}$$

where a, b, and c are the lower limit, peak, and upper limit of the term, taken from design standards where these exist and from expert judgement otherwise; the common zero-to-one scale lets factors of different units be combined without arbitrary weighting.

Rules take the form: if slope is steep and geology is weak, then earthwork importance is high, with firing strength equal to the minimum input grade for an AND rule. Table 3 shows an illustrative rule base.

Table 3. Illustrative rule base for the factor-filtering stage.

Slope	Geology	Settlement proximity	Earthwork importance	Land-use importance
Low	Strong	Far	Low	Low
Steep	Weak	Far	High	Low
Low	Strong	Near	Low	High
Steep	Weak	Near	High	High

For Mamdani inference the consequents are fuzzy sets, aggregated by union and defuzzified by the centroid of the combined area [10]. For Takagi-Sugeno inference each consequent is a function of the inputs, and the output is the firing-strength-weighted average of the rule outputs [11]:

$$y = (\ \Sigma\, w_i\, f_i(x)\ )\ /\ (\ \Sigma\, w_i\ ) \tag{4}$$

where w_i is the firing strength of rule i and f_i its output function; comparative studies report similar accuracy for both systems [12-13], so the choice is driven by the role of the output.

Decision trees trained on past projects suggest candidate rules and membership-function limits from their split points [18]; ensemble regressors such as random forests estimate the Takagi-Sugeno consequent functions f_i from observed cost and performance [18]; and an ANFIS-type neuro-fuzzy scheme can further tune membership parameters once enough corridor data exist [14-17]. The learned components only adjust an existing, human-readable rule base and are checked against design-standard limits before acceptance, so the result still explains itself as a list of if-then rules.

3.3 Comparison of Candidate Algorithms

Four candidate families cover the search strategies applied to this problem: population-based metaheuristics, swarm methods, ranking-based multi-criteria methods, and spatially driven heuristics. Exact mathematical programming and deep reinforcement learning were considered and set aside, the former for not scaling to the non-convex three-dimensional search in [15], the latter for too thin an alignment record to compare fairly.

Genetic algorithms have the longest record: established by Jha and Schonfeld for the coupled GIS cost model [1], extended to multi-objective search by Maji and Jha [2], refined with preference information and prescreening [3-16], and shown to scale to combined horizontal and vertical alignment [15].

Particle swarm optimisation, customised for alignment search [4] and extended with environmental constraints [5], often converges faster than genetic algorithms on smooth problems; ant colony optimisation appears mainly for vertical alignment [6].

MCDA is retained for problems dominated by qualitative criteria: Liu et al. [9] combined comprehensive weighting with TOPSIS to rank corridors transparently, complementing rather than substituting for the metaheuristics.

GIS-heuristic hybrids confine the search using a least-cost path [7] or a stepwise strategy [8] before a genetic algorithm runs, cutting computation but tying solution quality to the spatial layer.

Table 4 scores the four families on the selection criteria and interpretability. The scores are schematic, illustrating relative strengths drawn from the literature rather than a numerical benchmark from a solved case.

Table 4. Score matrix for the candidate methods (schematic scores, 1 = low, 5 = high, reflecting the reviewed literature).

Method	Computational efficiency	Multi-objective adaptability	GIS integration	Planning applicability	Interpretability
Genetic algorithm	3	5	3	5	2
Particle swarm optimization	4	4	2	3	2
MCDA (AHP / TOPSIS)	5	2	2	4	5
GIS-heuristic hybrid	3	4	5	4	3

Genetic algorithms lead on multi-objective adaptability and planning applicability but are hardest to interpret, since the search is stochastic. Particle swarm optimization is efficient and adapts well but has a shorter highway-planning record. MCDA leads on interpretability and efficiency yet only ranks a fixed set of alternatives. GIS-heuristic hybrids lead on GIS integration but their efficiency depends on the pre-screening step. No method dominates on every criterion, which is why the structured selection of Section 3.1 is needed rather than a default choice.

3.4 Implications for Practice

The common default is to reach for a genetic algorithm and a standard factor list, which is reasonable but not always best: a project dominated by qualitative concerns may be served better by MCDA, and a project with rich terrain data by a GIS-led search. This matters for defensibility as well as quality, since an explainable choice, covering both which factors and which algorithm, is easier to defend in review than one taken by habit; fixing the factor set first also moves analyst time to the cheaper task of agreeing which factors matter, and lets a scoping memo record the retained and dropped factors alongside the algorithm choice and its score.

4 Application Workflow

This section sets out, as a numbered procedure, how a practitioner would apply the framework, connecting the taxonomy, decision engine, and algorithm comparison of Section 3 into a single sequence usable with standard GIS and optimisation tools.

Step 1: Assemble data, priorities, and the criteria taxonomy. Gather corridor endpoints, terrain, geology, land-use, environmental, and traffic data and the investor brief; record project priorities as a short weighting of cost, environment, and service; and populate the seven domains of Table 1 with the indicators available, noting any that are missing.

Step 2: Run factor filtering. Feed the indicators to the fuzzy engine of Section 3.2, retain factors above the threshold, drop those below it, flag borderline factors for expert review, and never drop a factor tied to a hard regulatory limit.

Step 3: Score and select the algorithm. Score the four candidate families against the reduced factor set and the priorities, using the criteria of Section 3.3: a strongly multi-objective problem points to a genetic algorithm, a tight-runtime smooth problem to particle swarm, a qualitative fixed-corridor problem to MCDA, and a data-rich corridor to a GIS-heuristic hybrid.

Step 4: Configure, run, and review the optimisation. Encode only the retained factors as objectives or constraints, run the search, and present the alignment with the rule firings and algorithm score that produced it; if reviewers contest a dropped factor, reinstate it and re-run from Step 2.

Step 5: Record outcomes for learning. Log which factors proved decisive and how the algorithm performed; these records become training data that tune the membership functions and rule bases for the next project.

The workflow is tool-agnostic: each step maps to capabilities already present in commercial GIS and optimisation packages, and its value lies in the order and record it imposes.

5 Planned Case Study and Validation

The framework is now fully specified; what remains is empirical validation. A case study is planned on a real corridor with varied terrain, so that both stages are exercised, in three parts: filtering will be applied and the reduced factor set checked against experienced engineers' judgment; the algorithm-selection stage will be run so that the schematic scores of Table 4 are replaced by measured run time, solution quality, and trade-off spread; and the resulting alignment will be compared with a manually designed alternative to test whether the framework is competitive and whether the effort saved by filtering is real.

5.1 Implementation Challenges and Limitations

The framework assumes a record of past projects to tune the learned components; where history is thin, the machine-learning step degrades to expert-set rules.

A retention threshold set too high discards useful factors, and set too low defeats the purpose of filtering; the safeguards in Section 3.1 reduce but do not remove this sensitivity.

It is easy to check that a retained factor mattered, but harder to prove a dropped factor would not have changed the alignment, since the counterfactual is not run by default.

The four families do not exhaust the method space, and exact and reinforcement-learning methods may suit some problems as their alignment record matures; the framework also asks teams to document decisions they often make by habit, a process change the tool-agnostic design is meant to ease.

6 Conclusions

This paper proposes a two-stage framework for highway alignment optimization. The first stage filters factors to those that matter in a given context; the second selects an optimization algorithm through a structured comparison. A fuzzy inference engine, supported by machine learning, drives the decision logic in both stages.

The framework makes four contributions: it links two steps usually treated separately, which factors to consider and which algorithm to use; it grounds the first in a taxonomy of criteria with named indicators; it specifies the decision engine from membership functions to learned rule tuning; and it sets out a tool-agnostic workflow from raw criteria to a defensible alignment. Filtering first cuts computational load and focuses the model, while comparing algorithms against the filtered set replaces a default choice with a reasoned one.

The paper is conceptual and does not yet report a solved alignment. The planned case study will validate the framework on a real corridor, populate the algorithm comparison with measured outcomes, and test the fuzzy rule bases against expert judgment; the challenges in Section 5.1 define the questions that study must answer.

Abstract. Urban mobility in rapidly growing cities is shaped not only by conventional public transport but also by flexible services operating through cooperative and semi-formal arrangements. In Türkiye, the dolmuş remains an integral component of this mixed mobility landscape, yet the collective spatial and temporal structure produced by multiple cooperatives has received limited attention. This study examines the supply-side mobility patterns associated with four hub-based dolmuş cooperatives in Diyarbakır. The analysis integrates 50 declared route assignments, verified one-way lengths for 47 regularly documented routes, evidence of period-specific non-dispatch, and 3,433 field-observed vehicle movements aggregated into hourly intervals. Pairwise Jaccard similarity is used to identify the extent to which cooperative route footprints converge on common urban corridors, while hub-normalized hourly profiles reveal differences in the temporal distribution of observed activity. The results indicate a network structure characterized by strong convergence along the Şanlıurfa and Elazığ boulevard approaches and around the Dağkapı central area, followed by hub-specific branching towards peripheral districts. At a 250 m spatial resolution, 69.7% of the declared network footprint is occupied by at least two cooperatives, with the strongest pairwise similarity occurring between Dağkapı and Balıkçılarbaşı ($J = 0.782$). Route lengths are broadly comparable across the four hubs, whereas morning peaks, late-evening activity, and the regular activation of declared routes vary. These findings demonstrate how cooperative organization, shared-corridor use, and temporal differentiation jointly shape the operational geography of dolmuş mobility in Diyarbakır.

Keywords: Dolmuş; urban mobility patterns; cooperative transport; paratransit; route-network overlap; Diyarbakır.

1 Introduction

Urban mobility in rapidly growing cities is rarely produced by a single institutional system. Conventional public transport, walking, private travel, and flexible shared services interact across the same streets and activity centres. Small-vehicle collective transport is particularly important within this mixed landscape because it can extend access beyond high-capacity corridors and respond to spatially uneven demand [1]. Its urban role is therefore expressed not only by individual routes but also by the collective pattern of corridors served and the times at which service is supplied.

The dolmuş is the most established Turkish form of this service. Although vehicles are privately owned, route rights are locally regulated and daily operation is commonly organized through cooperatives [2–6]. This arrangement combines institutional continuity with operating discretion. Declared routes indicate where service is authorized, whereas rotation practices, vehicle assignment, and dispatch decisions influence when that mobility opportunity is produced. A city-scale assessment must consequently consider the spatial and temporal behaviour of the cooperative network rather than treating each route as an independent line.

Diyarbakır provides a revealing case because four hub-based cooperatives connect the historic and contemporary centre with western, northern, and southern districts while repeatedly converging on the same arterial approaches. Their records offer a supply-side view of urban mobility: mapped alignments show how service opportunities are distributed across the road network, and hourly movement records show when observed activity intensifies or persists. Urban mobility patterns are therefore interpreted here as the spatial organization and daily production of collective transport supply, not as individual passenger trajectories.

Against this background, the study addresses three related questions. First, to what extent do the four cooperative route networks converge on common urban corridors? Second, how do the hubs differ in route reach, spatial footprint, and the timing of observed vehicle movements? Third, how does period-specific non-dispatch affect the relationship between the formally declared network and the service that is regularly evidenced in practice? To answer these questions, the study distinguishes four complementary dimensions of the dolmuş system: declared route coverage, verified route extent, period-specific route activation, and the hourly distribution of observed vehicle movements. This distinction makes it possible to identify how an institutionally segmented cooperative system produces a mobility pattern characterized by a shared arterial core, hub-specific peripheral branches, and differentiated operating rhythms.

2 Literature Review and Research Position

Research on dolmuş services in Türkiye has developed along three complementary lines. The first examines passenger preferences and the service attributes through which dolmuş competes or interacts with municipal public transport [2,3]. The second interprets the persistence of the mode through its institutional flexibility, privately organized service production, and capacity to adapt to urban growth and changing regulatory conditions [4–6]. The third addresses integration and digitalization, emphasizing that route coordination, fare technology, operating costs, and organizational feasibility must be considered together rather than as isolated technical issues [7]. Collectively, this literature presents the dolmuş not as a residual transport mode outside the formal urban system, but as a regulated and institutionally embedded component of urban mobility whose operation reflects interactions among passenger demand, cooperative organization, and municipal governance.

Digitalization introduces a related governance issue. Recent research on smart payment in İstanbul shows that technological adoption depends on operating costs, maintenance capacity, and organizational feasibility in addition to technical performance [7]. The same concern extends to operational monitoring: route rights, vehicles, dispatches, and operating responsibility can be linked consistently only when identifiers are standardized across operators and public authorities. For cooperative networks, data standardization is therefore part of institutional integration rather than a purely technical improvement.

International research provides complementary methods for making semi-formal transport networks visible to planning. Mobile-phone and collaborative mapping have translated locally maintained route knowledge into standardized network data [8, 9]. Geometry-based classification has revealed differentiated route roles within apparently irregular systems [10], while studies of stopping behaviour [11], operating efficiency [12], vehicle movement [13], accessibility [14], and Global Positioning System (GPS) traces [15] have connected mapped structure with realized activity. These contributions establish that intended network form and observed operation represent related but analytically distinct dimensions of mobility supply.

A key research gap concerns regulated cooperative systems in which declared route rights, mapped alignments, and operating records exist at different levels of completeness. Existing studies commonly focus on passenger choice, individual routes, network mapping, or vehicle trajectories, whereas the relationship among declared network coverage, documented route

extent, period-specific activation, and hub-level temporal activity remains insufficiently explored. Diyarbakır provides an appropriate setting for addressing this gap because institutionally distinct cooperatives operate through extensively shared metropolitan corridors. The study therefore examines spatial convergence and operational differentiation as simultaneous features of the same cooperative mobility system.

3 Study Area, Network Structure and Data

3.1 Urban Road Structure and Cooperative Mobility Hubs

Diyarbakır's collective transport network is strongly shaped by its radial urban structure. The dense street system surrounding the historic walled city is connected to expanding residential and institutional districts through Şanlıurfa Boulevard from the west and Elazığ Boulevard from the north. These metropolitan approaches converge towards Yenişehir and Dağkapı Square, which functions as a transition between the peripheral arterials and the finer-grained central street network. Consequently, routes associated with separate terminals concentrate along a limited number of central corridors before branching towards different residential, commercial, educational, and peripheral areas (*Fig. 1*).

Balıkçılarbaşı, Dağkapı, Galeria, and Şehitlik serve as the principal operating terminals and spatial anchors of the dolmuş network. Each hub is associated with a registered limited-liability transport cooperative (*Sınırlı Sorumlu in Turkish, S.S.)* that organizes its vehicles and internal operating groups. *Table 1* summarizes the institutional scale and organizational structure of the four cooperatives. Although individual rotation schedules are not examined, the operating-group structure provides relevant context for interpreting hub-level activity. *Fig. 1* and *Fig. 2* further show how these institutionally distinct route portfolios connect hub-specific peripheral branches to a shared central road structure.

Table 1. Institutional scale and declared route inventory of the four cooperative hubs.

Hub/cooperative	Operating organization	Registered vehicles	Declared routes
Balıkçılarbaşı/S.S. 2 Nolu 3. Hat	Three groups (A-C)	109	16
Dağkapı/S.S. 1 Nolu 2. Hat	Four groups (A-D)	111	16
Galeria/S.S. 3 Nolu 1. Hat	Six operating groups	103	10
Şehitlik/S.S. 6 Nolu 4. Hat GAP	Eight operating groups	54	8
System total	Four hub-based cooperatives	377	50

3.2 Route Network and Operational Records

The spatial dataset comprised route geometries and the route inventories maintained for the four cooperatives. The reconciliation of route names, terminal affiliations, and mapped alignments identified 16 declared routes for Balıkçılarbaşı, 16 for Dağkapı, 10 for Galeria, and 8 for Şehitlik. Auxiliary common-trunk geometries, duplicated line segments, and unmatched mapping elements were excluded from the route count. The hub-specific panels in *Fig. 1* display the peripheral reach and branching structure of each cooperative network against the Diyarbakır street system. *Fig. 2* provides a complementary city-wide representation by showing the number of cooperative route networks occupying each 250 m cell. Darker cells therefore indicate corridor-scale spatial convergence rather than traffic volume, passenger demand, service frequency, or vehicle activity. The mapped alignments represent declared route paths and should not be interpreted as reconstructed vehicle trajectories.

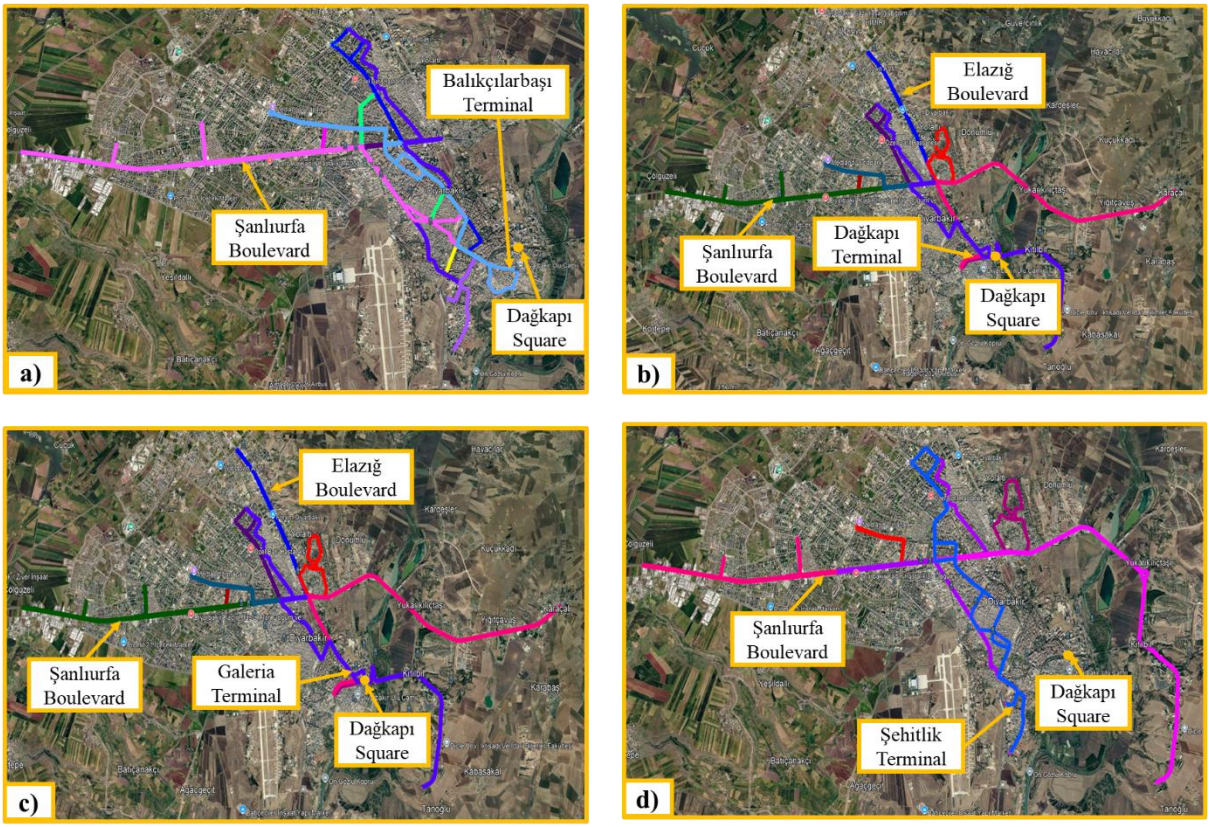

Fig. 1. Hub-specific dolmuş route networks and terminal locations: (a) Balıkçılarbaşı; (b) Dağkapı; (c) Galeria; and (d) Şehitlik; base imagery adopted from Google Earth [16].

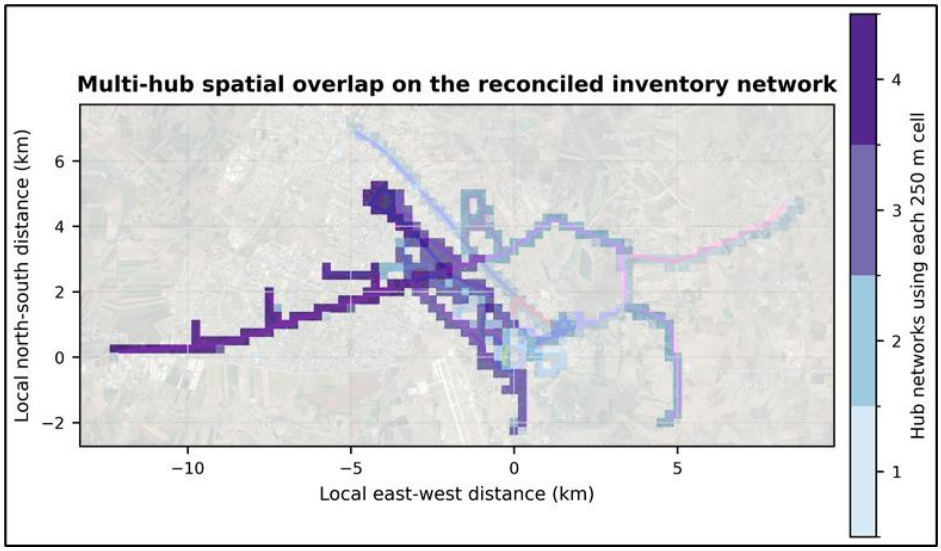

Fig. 2. Spatial convergence of the four cooperative route networks on a 250 m grid.

The declared network and the evidence of regular operation did not coincide fully. Schedule reconciliation and consultation with cooperative representatives indicated that one Balıkçılarbaşı alignment and two Dağkapı alignments received no regular vehicle assignment during some operating periods. These routes remained institutionally recognized but were selectively left without dispatch when anticipated passenger volumes and fare revenues were considered insufficient relative to operating costs. Their status is therefore interpreted as period-specific non-dispatch rather than formal route closure or permanent withdrawal from the

cooperative inventory. All 50 declared alignments were retained in the spatial topology analysis because they represent the formally recognized network footprint. Route-length statistics, however, were restricted to the 47 routes for which both regular operation and one-way length could be documented: 15 from Balıkçılarbaşı, 14 from Dağkapı, 10 from Galeria, and 8 from Şehitlik.

Temporal activity was examined using 3,433 vehicle-movement records collected over 12 survey days between April and June 2026. For the purposes of the analysis, a vehicle movement was defined as an observed departure from the corresponding cooperative hub. Field observations were conducted from 06:00 to 23:00, and the recorded movements were subsequently aggregated into 18 one-hour intervals, extending from 06:00–07:00 to 23:00–24:00. The resulting dataset comprised 927 records for Balıkçılarbaşı, 952 for Dağkapı, 592 for Galeria, and 962 for Şehitlik. Route-code coverage was incomplete and uneven, with identifiable codes available for 13 routes in Balıkçılarbaşı, 13 in Dağkapı, 9 in Galeria, and 7 in Şehitlik. Temporal comparisons were therefore conducted at the hub level rather than at the individual-route level. The absence of a route code from the movement dataset was not interpreted as evidence of route inactivity, because the movement records did not provide complete coverage of every declared route. Accordingly, the observations characterize the temporal distribution of recorded vehicle activity; they do not represent passenger demand, scheduled service frequency, or the number of vehicles simultaneously in operation. Because observation exposure was not identical across all hubs and time intervals, the normalized profiles are interpreted as distributions of observed activity rather than as direct estimates of comparative service frequency.

4 Analytical Framework

4.1 Network Structure and Spatial Convergence

Route geometry represents the spatial opportunity structure associated with the four cooperatives. The declared 50-route inventory was used to characterize the potential spatial footprint of the cooperative system, whereas verified one-way lengths for 47 routes were used to compare the documented scale of route reach. Route length was not treated as a direct measure of service intensity; it was used to determine whether the cooperative hubs differed systematically in the spatial extent of their regularly documented routes.

Spatial convergence among cooperative route networks was quantified with a regular-grid overlay referenced to a common local origin. Geographic coordinates were converted to local east–west and north–south distances relative to 40.22° E and 37.91° N, and the sampled points were assigned to the nearest grid cell. Route polylines were sampled at approximately 50 m intervals, and the resulting points were assigned to 250 m cells. For any pair of cooperative hubs h and k, the similarity between their spatial footprints was calculated using the pairwise Jaccard (J) similarity index as:

$$J(h,k) = |C_h \cap C_k| / |C_h \cup C_k| \quad (1)$$

where h and k represent the two cooperative hubs included in a pairwise comparison; C_h and C_k denote the sets of 250 m grid cells occupied by their respective route networks; $C_h \cap C_k$ is the set of cells shared by both networks; $C_h \cup C_k$ is the complete set of cells occupied by either network; and the vertical bars denote the number of cells in the corresponding set (Eq. (1)).

Jaccard similarity ranges from 0, indicating no shared cells, to 1, indicating identical spatial footprints. Higher values represent stronger corridor-scale convergence, not similarity in service frequency, passenger volume, or route multiplicity. Values in *Fig. 3(b)* are reported as percentages. The 250 m grid limits sensitivity to minor geometric offsets and parallel

carriageways. Network-wide convergence was evaluated from the footprint shared by two or more cooperatives, and the analysis was repeated at 500 m to test the stability of the results.

4.2 Daily Operating Rhythms and Selective Route Activation

To compare the temporal distribution of activity among hubs with different numbers of observations, the count recorded in each hourly interval was divided by the total number of usable movement records for the corresponding hub. The resulting percentages describe how each hub's observed activity was distributed across the operating day; they do not provide direct estimates of absolute service frequency. Morning differentiation was examined from the hourly peak between 06:00 and 10:00, while daytime activity was summarized for 10:00–16:00 and late activity for the period from 20:00 onward.

Selective route activation was interpreted from the relationship between declared route status and period-specific evidence of dispatch. Routes retained in the institutional inventory but not regularly assigned a vehicle during a given period were treated as potential rather than continuously realized coverage. Because continuous digital dispatch and automatic vehicle location records were unavailable, this component remains descriptive and does not support a definitive route-by-route estimate of service reliability.

5 Results

5.1 Spatial Structure of the Dolmuş Mobility Network

Verified one-way route lengths exhibit only modest differences among the four cooperative hubs. Mean route length is 12.22 km for Balıkçılarbaşı, 13.38 km for Dağkapı, 13.72 km for Galeria, and 12.51 km for Şehitlik. The 1.50 km difference between the lowest and highest hub means is smaller than the variation observed within the individual hub distributions shown in *Fig. 3(a)*. The verified-length subset comprises 15 Balıkçılarbaşı, 14 Dağkapı, 10 Galeria, and 8 Şehitlik routes, giving a total of 47 regularly documented routes. These results suggest that the four cooperative networks operate at a broadly comparable scale of route reach. Their mobility roles appear to be differentiated more clearly by their spatial footprints, peripheral branching patterns, and temporal distributions than by systematically longer or shorter routes. Pairwise spatial similarities calculated from the complete 50-route declared inventory are presented in *Fig. 3(b)*.

In contrast to the modest differences in route length, corridor-scale spatial convergence is pronounced. The declared network occupies 432 unique 250 m cells, of which 301 (69.7%) are used by at least two cooperatives, 194 (44.9%) by at least three, and 96 (22.2%) by all four (*Fig. 2*). The strongest pairwise similarity occurs between Dağkapı and Balıkçılarbaşı ($J = 0.782$), followed by Balıkçılarbaşı and Şehitlik ($J = 0.530$; *Fig. 3(b)*). The Dağkapı–Balıkçılarbaşı value means that 78.2% of their combined grid footprint is common to both networks; it is not a common share of trips, vehicles, or passengers. Shared cells cluster along the Şanlıurfa Boulevard approaches, around the Dağkapı central hinge, and on the Elazığ Boulevard spine before routes divide towards peripheral districts. The system therefore exhibits a convergent arterial structure with cooperative-specific branches rather than four independent service territories. The concentration of shared cells around the Şanlıurfa and Elazığ boulevard approaches and the Dağkapı central area indicates that institutional separation among cooperatives does not produce spatially independent networks. Instead, the system combines a common metropolitan movement structure with hub-specific branches serving different peripheral areas.

The dominant relationship remains stable at the 500 m resolution. Dağkapı and Balıkçılarbaşı continue to form the strongest pair ($J = 0.848$), and 73.1% of the coarser spatial footprint is occupied by at least two hubs. As expected, aggregation increases measured overlap; several closely valued secondary pairs change rank. The persistence of the strongest pair and the multi-hub central core, rather than complete rank invariance, supports the robustness of the central-convergence interpretation.

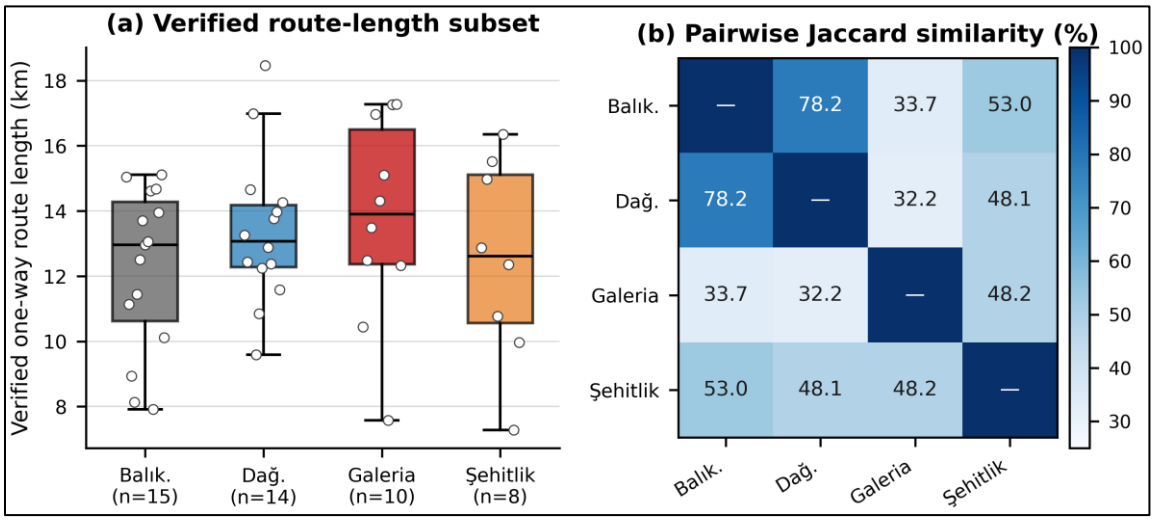

Fig. 3. Route-length distributions and pairwise spatial similarity by cooperative hub.

5.2 Temporal Rhythms and Selective Route Activation

Although the route networks converge spatially, the observed hourly profiles exhibit different morning peak times. Galeria records its largest hourly share between 07:00 and 08:00, Şehitlik between 08:00 and 09:00, and Balıkçılarbaşı and Dağkapı between 09:00 and 10:00 (*Fig. 4*). The period from 10:00 to 16:00 accounts for 35.5–39.4% of the usable observations at each hub, indicating a comparatively sustained distribution of activity during the middle of the operating day. The sequence of morning peaks suggests that the four hubs do not contribute to the city's daily operating pattern in an identical temporal manner, despite their extensive use of common corridors.

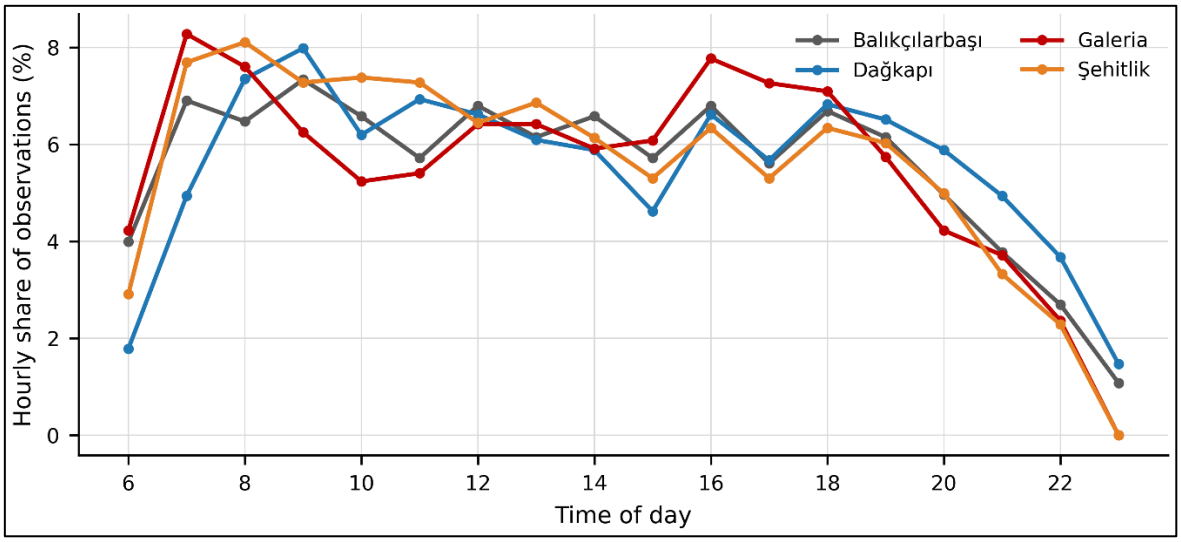

Fig. 4. Hourly distribution of observed vehicle movements by cooperative hub.

Activity from 20:00 onward also varies among the hubs. This period accounts for 16.0% of Dağkapı observations, compared with 12.5% for Balıkçılarbaşı, 10.6% for Şehitlik, and 10.3% for Galeria. These proportions describe the temporal distribution of observed movements within each hub and should not be read as absolute service frequencies. Together with the period-specific non-dispatch of selected alignments, these results show that shared spatial coverage coexists with differentiated operating rhythms and selectively realized route supply.

6 Discussion

The findings reveal a supply-side urban mobility pattern characterized by arterial convergence, hub-specific branching, and temporal differentiation. Diyarbakır's road hierarchy channels institutionally separate cooperative networks through the Şanlıurfa and Elazığ boulevard approaches and the Dağkapı central area before they disperse towards different peripheral districts. The broadly comparable route-length distributions suggest that the hubs are differentiated less by route distance than by their spatial footprints, peripheral branching patterns, and the timing of observed vehicle activity.

Strong convergence along shared corridors highlights the need for coordinated stopping locations, terminal access, dispatch practices, and digital identification of vehicles and route rights. The analysis identifies where such coordination may be required rather than directly measuring congestion, passenger-search behaviour, or roadside stopping. Temporal differences further qualify the shared spatial structure: Galeria exhibits the earliest observed morning peak, whereas Dağkapı records the largest proportion of activity from 20:00 onward. Period-specific non-dispatch also demonstrates that a formally recognized route does not necessarily produce regular service throughout every operating period. Declared network coverage and documented service activation should therefore be monitored as related but distinct characteristics of the dolmuş system.

Unlike paratransit systems whose route structures must first be reconstructed from local knowledge or vehicle traces [8–10], Diyarbakır has institutionally defined route rights and cooperative affiliations, alongside flexible dispatch practices responsive to operating conditions. The study contributes to mobility-pattern research by distinguishing declared network topology, verified route extent, period-specific activation, and observed hourly activity within a common analytical framework. This distinction connects institutional research on Turkish dolmuş operation [3–7] with international studies of paratransit mapping and vehicle activity [8–13, 15], while showing how institutional separation can coexist with spatial convergence and differentiated operating rhythms.

6.1 Limitations and Monitoring Implications

The study relies on supply-side operational evidence and therefore does not support direct inferences about passenger demand, vehicle occupancy, service reliability, commercial speed, or congestion effects. Mapped alignments represent declared routes rather than continuously observed vehicle trajectories. Uneven route-code coverage restricts the temporal analysis to the hub level, while differences in observation exposure require the hourly profiles to be interpreted as within-hub distributions rather than comparative service frequencies. Period-specific non-dispatch was identified through schedule reconciliation and operator consultation rather than independent demand or cost analysis. Grid-cell co-occupation indicates corridor-scale spatial proximity but does not imply identical carriageways, directions, stopping patterns, or service intensity; binary cell occupancy also disregards route multiplicity. Future research should integrate standardized route and vehicle identifiers with digital dispatch records, automatic vehicle location (AVL) data, and passenger observations to examine realized service and accessibility more comprehensively [8, 9, 13, 15].

7 Conclusions

The operational geography of Diyarbakır's dolmuş system is characterized by the coexistence of spatial convergence and institutional differentiation. Although the four cooperatives are organized around separate hubs, 69.7% of the declared network footprint is shared by at least two cooperative networks at the 250 m resolution, and the strongest pairwise relationship occurs between Dağkapı and Balıkçılarbaşı ($J = 0.782$). Comparable route-length distributions indicate that the hubs are not principally distinguished by the distance of their routes. Their roles appear more clearly differentiated through peripheral branching, morning peak timing, late-day activity, and the selective activation of declared alignments.

These findings underline the importance of distinguishing the formally declared network from the service regularly evidenced in operation. The 50-route inventory describes the institutional and spatial potential of the cooperative system, whereas the 47-route verified-length subset and the field-observed movement records represent narrower forms of operating evidence. For urban transport planning, the results support corridor-based coordination, consistent route and vehicle identifiers, and routine monitoring of route activation and operating time. Such measures would provide a stronger basis for integrating regulated cooperative transport into Diyarbakır's wider public-transport planning framework without disregarding the organizational flexibility through which the dolmuş system currently operates.

Abstract. Semi-flexible pavement is produced by filling an open-graded asphalt skeleton with cementitious grout. The asphalt skeleton must therefore remain permeable enough for grout penetration while retaining sufficient stability before grouting. This study evaluated porous asphalt skeleton mixtures for semi-flexible pavement using two aggregate gradations (G1 and G2), and three bitumen contents (3.5%, 4.0%, and 4.5%). Two compaction levels (25X2 and 50X2) were used. Bulk specific gravity, air void content, falling-head permeability, and Cantabro abrasion loss tests were used as screening variables. All tested group means remained above the advised minimum permeability limit of 100 m/day. However, the most open structure did not provide the best overall outcome. The preliminary G1-25X2 -3.5% mixture showed the highest mean permeability, 512.63 m/day, but also the highest mean Cantabro loss which was 40.67%. This result indicated that G1 was too open for the present objective and shifted the optimization effort to the G2 mixtures. Within the G2 series, higher compaction reduced air voids and permeability and improved Cantabro performance. At 4.0% bitumen content, increasing compaction from 25X2 to 50X2 reduced mean permeability by 106.17 m/day and reduced mean Cantabro loss by 15.25 percentage points. The G2-50X2-4.0% group satisfied both screening limits, with mean air voids of 17.82%, mean permeability of 196.73 m/day, and mean Cantabro loss of 15.51%. The results suggest that this porous asphalt skeleton can be a good candidate for semi-flexible pavement production based on a balance between grout penetrability and pre-grouting durability.

Keywords: semi-flexible pavement; porous asphalt skeleton; permeability; Cantabro abrasion loss

1 Introduction

Heavy-duty pavement areas are exposed to severe traffic loading and are vulnerable to rutting and surface distress. Semi-flexible pavement is used for such conditions because it combines an open-graded asphalt skeleton with cementitious grout [1,2]. The grouted layer is intended to retain the continuity of asphalt while gaining the stiffness associated with cement-based materials [1,2].

The porous asphalt skeleton governs the pre-grouting stage of the system. If the skeleton is too dense, grout penetration may be restricted. If it is too open, particle loss and insufficient pre-grouting integrity may occur. Previous studies indicate that connected porosity, pore size,

and permeability control grout infiltration, while open gradations can reduce durability-related performance [1,3,4]. Porous asphalt skeleton design therefore requires a balance between openness and stability.

Permeability and Cantabro abrasion loss provide practical indicators for this balance during laboratory screening. Permeability reflects the continuity of the void network needed for grout infiltration. Cantabro abrasion loss reflects the resistance of the open-graded skeleton to particle loss before grout injection. Studies on porous and open-graded asphalt commonly use Cantabro loss as a durability indicator, and acceptable limits around 20% are frequently reported for unconditioned mixtures [5,6]. Recent studies on semi-flexible pavement also emphasize the coupled influence of pore structure, grout penetration, interface behavior, and mixture durability [8-15]. In addition, previous studies commonly accepted minimum 100 m/day permeability as sufficient for cement grout to penetrate the voids in the porous asphalt [16].

The available literature identifies the governing variables, but it provides limited guidance on selecting the porous asphalt skeleton itself through a stepwise pre-grouting screen that combines gradation, bitumen content, compaction, permeability, and Cantabro loss in one decision framework [8-11,13-15]. More specifically, the literature cited above offers limited detail on how these variables can be used to narrow candidate skeleton mixtures before grout injection under a defined laboratory screening procedure.

Accordingly, this study evaluated porous asphalt skeleton mixtures for semi-flexible pavement by varying aggregate gradation, bitumen content, and compaction level. Marshall-type specimens were prepared using two gradations (G1 and G2), three bitumen contents (3.5%, 4.0%, and 4.5%), and compaction levels of 25X2 and 50X2. Bulk specific gravity, air void content, falling-head permeability, and Cantabro abrasion loss were measured for mixture screening. The screening stage used a minimum permeability limit of 100 m/day and a maximum Cantabro loss of 20%.

2 Materials and Methods

2.1 Materials

The porous asphalt mixtures were produced using 50/70 penetration grade paving bitumen and graded mineral aggregates. The measured softening point was 50.55 °C. The mean penetration was 55.44 (0.1 mm). Bitumen specific gravity was assumed as 1.03 for mixture calculations as common practice. The bitumen properties used in the study are summarized in Table 1.

Aggregate specific gravity and water absorption were determined for the filler, 2 mm, and 4 mm fractions using pycnometer method (EN 1097-6). The 8 mm, 12 mm, 16 mm, and 22 mm fractions were evaluated using Archimedes scale method (EN 1097-6). Table 2 reports the full set of aggregate properties.

Table 1. Basic measured properties of the paving bitumen used in the porous asphalt mixtures.

Property	Unit	n	Mean	Min	Max
Softening point (Ring and Ball)	°C	2	50.55	50.30	50.80
Penetration	0.1 mm	9	55.44	52.00	69.00
Specific gravity	-	0	1.03	1.03	1.03

Table 2. Aggregate specific gravity and water absorption values used in the mixture calculations.

Aggregate Size	Method	Bulk Dry Gsb	Apparent Gsa	Water Absorption (%)
Filler	EN 1097-6	2.760	2.777	0.225
2 mm	EN 1097-6	2.562	2.682	1.736
4 mm	EN 1097-6	2.614	2.657	0.631
8 mm	EN 1097-6	2.594	2.681	1.270
12 mm	EN 1097-6	2.639	2.681	0.594
16 mm	EN 1097-6	2.643	2.682	0.548

2.2 Aggregate Gradations and Mixtures

Two porous asphalt aggregate gradations, designated G1 and G2, were investigated. Both gradations were fully passing the 16 mm sieve, but G2 contained a higher proportion of material in the intermediate and fine sieve range than G1. For example, the percent passing values at 8 mm, 4 mm, and 2 mm were 58.01%, 18.59%, and 10.14% for G2, compared with 50.02%, 11.53%, and 7.15% for G1. The corresponding gradation curves are summarized in Table 3 and illustrated in Fig. 1. The first screening observations indicated that G1 produced a structure that was too open for the current design objective, so the subsequent optimization effort focused on G2.

G1 was tested only at 3.5% bitumen content and 25X2 compaction as an initial gradation-screening case. The G2 series was evaluated at 3.5%, 4.0%, and 4.5% bitumen content under 25X2 compaction, and at 3.5% and 4.0% bitumen content under 50X2 compaction.

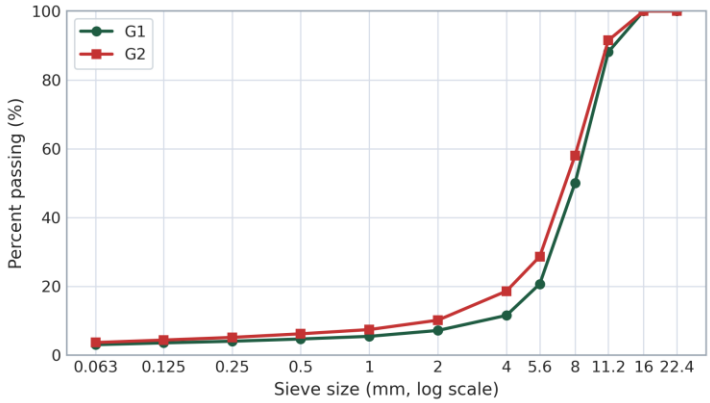

Fig. 1. Aggregate gradation curves for the two porous asphalt gradations used in the study.

Table 3. Aggregate gradation curves expressed as percent passing for gradations G1 and G2.

EN Sieve (mm)	G1 Passing (%)	G2 Passing (%)
22.4	100.00	100.00
16	100.00	100.00
11.2	88.13	91.51

0.125	3.54	4.36
0.063	3.01	3.64

Specimen Preparation and Bulk Specific Gravity

Marshall-type standard cylindrical porous asphalt specimens were prepared using 25 and 50 blows to each side of the specimens (EN 12697-30). Bulk specific gravity (Gmb) was determined using the ASTM D6752-02 vacuum-sealing method. Each specimen was enclosed in a sealed vacuum bag before weighing so that the connected void structure could be evaluated without uncontrolled water entrance. A representative vacuum-sealed specimen used for the Gmb measurement is shown in Fig. 2. Maximum specific gravity on the other hand was found using EN 12697-5 Procedure C. Then, volumetric properties were calculated according to EN 12697-8 standard.

Fig. 2. Vacuum-sealed porous asphalt specimen used for bulk specific gravity (Gmb) measurement in accordance with ASTM D6752-02.

2.3 Falling-Head Permeability Test

Permeability was evaluated using a falling-head procedure. The test setup consisted of a PVC pipe fitted to the specimen. A transparent tube was attached outside the pipe to monitor the water head, and two level-marks separated by 20 cm were used to define the falling-head interval. The specimen circumference was wrapped with duct tape to reduce leakage, and the connection between the pipe and the specimen was insulated using teflon tape. The custom setup is shown in Fig. 3. Water is filled from the upper side of the pipe quickly to a overfilling level. Then, the time was measured for the water level to fall from the upper level sign to below level sign which was 20 cm height. Permeability was included as a screening variable because prior work indicates that pore connectivity and porosity strongly influence grout penetration in porous asphalt skeletons for semi-flexible pavement [3].

$$k = \frac{(a \cdot L)}{A \cdot t} \cdot \ln \frac{h_1}{h_2} \cdot 86.4 \qquad (1)$$

Permeability was calculated using Eq.1 where k is the permeability (m/day); a is the standpipe cross-sectional area (mm²); A is the specimen cross-sectional area (mm²); L is the specimen height (mm); t is the elapsed time (s); h_1 is the initial head (mm); $h_2 = h_1 - \Delta h$ is the final head (mm); and Δh is the head drop recorded over the measurement interval (mm). The factor 86.4 converts the result from mm/s to m/day.

2.4 Cantabro Abrasion Loss Test and Screening Criteria

Cantabro abrasion loss was used as the pre-grouting durability indicator. Testing followed EN 12697-17. Cantabro loss was calculated as the percentage mass loss after drum rotation from the specimen masses measured before and after testing. Specimens were conditioned at 25 °C for 4 hours prior testing. Each time one Marshall specimen was put in the drum without any additional steel balls, and it was tested using 300 rotations. Rotation speed was 30-33 revolutions per minute, and test was lasted 10 minutes. Representative Cantabro test photographs are shown in Fig. 4.

Two thresholds were used during screening. The first was a minimum permeability of 100 m/day [16]. The second was a maximum Cantabro loss of 20%. The Cantabro limit is consistent with durability-oriented guidance reported for porous and open-graded asphalt mixtures [5,6].

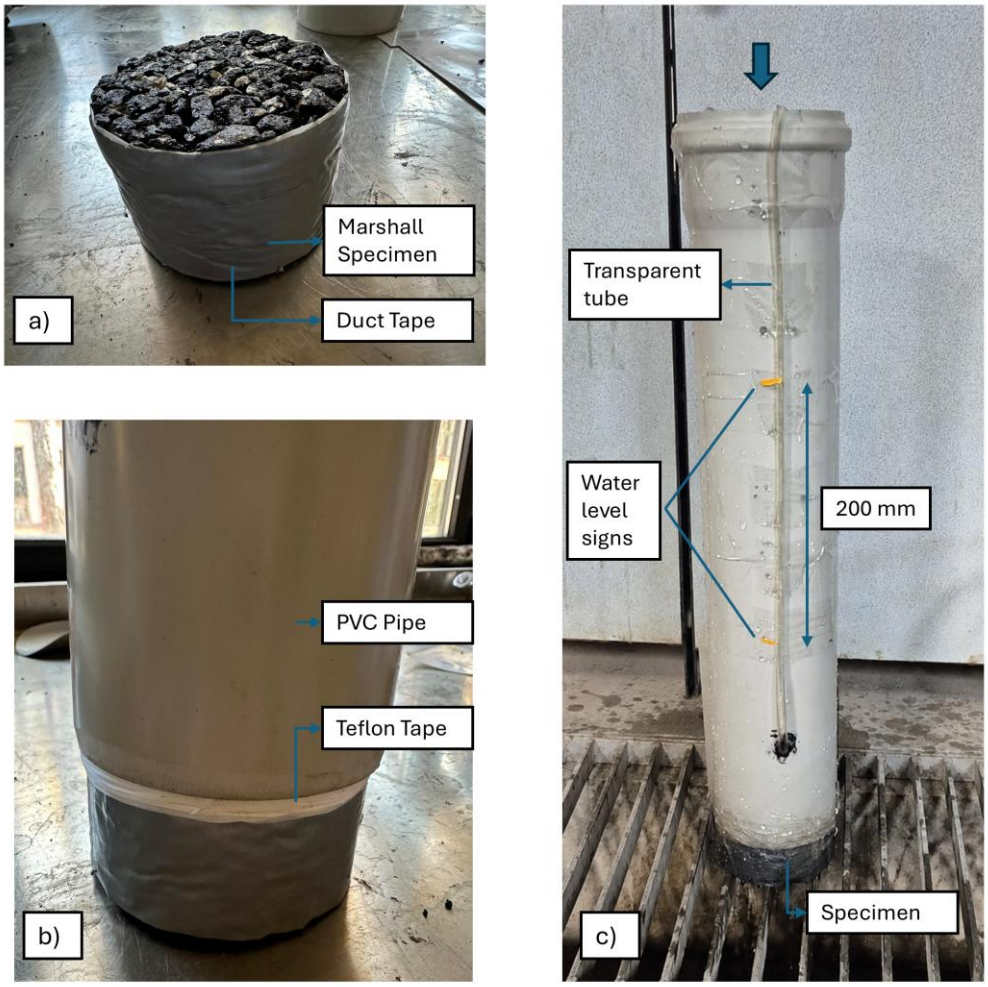

Fig. 3. Custom falling-head permeability setup showing (a) the Marshall specimen wrapped with duct tape, (b) the PVC pipe insulated with teflon tape at the specimen-pipe connection, and (c) the complete assembly with the external transparent tube and the 200 mm falling-head interval used during measurement.

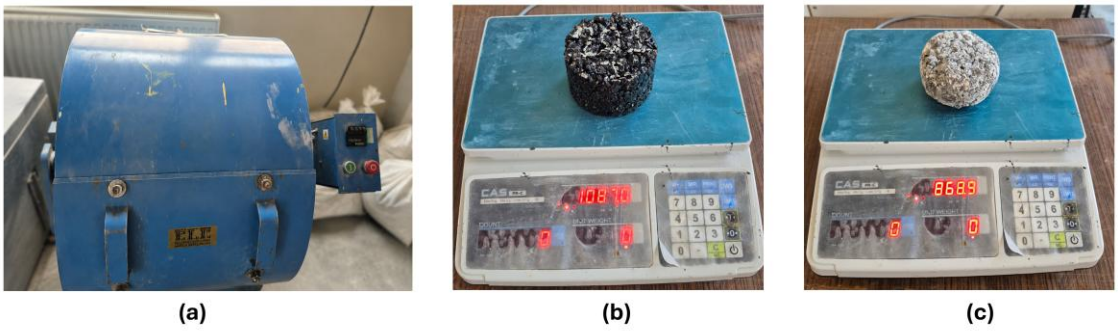

Fig. 4. Cantabro abrasion loss test showing (a) the Los Angeles drum used for abrasion, (b) a representative specimen before testing, and (c) the same specimen after testing.

3 Results and Discussion

3.1 Gradation Screening and Volumetric Behavior

Table 4 summarizes the volumetric and performance results used in the present screening stage. The gradation contrast between G1 and G2 is shown in Fig. 1, whereas the corresponding Gmb and air-void trends are plotted in Fig. 5(a-b). The first screening result from G1 confirmed that

a very open gradation could provide high permeability but remain insufficient in terms of pre-grouting durability. The G1-25X2-3.5% group showed a mean Gmb of 1.946, mean air voids of 22.86%, mean permeability of 512.63 m/day, and mean Cantabro loss of 40.67%. This combination indicated that the void structure was highly connected. It also showed that the abrasion resistance was inadequate for the current screening objective. After this first-stage observation, the optimization effort was directed toward the G2 family.

Within the G2 groups, the volumetric results showed that the higher compaction level produced a denser but still open structure. Under 25X2 compaction, mean air voids remained close to 20%, ranging from 19.85% to 20.30%. Under 50X2 compaction, mean air voids dropped to 17.44% at 3.5% bitumen and 17.82% at 4.0% bitumen. The same trend was reflected in Gmb, which increased from about 2.0 for the 25X2 groups to 2.056-2.082 for the 50X2 groups. These changes indicate that the higher compaction level tightened the internal structure while still maintaining a porous matrix.

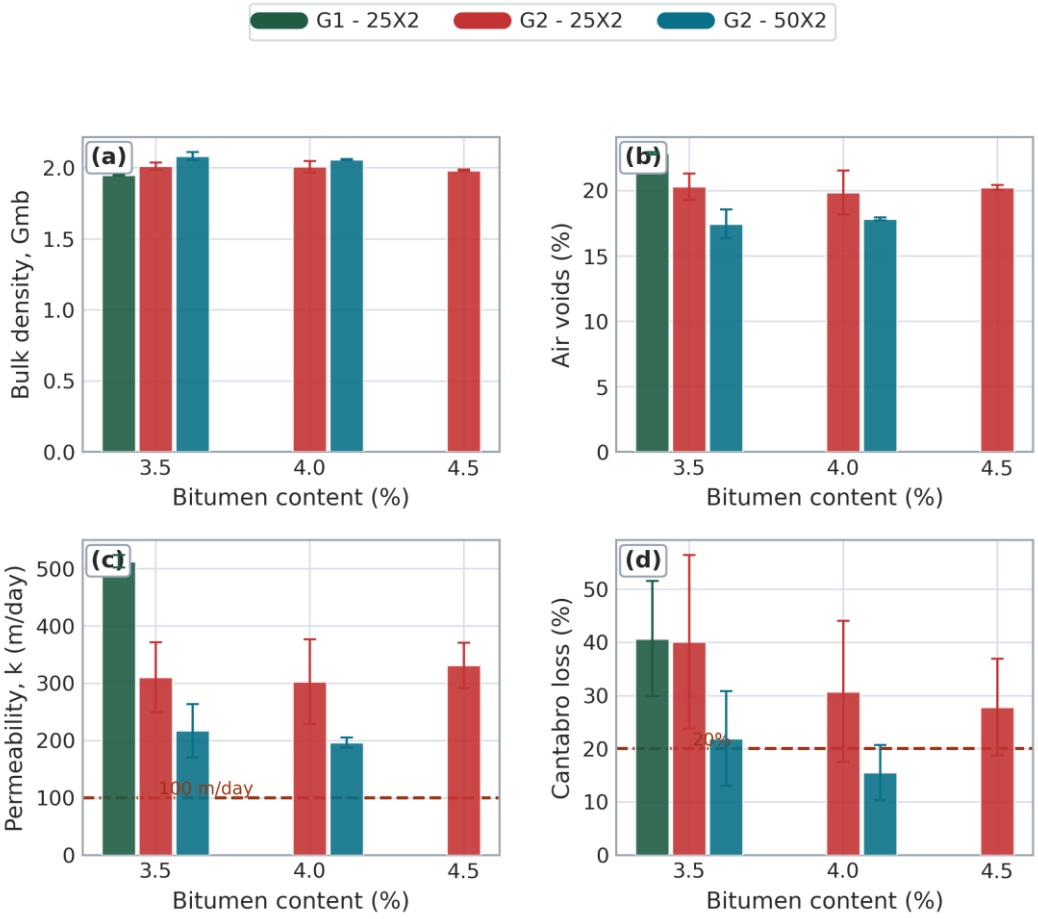

Fig. 5. Four-panel grouped bar charts showing mean values and standard-deviation error bars versus bitumen content for each gradation-compaction group. Panels (a), (b), (c), and (d) show bulk density, air void content, permeability, and Cantabro abrasion loss, respectively.

Table 4. Summary volumetric and pre-grouting performance values reported as mean +/- standard deviation.

Gradation	Compaction	Pb (%)	n	Gmb	Va (%)	Permeability k (m/day)	Cantabro Loss (%)
G1	25X2	3.5	2	1.946 +/- 0.002	22.86 +/- 0.09	512.63 +/- 10.85	40.67 +/- 10.83
G2	25X2	3.5	3	2.009 +/- 0.025	20.30 +/- 1.01	310.71 +/- 60.85	40.07 +/- 16.31
G2	25X2	4.0	3	2.006 +/- 0.042	19.85 +/- 1.67	302.90 +/- 73.99	30.76 +/- 13.27
G2	25X2	4.5	3	1.981 +/- 0.005	20.25 +/- 0.19	331.08 +/- 39.48	27.81 +/- 9.06
G2	50X2	3.5	4	2.082 +/- 0.028	17.44 +/- 1.11	217.24 +/- 46.54	21.93 +/- 8.89
G2	50X2	4.0	3	2.056 +/- 0.003	17.82 +/- 0.11	196.73 +/- 8.74	15.51 +/- 5.15

3.2 Permeability Behavior

Figure 5(c) shows that all group means in the current dataset remained above the working permeability limit of 100 m/day. Even the lowest measured group mean, 196.73 m/day for G2-50X2-4.0%, was still well above the minimum threshold adopted for this screening stage. This result indicates that all tested mixtures retained connected voids that would be expected to support grout infiltration.

However, the permeability results also showed that higher permeability was not automatically desirable. The preliminary G1 group had the highest mean permeability (512.63 m/day), but it also had poor Cantabro performance. Within the G2 mixtures, the 25X2 groups showed higher permeability than the 50X2 groups, with mean values between 302.90 and 331.08 m/day, whereas the 50X2 groups showed lower but still adequate means of 217.24 and 196.73 m/day. At 4.0% bitumen content, increasing compaction from 25X2 to 50X2 reduced mean permeability by 106.17 m/day. A similar reduction of 93.47 m/day was observed at 3.5% bitumen content. These results show that compaction was an effective tool for moderating the openness of the skeleton without eliminating the permeability needed for the next stage of grout injection. This interpretation is consistent with previous porous asphalt studies showing that higher porosity tends to improve permeability while compromising durability-related responses [4,13-15].

3.3 Cantabro Behavior

Figure 5(d) shows that Cantabro loss was the controlling response in the present mixture selection. The 25X2 groups all failed the current 20% target. For G2-25X2, the mean Cantabro loss decreased from 40.07% at 3.5% bitumen to 30.76% at 4.0% and to 27.81% at 4.5%. This trend indicates that increasing bitumen content improved cohesion and reduced aggregate loss, but the improvement was still insufficient to bring the 25X2 mixtures within the target limit.

The effect of higher compaction on Cantabro performance was more pronounced. For G2-3.5%, increasing compaction from 25X2 to 50X2 reduced mean Cantabro loss from 40.07% to 21.93%, an improvement of 18.14 percentage points. At 4.0% bitumen content, the corresponding reduction was from 30.76% to 15.51%, an improvement of 15.25 percentage points. Therefore, although higher compaction reduced permeability, it simultaneously produced a major gain in abrasion resistance.

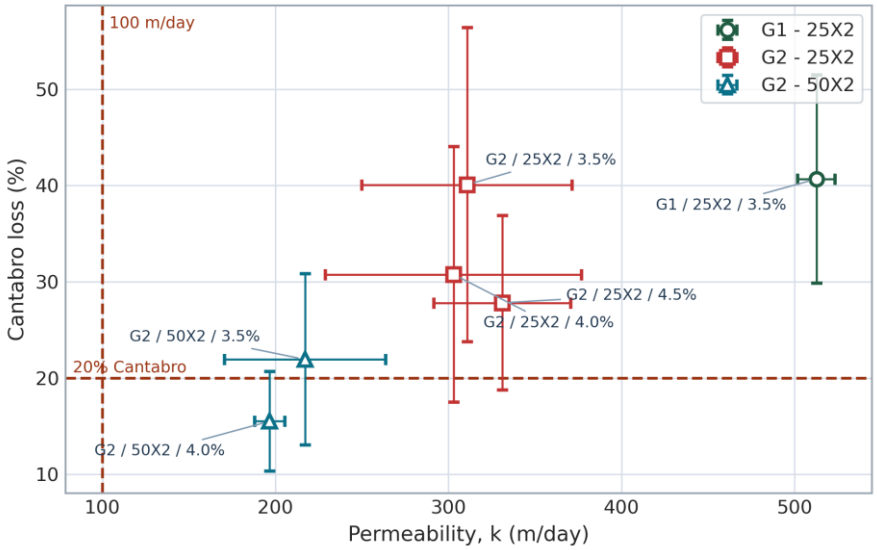

Fig. 6. Trade-off between permeability and Cantabro abrasion loss for the tested mixture groups, shown using group means and standard-deviation error bars. Each averaged point is labeled by gradation, compaction level, and bitumen content, and the current screening limits are shown as reference lines.

3.4 Trade-Off and Candidate Selection

The combined permeability-Cantabro trade-off is plotted in Fig. 6. The permeability and Cantabro results highlight the central design trade-off of the porous asphalt skeleton. A more open structure was beneficial for permeability, but it also tended to be more vulnerable to abrasion loss. Conversely, the denser 50X2 structures had lower permeability, yet their permeability remained above the screening limit and their pre-grouting stability improved substantially. The results indicate that the most permeable mixture is not necessarily the most suitable porous asphalt skeleton. The preferred mixture should preserve sufficient grout penetrability while avoiding excessive Cantabro loss. The screening outcome is summarized in Table 5.

Among the tested groups, G2-50X2-4.0% was the most suitable current candidate. This group had mean air voids of 17.82%, mean permeability of 196.73 m/day, and mean Cantabro loss of 15.51%, making it the only mixture that satisfied both working limits in the current mean-based screening pass. G2-50X2-3.5% was the next most competitive case because its permeability remained adequate at 217.24 m/day, but its mean Cantabro loss of 21.93% exceeded the target slightly. All 25X2 groups failed on Cantabro performance, even though their permeability remained favorable. Selected mixture should be assessed in subsequent mechanical and durability studies after grout injection.

Table 5. Preliminary candidate mixtures screened against the current permeability and Cantabro abrasion criteria.

Gradation	Compaction	Pb (%)	Va (%)	Permeability	Cantabro Loss	Criteria Check	Assessment
G2	50X2	4.0	17.82	196.73	15.51	Pass	Satisfies both screening limits; strongest current recommendation.
G2	50X2	3.5	17.44	217.24	21.93	Near miss	Permeability is sufficient, but Cantabro loss is slightly above the target.
G2	25X2	4.5	20.25	331.08	27.81	Fail	Permeability is sufficient, but abrasion resistance remains inadequate.
G2	25X2	4.0	19.85	302.90	30.76	Fail	Permeability is sufficient, but abrasion resistance remains inadequate.
G2	25X2	3.5	20.30	310.71	40.07	Fail	Permeability is sufficient, but abrasion resistance remains inadequate.

Engineering Implication

The present screening stage indicates that the selected porous asphalt skeleton should be evaluated further through grout injection rather than interpreted as a final field-ready mixture on its own. From that standpoint, G2-50X2-4.0% appears suitable as the primary current candidate for the next phase because it offers a balanced combination of openness and pre-grouting stability. Nevertheless, the final suitability of the semi-flexible system still depends on the behavior of the grouted composite, which

Conclusions

The following conclusions were drawn from the current laboratory screening study.

1. The porous asphalt skeleton for semi-flexible pavement should be selected by balancing permeability and pre-grouting abrasion resistance rather than by maximizing permeability alone.

2. The first screening gradation, G1, produced the highest permeability but also excessive Cantabro loss, which showed that it was too open for the present design objective.

3. All tested group means in the curated dataset remained above the current minimum permeability limit of 100 m/day, indicating that interconnected void paths were maintained throughout the tested range.

4. Cantabro abrasion loss was the controlling constraint in mixture selection. Increasing bitumen content improved Cantabro performance within the G2-25X2 groups, but none of those groups satisfied the 20% target. Increasing compaction from 25X2 to 50X2 reduced permeability but produced a substantial improvement in Cantabro resistance.

5. G2-50X2-4.0% is the most suitable current candidate for the porous asphalt skeleton because it is the only tested group that satisfies both working screening criteria, with mean permeability of 196.73 m/day and mean Cantabro loss of 15.51%.

6. The selected porous asphalt skeleton appears suitable for the next grout-injection stage, but post-grouting mechanical performance still needs to be evaluated before broader engineering conclusions are made.

Abstract. Remote island power plant construction face a combination of engineering, contractual, logistical, and severe weather conditions that are frequently underestimated during the planning phase of Engineering, Procurement, and Construction (EPC) projects. This study introduces a probabilistic Monte Carlo simulation (MCS) framework to quantify cost overrun and schedule delay risks in hybrid energy EPC projects executed in remote environments.

The model is calibrated using project specific technical and contractual specifications derived from a hybrid energy project that integrates natural gas fired engine generation, solar photovoltaic (PV), and battery energy storage systems (BESS). Nine risk parameter structure is adopted to capture critical risk drivers: contract structure, pricing mechanisms, procurement strategy, technology integration, political stability, logistics complexity, foreign currency exposure, regulatory compliance, and extreme climate risks.

This study works on 50,000 iterations with Monte Carlo simulation to modeling cost and schedule data's with the correlation $\rho = 0.65$ log-normal distributions to show the uncertain risks of the energy investment project. The initial results indicates a median (P50) cost overrun of 29.1% and a schedule delay of 20.1%, which is matching usual industry practice. On the other hand, under extreme risk scenarios (P90), cost variation can exceed 100%, which is also shows that planning application in traditional contract management practice does not work for such remote island projects. Main aspects of the cost variations are political stability, foreign exchange volatility, and severe logistics constraints. The assessment which is executed for both risks also shows that 35% outcomes of the simulation, cost and schedule overruns can be expected above median values. This result shows that cost and delay risk are linked each other.

Thanks to this study, contract managers found a practical way to establish realistic contingency allocations to prevent project budget for the expected risks. As a final note, the study helps the construction professional under the such mega contracts to use insights into variation orders, mitigation of claims, and risk assessment mechanisms.

Keywords: Monte Carlo simulation, EPC risk, contractual risk determination, hybrid energy, FIDIC Silver Book, remote island.

1 Introduction

Complexity of the hybrid energy investments on remote island environment is very high. These projects are encounter unique challenges; such as fluctuations and changes on power grids, difficulty with logistics operations, extreme and unexpected climate, and a complete reliance on imported energy. Because these systems operation requires isolated grids for multiple sites, it is not surprising to encounter complex risk environment in such international EPC turnkey contracts.

This study is adopted from a real hybrid energy project which is built across two different locations on isolated islands. The project combines gas based generation system (Genset), solar power, and battery energy storage (BESS) into a single system. At Site A, the production capacities of Gensets are up to 25–35 MW, 10–15 MW for solar, and 15–25 MWh for batteries, while Site B has slightly smaller capacities than Site A.

Execution team projected some several factors which may create high uncertainty during construction. One of them, relying on a single gas source, with LNG storage system, without any backup source creates fuel risks. Secondly, strict environmental standards for example; durability strong winds and corrosion risk due to ocean evaporation, makes the design process much more difficult. Finally, and most generic and serious challenge that several turnkey contracts encountered is that lack of information about the soil data on the Site B creates a risk of working with unexpected soil conditions during construction.

2 Literature Review

With this section, researchers deeply investigate related academic research to finding out why complex projects completed over budget and finish late than scheduled. In the beginning of this section main reasons can be found for these delays and extra budget in traditional projects. Then, it shows how using Monte Carlo simulations helps to manage risks and handle financial uncertainties in latest energy projects.

2.1 Cost Overrun and Schedule Delay in Infrastructure Projects

In real construction projects, especially major energy investments, often exceeds its budget more than expected. Research by Flyvbjerg et al. [1] indicates that construction experts usually underestimate project costs because they are too optimistic or hide the real costs in purpose. On the other hand, when a project duration lasts more than one year, Touran and Lopez [2] used Monte Carlo modeling to show that cost uncertainties increase much faster and become harder to predict in the beginning. In complex environments, such as energy projects, this risk may getting worse because stakeholders of the project has not got the same information. For example, before the signature phase, parties of contract has insufficient data regarding the ground conditions and it causes uncertainty than expected. This often concludes rising the actual costs and contractual disputes during construction execution. Under fixed price contracts like the FIDIC Silver Book, all these risks regarding the soil based are under the contractor responsibility, which heavily increases their financial risk.

2.2 Monte Carlo Simulation in Construction Risk Analysis

To calculate the project risks and contingency, in general practice uses AACE International, and it recommends to use Monte Carlo simulation (MCS). When researcher apply this integration, according to Baghalzadeh Shishehgarkhaneh et al. [3] supply chain and design limits are vital components to analyze. Arnold and Yildiz [4] showed that log-normal distributions work best because cost risks are usually skewed toward higher numbers for especially renewable energy investments.

Another essential part in probabilistic modeling is that project costs and schedules are highly interact with each other. Common suspension during the construction; such as unexpected

weather, failures in supply chain, or delays caused by permits etc., has effect both of them at the same time. In fact, statistics also show a high correlation (ρ between 0.60 and 0.85) between these two, which shows that models must simulate them together.

3 Project Description

This master thesis investigates on a project which has specific technical rules. It uses a lump sum pricing mechanism of an EPC turnkey contract which is also linked to a long term power purchase agreement (PPA) of the owner with the government. Contractor work describing in the contract; install and complete commissioning of the Gensets that can work only on LNG supply, combined with solar PV panels and battery storage system (BESS). Because of the location of the islands, the structures must be resistant strong winds and salty ocean air, requiring high-level (C4 equivalent) rust protection for the whole operation duration which is defined in PPA. The major defined risk here is the soil condition: while Site A has finished all its soil and geology tests on site, Site B lacks complete geotechnical information, which makes the project much riskier. Technical details can be seen in Table 1.

Table 1. Key Project Characteristics (taken from project specification).

Parameter	**Site A**	**Site B**
Genset Capacity	25-35 MWe	15-25 MWe
Solar PV Capacity AC	10-15 MWe	5-10 MWe
BESS Energy Capacity	15-25 MWh	10-20 MWh
BESS Response Time	≤ 200 ms	≤ 200 ms
Fuel Supply	LNG (No backup)	LNG (No backup)
Contract Framework	Bespoke FIDIC Silver Book	Bespoke FIDIC Silver Book
Geotechnical Status	Complete	Incomplete (high risk)

Hybrid projects combine different types of technologies, like this, makes the construction much harder to manage. This complex technology environment becomes a vital problem especially before the facility's commercial operation and most importantly the test and commissioning phases. To achieve commercial operation, the EPC contractor must strictly follow the local grid code and project specification and also pass all grid compliance tests for sure the systems product energy within the feasible levels. Achieving these rules regarding the tests are a mandatory requirement for both provisional acceptance of the EPC contract and the PPA framework.

4 Methodology

Calculation model follows plain and simple process. It takes descriptive, qualitative risks and turns them into mathematical probability curves. This model uses nine separate risk categories (M_1–M_9). Each category uses a specific scale that links risk descriptions to simple multiplier numbers with no units. Depending on the given data of the respective project, researchers assign each of these nine categories a specific rating.

Table 2. Nine Risk Dimensions, Multiplier Ranges, and Base Case Ratings.

#	Risk Dimension	Range	Base Case Rating	ERQ Calibration Basis
M_1	Contract Type	0.85–1.35	1.35	FIDIC Silver Book; contractor risk concentration
M_2	Pricing Mechanism	0.80–1.35	1.35	Fixed Lump Sum; delay damages included
M_3	Procurement Strategy	1.00–1.40	1.40	Owner Furnished Equipment interface risks
M_4	Technology Maturity	0.85–1.80	1.15	Hybrid system integration complexity
M_5	Political Stability	0.80–2.20	1.10	Stable environment with moderate permitting risk
M_6	Logistics Complexity	0.70–1.90	1.45	Extreme remote island; transport restrictions
M_7	FX Volatility	0.85–2.00	1.15	EUR/USD procurement; no currency hedging
M_8	Climate/Hurricane Risk	0.80–1.70	1.35	Exposure to severe tropical storm windows
M_9	Regulatory Complexity	0.80–1.70	1.40	Permitting from several authority and determined grid codes for both sides

To get the cost (Rc) and schedule (Rd) risk factors, it is combined the individual multipliers together. To do this, the model uses a geometric mean formula with fractional exponents. Researchers select this mathematical method because the its advantages regarding the final risk scores from being distorted by extreme numbers:

$$R_c = (M_1 \cdot M_2 \cdot M_3 \cdot M_4 \cdot M_5 \cdot M_6 \cdot M_7 \cdot M_8 \cdot M_9)^{1/3.5} \quad (1)$$

$$R_d = (M_3 \cdot M_4 \cdot M_5 \cdot M_6 \cdot M_8 \cdot M_9)^{1/2.8} \quad (2)$$

In this study, a Cholesky decomposition method is used to show how shared risks has linked cost and schedule together. The model runs the calculation through 50,000 iterations. In each turn, it samples cost overruns (C) and schedule delays (D) together using correlated log-normal formulas, based on a real world correlation coefficient of $\rho = 0.65$. Finally, it has been tested four different situations: Optimistic, Base Case, Conservative, and Stress.

5 Results and Discussion

The probability curves from the simulation lean heavily to the right. When data clustered on the right side of the graph, it shows us that using a log-normal model was the right choice to study on it. Each scenarios tested and results can be seen on the Table 3 below.

Table 3. Monte Carlo Simulation Percentile Results (N = 50,000).

Percentile Metric	Optimistic Scenario	Base Case Scenario	Conservative Scenario	Stress Scenario
P10 Cost %	7.6	13.4	15.6	22.7
P50 Cost %	16.5	29.1	34.2	49.2
P80 Cost %	27.5	48.5	56.9	82.1

P90 Cost %	35.9	63.2	74.1	107.4
P10 Delay %	5.5	8.8	10.3	14.6
P50 Delay %	12.5	20.1	23.4	33.1
P80 Delay %	21.4	34.6	40.2	56.9
P90 Delay %	28.3	45.5	53.3	75.3

According to Base Case results, the median (P50) cost overrun is 29.1%. This is very close to global infrastructure benchmarks of around 28%, which shows our model is accurately calibrated. On the other hand, the P80 cost overrun reaches 48.5%, meaning a standard lump sum pricing risk needs a large and contingency buffer for better risk adjustments. Under Stress conditions, worst-case outcomes (P90) jump past 100% cost escalation. This proves that even more than one problem happen at the same time in remote sites, they multiply each other's risk impact.

When researchers check the one-way sensitivity analysis, it has been found three main drivers behind these cost changes: political stability (M_5, ±8.6 pp range), foreign exchange volatility (M_7, ±7.5 pp range), and logistics constraints (M_6, ±7.4 pp range). Finally, the joint distribution analysis shows that 35% of all simulated cycles suffer from both cost and schedule overruns above their median values. This is clearly proved that cost and time risks are structurally linked.

6 Change Order and Claim Analysis

Study turned these results regarding the risk into practical tools for the contract administration phase. To achieve this, researchers linked a structured change order register directly to the specific EPC contract terms. It can be seen how these commercial risks has been categorized in Table 4.

Table 4. Change Order and Claim Register under EPC Framework.

CO Type	**Probability %**	**Cost Impact**	**Typical Trigger**	**Contractual Basis (FIDIC)**
Fuel Logistics Escalation	90%	8-15% contract	Isolated fuel supply, marine unloading restrictions	Unforeseen physical conditions / Interface risk
Geotechnical Uncertainty	65%	4-12% civil scope	Incomplete site survey data at Site B, latent conditions	Sub-Clause 4.12 Unforeseen Physical Conditions
Grid Connection Scope Variation	75%	5-20% electrical	Grid code compliance adjustments for different Sites	Interconnection and test and commissioning clauses
FX Rate Deviation	60%	5-18% exposure	Currency mismatch in major	Absence of Price

			equipment orders	Adjustment provisions

7 Contract Administration Implications

This section analyses the risk numbers from the Monte Carlo simulation into practical strategies for managing the EPC contract. By comparing probability limits with turnkey delivery rules, project teams can draw a solution and handle uncertainties during construction. Before conclusion, following parts show specific steps to reduce claims, schedule delays, and logistical issues in remote island projects with commercial precautions.

7.1 Geotechnical Uncertainty and Turnkey Risk Allocation

In general, standard lump sum turnkey frameworks, including FIDIC Silver Book [5] Sub-Clause 4.12, financial responsibility of unforeseen ground conditions is on the contractor. Site B geotechnical survey was not completed before the contract execution which is highly common situation to face with multiple claims and brings contractual risks. There is no need to awoke this situation during the negotiation phase, contract administrators can estimate buffer for the geotechnical works, which is approximately 4-12% of civil works or they can determine until the final site data available.

7.2 Performance Guarantees and Sequential Commissioning Milestones

Any delay during the commissioning phase makes delay escalate exponentially because of actions during the commissioning happens because commissioning milestones happen step by step. Not until the hybrid energy production control system satisfies specific grid requirements, ramp rates, and voltage setups under island mode startup can reliability testing even begin. This reliability test phase typically needs 240 uninterrupted hours, approximately 10 days, of operation at a minimum of 99% availability of the energy production equipment. To avoid entire test repetition for the minor interruption cases, project schedules must include sufficient float for those minor interruptions. Additionally, schedule has to be prepared to allow at least two or maximum three failures to avoid possible delay liquidated damages (LDs) executed by the employer.

7.3 Fuel Supply Chain and Environmental Resilience

The facility relying on single LNG shipment route and it creates risks during execution pahse of contract. Additionally, during operation and maintenance period, contract managers should enforce the operators of facility to backup fuel reserve for strategic use (e.g., 72 hours of operation) as a condition for commissioning and prevent un expected cutoffs. Additionally, Construction All Risks (CAR) policies must cover tropical storm damages to protect the facility from extreme weather damages and facility should protective structures during the vulnerable installation and execution phases of construction.

8 Conclusions

In conclusion, this research using a probabilistic Monte Carlo simulation with the data of a hybrid energy EPC investments in remote island. Using 50,000 simulation iterations and a bivariate correlation structure ($\rho = 0.65$), this model demonstrated that fixed budgeting fails to determine the realities of isolated microgrid infrastructures. The Base Case calculated a P50 cost overrun of 29.1% alongside a 20.1% timeline delay.

In the end, external risks like political stability, foreign exchange volatility, and island logistics played a significant role in cost change in comparison of engineering metrics. By using this simulation outputs into contract administration tools, for example given enough float for possible retesting and contingency for the unexpected ground conditions, allows contract

managers to find a proactive solution and/or provide to prevent some disputes during the execution phase for such energy construction projects.

Abstract. Building Information Modelling (BIM) can reduce manual effort in quantity take-off (QTO) and cost estimation, but model-derived quantities remain sensitive to modelling practice, object representation, software behaviour, and measurement assumptions. This focused review examines the relationship between IFC-based QTO, IDS-based information compliance, and BIM quantity verification. Three focused searches were conducted in the Web of Science Core Collection for the 2013–2026 period, and nine peer-reviewed studies were included in the qualitative synthesis. The review shows that IFC-based quantity extraction and IDS-based compliance checking address related but distinct problems. IDS can verify predefined information requirements, but it does not independently establish whether stored IFC BaseQuantities are geometrically consistent. Based on this distinction, the paper proposes a wall-focused conceptual workflow that separately reports information compliance, geometric assessability, quantity consistency or discrepancy, non-assessable cases, and human-review needs. The proposed structure aims to prevent information compliance from being interpreted as proof of quantity reliability in downstream cost-estimation workflows.

Keywords: BIM; IFC; IDS; Quantity Take-Off; Model Checking

1 Introduction

Quantity take-off (QTO) extends beyond the measurement of building components. In construction projects, quantity information supports tendering, cost estimation, procurement, progress valuation, and cost control. Consequently, quantity errors may extend beyond the modelling environment and affect contractual and financial decisions. Although BIM-based QTO can reduce repetitive manual measurement, the availability of a digital model does not eliminate the need to examine how quantities are generated, represented, exported, and verified [1, 2].

Research on BIM-based QTO presents two complementary findings. On the one hand, IFC-based openBIM workflows demonstrate that quantities can be extracted from vendor-neutral model data and integrated into cost-estimation processes [3–6]. On the other hand, empirical and methodological studies show that model-derived quantities may vary according to modelling practices, object representation, software interpretation, parameter completeness, and checking procedures [1, 2, 7]. The central issue is therefore not whether BIM can support QTO, but under which modelling, information, and verification conditions model-derived quantities can be considered sufficiently reliable for cost-related use.

The Information Delivery Specification (IDS) introduces an important information-compliance layer to this discussion. buildingSMART defines IDS as a standard for expressing information requirements in a computer-interpretable form and checking their delivery in IFC models [8]. IDS can specify requirements concerning IFC entities or objects, classifications, materials, properties, quantities, and permitted values. However, buildingSMART also states that IDS is limited to alphanumeric information and does not address geometrical aspects [8]. This limitation is particularly important for QTO. A wall may comply with IDS requirements concerning its classification, material, or the presence of a quantity field while the numerical value stored in that field remains inconsistent with the wall geometry or with the intended measurement basis.

Recent studies have begun to integrate IDS into cost-estimation workflows. Cassandro et al. connected structured cost data, IFC, IDS, and model validation within cost-estimation data management [9], while Dias et al. proposed an IDS-based openBIM verification workflow for construction cost estimation [10]. These studies demonstrate the potential of IDS to verify whether predefined information requirements have been satisfied before QTO. Nevertheless, information compliance alone does not establish whether a stored IFC quantity is consistent with the corresponding model geometry.

This paper therefore treats information compliance and geometric quantity consistency as complementary but analytically distinct verification dimensions. Compliance with task-essential information requirements may be necessary to perform a particular quantity comparison. However, general IDS compliance neither proves quantity consistency nor necessarily determines whether a geometry-based comparison can be conducted. Building on this distinction, the paper reviews relevant IFC-, IDS-, and BIM-QTO studies and proposes a wall-focused conceptual workflow that separately reports information compliance, geometric assessability, quantity discrepancies, non-assessable cases, and the need for human review.

Throughout the paper, information compliance refers to conformity with predefined information requirements, whereas quantity consistency refers to agreement between a stored IFC quantity and an independently derived comparison value under equivalent measurement assumptions. Accuracy and correctness are reserved for comparisons against an accepted reference or authoritative measurement rule. A discrepancy therefore indicates a difference requiring interpretation rather than automatically implying an error.

2 Scope and Methodological Position

2.1 Review Aim and Research Questions

This paper aims to clarify how research on IFC-based quantity take-off (QTO), IDS-based information compliance, and BIM verification can be connected to support the reliability of wall quantity take-off. Walls are selected as a focused demonstrator because their quantity assessment may involve semantic and classification requirements, material and layer information, stored IFC BaseQuantities, gross and net quantity definitions, openings, joins and intersections, composite or decomposed representations, and differences arising from modelling and export procedures.

The review is guided by the following research questions:

1. How has IFC been used in BIM-based quantity take-off and cost-estimation workflows?
2. What reliability problems have been reported for BIM-derived quantities?
3. What types of information checking can IDS support in IFC-based workflows?
4. How can IDS-based information compliance be coordinated with geometry-based quantity-consistency assessment for wall elements?

2.2 Review Method and Scope

This study adopts a focused review approach supported by qualitative thematic synthesis. It is not intended as a PRISMA-based systematic review, meta-analysis, or exhaustive review of the BIM-QTO literature, but focuses on the intersection of IFC-based quantity extraction, IDS-based information checking, and quantity-consistency concerns relevant to cost-estimation workflows.

The literature search was conducted in the Web of Science Core Collection between 25 and 29 June 2026 for publications from 2013 to 2026. Three focused search strings addressed IFC-based QTO and cost estimation, IDS-based information checking, and geometry- or quantity-related verification. The search strategy and initial retrieval results are summarised in Table 1. The three searches returned 142 records in aggregate before consideration of possible overlap among the search sets.

Table 1. Web of Science search strategy and initial retrieval results

Search focus	Search string	Records
IFC-based QTO and cost estimation	("Building Information Modeling" OR BIM) AND (IFC OR "Industry Foundation Classes") AND ("quantity take-off" OR QTO OR "quantity surveying" OR "cost estimation")	47
IDS-based information checking	("Information Delivery Specification" OR IDS) AND (BIM OR IFC OR "Industry Foundation Classes") AND ("compliance checking" OR validation OR "information requirements")	26
Geometry/quantity verification	(IFC OR BIM OR openBIM) AND ("quantity take-off" OR QTO OR BaseQuantities OR "cost estimation") AND ("geometry-based" OR "geometric verification" OR "quantity validation" OR accuracy)	69

The search and initial screening were conducted by the first author. Candidate records were screened by title and abstract, and nine peer-reviewed studies were retained for qualitative synthesis [1–7, 9, 10]. Studies were included when they directly addressed IFC-based quantity extraction, BIM-QTO reliability, quantity- or cost-related model checking, IDS-based information requirements, or IFC-based cost-data structuring. Studies without a direct relationship to IFC, IDS, QTO, or cost estimation were excluded. The selected full texts were examined for research aim, method, model or project scope, IFC/IDS context, comparator or checking basis, key findings, and limitations.

Official buildingSMART documentation was reviewed separately for technical definitions of IFC, IDS, quantity sets, and wall BaseQuantities [8, 11–13]. These sources were not counted among the nine peer-reviewed studies. The synthesis focused on four themes: IFC-based QTO and interoperability, BIM-QTO reliability, IDS-based information compliance, and IFC/IDS-supported verification for cost estimation.

The review is limited to one bibliographic database, three focused search strings, a 2013–2026 publication period, nine peer-reviewed studies, single-author screening, and heterogeneous study designs. Accordingly, the findings should be interpreted as a focused qualitative synthesis rather than a comprehensive review of the BIM-QTO literature.

3 Scope and Methodological Position

3.1 IFC-Based Quantity Take-Off

Industry Foundation Classes (IFC) provide a vendor-neutral schema for exchanging building objects, properties, relationships, geometry, and quantity information across software

environments [12]. Within QTO research, IFC is used primarily as an interoperable data source rather than as a costing method. The reviewed IFC-based studies employ IFC data for specification-compliant tender estimation, schematic-stage estimation, and interoperable QTO algorithm development [3–6]. Although these studies collectively demonstrate that IFC can support quantity extraction, computation, classification, and linkage between model objects and cost items, their comparison and validation bases differ. Ma et al. use formal measurement rules as the basis for quantity calculation; Choi et al. combine model-quality checking with comparison against commercial software; and Akanbi et al. examine the robustness of QTO algorithms across different IFC representations and authoring-tool outputs [3–6]. These approaches provide evidence of implementation feasibility, interoperability, and rule-based processing, but they do not directly address whether stored IFC BaseQuantities are numerically consistent with quantities independently derived from the corresponding geometry. This distinction is particularly relevant to wall QTO. A quantity may be successfully extracted from IFC, agree with commercial software output, or satisfy a formal measurement specification while still requiring explicit interpretation of openings, intersections, boundaries, material layers, and gross or net definitions. Consequently, IFC-based QTO methods support traceable extraction and rule-based calculation, but a separate comparison basis is required when the objective is to assess the consistency of a stored quantity with model geometry.

3.2 Reliability Problems in BIM-QTO

Research on BIM-QTO reliability shows that quantity outcomes are influenced not only by the availability of model data but also by how building elements are represented, parameterized, and processed. Wahab and Wang, Kim et al., and Valinejadshoubi et al. investigate this issue using different comparison bases, including project reference quantities and workflow comparisons, study-defined target representations, and internal parameter-consistency checks [1, 2, 7]. Their findings are therefore complementary rather than directly comparable. Across these studies, quantity variation is associated with workflow selection, object composition, material representation, missing or inconsistent parameters, alternative parameter-based calculations, and differences between manual and automated checking procedures [1, 2, 7]. Ma et al. further demonstrate that formal measurement rules concerning openings, accessories, and intersections can alter quantities calculated from model information [3]. Taken together, these studies indicate that BIM-based QTO depends on four closely related factors: model representation, information completeness, measurement rules, and computational procedure.

An important implication is that neither a stored model quantity nor a geometry-derived quantity should be treated as inherently correct without first defining a common measurement basis. Differences may arise from actual modelling or export errors, but they may also reflect legitimate differences in quantity definitions, deduction rules, object decomposition, or measurement conventions. Quantity comparison therefore requires explicit alignment of the quantity definition and the assumptions under which each value has been produced.

3.3 IDS and Information Compliance

The Information Delivery Specification (IDS) provides a computer-interpretable mechanism for defining information requirements and checking their delivery in IFC models [8]. Depending on the specified requirement, IDS checks may concern IFC entities and predefined types, attributes, properties, quantities, classifications, materials, relationships, and permitted values. This capability is relevant to QTO because cost-estimation workflows often depend on information that is not guaranteed to be present or consistently structured in every IFC model. IDS can make such expectations explicit and support repeatable compliance checking before model information is used downstream. However, IDS is designed for alphanumeric information requirements, while geometrical definitions and spatial calculations fall outside its

scope [8]. For example, an IDS requirement may verify that a wall contains a NetVolume quantity and that the value satisfies the specified information requirement. It does not reconstruct the wall geometry, calculate deductions for openings, resolve wall intersections, or independently determine whether the stored value corresponds to the intended gross or net geometric volume. The presence and formal compliance of a quantity field therefore constitute a different type of evidence from geometric consistency.

Information compliance and geometric quantity consistency should consequently be treated as related but analytically distinct dimensions. An element may fail an IDS requirement unrelated to the selected quantity while remaining geometrically assessable. Conversely, an element may satisfy all required classifications, properties, materials, and quantity fields while its stored quantity differs from an independently derived geometric value. IDS results should therefore be interpreted as evidence of information conformance and readiness for a defined workflow, rather than as proof of quantity accuracy, correctness, or geometric consistency.

3.4 IFC/IDS-Based Verification for Cost Estimation

Recent research has begun to operationalize IDS within cost-estimation workflows. Cassandro et al. and Dias et al. connect formalized information requirements with IFC-based cost processes, although their principal contribution is information control rather than independent geometric verification of stored quantities [9, 10]. Cassandro et al. show how IDS can formalize cost-workflow requirements and how IFC cost entities can structure relationships between model objects and cost items [9]. Dias et al. demonstrate the use of IDS-based requirements for assessing information readiness, supporting semantic enrichment and remediation, and communicating non-conformities before QTO [10]. These studies strengthen the role of explicit and machine-readable information requirements in cost-estimation workflows. However, they should not be interpreted as demonstrating independent geometric recalculation of stored wall quantities. Their contribution lies primarily in ensuring that required information is present, structured, and suitable for downstream use.

The reviewed literature therefore reveals a specific gap at the intersection of information compliance and quantity verification. IFC-based QTO studies explain how model information can be extracted, interpreted, and computationally processed [3–6]. BIM-QTO reliability studies demonstrate how quantities may vary according to representation, model detail, parameter completeness, workflow, and measurement procedure [1, 2, 7]. IDS-related cost-estimation studies show how cost-related information requirements can be formalized and checked before QTO [9, 10].

What remains insufficiently addressed is the coordinated reporting of these two verification dimensions at the level of individual model elements. Checking that a stored wall quantity exists, is located in the expected quantity set, or satisfies an IDS requirement does not establish that its numerical value is consistent with the IFC geometric representation under equivalent measurement assumptions. Conversely, failure of an information requirement does not necessarily make a selected geometric quantity comparison impossible. Within the studies included in this review, no approach was identified that explicitly combines IDS-based information-conformity reporting with an independently derived wall-quantity comparison while also distinguishing assessable, discrepant, and non-assessable cases. This coordination gap provides the basis for the conceptual verification workflow proposed in Section 4. The methodological roles and comparison bases of the nine studies included in the review are summarised in Table 2.

Table 2. Methodological focus of the studies included in the qualitative synthesis

Ref.	Main focus	Comparison/checking basis	Relevance to the present study
[1]	BIM-based vs. traditional QTO	Project/reference quantities and workflow comparison	Shows workflow-related quantity variation
[2]	BIM QTO discrepancy analysis	Study-defined representation/comparison basis	Shows effects of modelling representation
[3]	IFC-based tender cost estimation	Formal measurement rules	Demonstrates rule-based IFC quantity processing
[4]	openBIM schematic QTO	Model-quality checking and commercial-software comparison	Demonstrates interoperable QTO feasibility
[5]	Interoperable QTO algorithm development	IFC representations and authoring-tool variation	Addresses robustness across model representations
[6]	Automated IFC-based QTO	IFC-based architectural model case study	Demonstrates automated quantity extraction/calculation
[7]	High-accuracy BIM QTO	Parameter and quantity consistency checking	Highlights model-information consistency issues
[9]	IFC/IDS-supported cost information	Information requirements and IFC cost structures	Connects IDS with cost-workflow readiness
[10]	IDS-based openBIM cost verification	Information requirement compliance	Demonstrates IDS-supported pre-QTO information checking

4 Proposed Conceptual Verification Workflow

Building on the review synthesis, this section proposes a conceptual, wall-focused verification workflow rather than an implemented or empirically validated software system. Walls are selected as a manageable analytical case because their quantity assessment may involve stored BaseQuantities, classifications, properties, material layers, openings, joins and intersections, gross and net quantity definitions, and alternative geometric representations. Although the workflow is illustrated through wall elements, the underlying distinction between information compliance and quantity consistency is not limited to walls.

The initial scope is restricted to ordinary IFC wall instances and selected stored wall BaseQuantities. IFC quantity sets provide standardised structures for storing quantity information [12], and Qto_WallBaseQuantities may include quantities such as Length, Width, Height, GrossSideArea, NetSideArea, GrossVolume, and NetVolume [13]. The treatment of more complex cases, including curved, layered, decomposed, curtain, covering, hosted, and irregular wall configurations, is outside the initial conceptual scope and should be addressed during implementation.

4.1 IFC Information Layer

The workflow begins by identifying the relevant wall instance and the specific stored quantity to be assessed. For each wall, the IFC information layer records the element identifier, object type, quantity-set name, quantity name, stored value, unit, available properties, material information, classifications, and geometric representation.

This element-level traceability is necessary because quantity assessment should not be performed independently of the object and quantity definition from which the value originates. In particular, the stored quantity must be explicitly associated with its quantity name and unit before any geometric comparison is attempted.

4.2 IDS Information-Compliance Layer

The IDS layer evaluates predefined information requirements associated with the intended QTO or cost-estimation task. A distinction is made between task-essential information and broader workflow information. Task-essential information comprises the data required to perform the selected quantity comparison, such as the wall identifier, selected quantity, unit, quantity definition, and information necessary to establish an equivalent measurement basis. If such information is unavailable or incompatible, a meaningful geometric comparison may not be possible. Broader workflow information may include cost classification, material naming, load-bearing status, or other attributes required for downstream cost-estimation activities. Failure to satisfy such requirements may affect overall workflow readiness without necessarily preventing a selected quantity from being geometrically assessed.The IDS result is therefore recorded as an information-compliance outcome and is not interpreted as evidence that the numerical quantity value is geometrically consistent.

4.3 Quantity-Consistency Layer

The quantity-consistency layer compares a specifically identified stored IFC quantity with an independently derived geometric value, provided that an equivalent measurement basis can be established.

Before the comparison is performed, the following conditions must be defined:

- whether the stored quantity represents a gross or net measurement;
- how openings are treated;
- how joins and intersections are treated;
- which geometric boundaries are included;
- whether material layers are evaluated collectively or separately; and
- whether the stored and independently derived values use compatible units and quantity definitions.

These conditions are essential because a numerical difference does not necessarily indicate an error. It may instead result from different measurement rules, geometric interpretations, deduction procedures, or model representations. Once an equivalent comparison basis has been established, units are normalised and an independent geometric value is derived. The numerical difference between the stored quantity and the independently derived value is then reported. A tolerance threshold is applied only where a technically justified threshold is available. The geometry-derived value is treated as an independent comparison value rather than as automatic ground truth.

4.4 Outcome Classification and Reporting

The result of the assessment is classified according to the information-compliance and quantity-consistency outcomes. Four principal situations may occur:

1. *Information-compliant and quantity-consistent:* the required information is available and the stored quantity agrees with the independently derived value within the defined comparison basis and, where applicable, tolerance.
2. *Information-compliant and quantity-discrepant:* the required information is available, but the stored and independently derived quantities differ beyond the accepted comparison condition.
3. *Information-non-compliant but quantity-comparison-assessable:* one or more broader IDS requirements are not satisfied, while the information required for the selected geometric quantity comparison remains available.
4. *Quantity-comparison-non-assessable:* an equivalent comparison cannot be established because essential quantity, unit, geometry, or measurement-basis information is missing, unsupported, or incompatible.

The reporting structure should therefore maintain separate fields for information-compliance status, quantity-comparison assessability, stored quantity, independently derived comparison value, numerical discrepancy, applied assumptions, tolerance where applicable, and the need for human review. This separation is important because it prevents IDS compliance from being interpreted as proof of quantity consistency and prevents the failure of an unrelated information requirement from automatically stopping a geometrically valid comparison. The proposed workflow does not prescribe a specific geometry-processing engine, support every IFC wall representation, establish universal tolerance thresholds, modify IFC files, or automatically determine which quantity value is correct. Its purpose is instead to provide a traceable conceptual structure for coordinating information-compliance checking with independent quantity-consistency assessment.

5 Discussion

The reviewed literature indicates that IFC-based QTO, BIM-QTO reliability research, and IDS-supported information checking address related but distinct verification problems. As summarised in Table 2, IFC-based studies demonstrate that vendor-neutral model information can support quantity extraction, calculation, interoperability, and linkage with cost-estimation workflows [3–6]. However, their comparison bases differ, including formal measurement rules, commercial-software outputs, and alternative model representations. Therefore, successful extraction or agreement within a particular workflow should be interpreted as evidence of feasibility or consistency under a defined comparison basis, rather than as independent proof of quantity accuracy.

The reliability studies further show that BIM-derived quantities are influenced by modelling representation, object composition, parameter completeness, software workflows, and measurement assumptions [1, 2, 7]. Although these studies use different comparators, their findings are complementary in showing that quantity results depend on both model content and the rules used to interpret that content. Quantity assessment should therefore explicitly define what is being compared, how the quantity has been produced, and which measurement basis or comparator is being applied.

IDS contributes primarily to information compliance by formalising and machine-checking predefined requirements concerning model entities, classifications, properties, materials, quantities, and related information [8–10]. This provides an important control layer before QTO, but IDS does not independently reconstruct geometry or determine whether a stored quantity is numerically consistent with the corresponding geometric representation. Information compliance and quantity consistency should therefore be coordinated as separate verification dimensions.

The proposed workflow addresses this distinction by separating task-essential information, broader cost-estimation readiness, geometric assessability, quantity discrepancy, and professional interpretation. This separation represents the main conceptual contribution of the study. Rather than treating model quality as a single pass-or-fail condition, the framework allows an element to be information-compliant but quantity-discrepant, information-non-compliant yet still assessable, or non-assessable when an equivalent measurement basis cannot be established.

The non-assessable category is particularly important. A numerical difference should not automatically be classified as an error when the stored and independently derived quantities are based on different assumptions. Differences may arise from the treatment of openings, intersections, layers, boundaries, gross or net definitions, or software-export behaviour. In such cases, withholding a consistency judgement may be more appropriate than forcing a binary result.

The framework is intended to support, rather than replace, professional judgement. It does not automatically identify which quantity is correct, modify IFC files, or guarantee the accuracy of a downstream cost estimate. Instead, it structures the available evidence so that discrepancies and non-assessable cases can be traced to specific elements, assumptions, and comparison conditions.

The findings should be interpreted within the limits of the review, which is based on nine peer-reviewed studies, a single-author screening process, and heterogeneous study designs. In addition, the proposed workflow remains conceptual and has not yet been empirically validated. Future research should therefore implement the approach using real IFC wall models, explicit quantity-specific measurement rules, and alternative modelling and export conditions, and evaluate whether the resulting reports improve traceability and decision support for BIM-based QTO.

6 Conclusion

This focused review examined how IFC-based quantity take-off, BIM-QTO reliability research, and IDS-supported information checking can be coordinated for wall quantity assessment. The evidence indicates that IFC enables interoperable extraction and processing of quantity information, while quantity outcomes remain sensitive to modelling representation, information completeness, software workflows, and measurement definitions. IDS can formalise and verify information requirements, but such compliance does not independently demonstrate that a stored IFC quantity is geometrically consistent.

The principal contribution of the study is a conceptual verification workflow that treats information compliance, geometric assessability, and quantity consistency as related but separate dimensions. The framework distinguishes information-compliant and quantity-consistent cases, information-compliant but discrepant cases, information-non-compliant yet assessable cases, and cases in which an equivalent geometric comparison cannot be established. This structure avoids treating either IDS compliance or an independently derived geometric value as automatic proof of quantity correctness.

The workflow remains conceptual and requires empirical implementation. Future work should test it using real IFC wall models, explicitly defined measurement rules, alternative modelling and export conditions, and element-level discrepancy reports. Such testing will determine whether the proposed reporting structure improves traceability and supports professional decisions concerning the suitability of BIM-derived quantities for cost-estimation use.

Identifying Key Business Survey Indicators to Predict Construction Production and Cost Indices

Serkan Aydınlı[1]
[1] https://orcid.org/0000-0002-2897-4144, Çukurova University, Civil Engineering Department, Adana, Türkiye, saydinli@cu.edu.tr

Abstract. The construction sector is characterized by long project durations, which necessitates the precise forecasting of changes in sectoral parameters. Business surveys, such as sector confidence indicators and sentiment surveys, are widely monitored as leading indicators for the sector. However, determining which surveys accurately predict future actual construction indicators presents a complex analytical challenge. Construction-related production and cost indexes are frequently delayed indicators, published a month subsequent to actual occurrences. Conversely, business surveys serve as high-frequency, leading indicators. Establishing a mathematically valid causal relationship between them enables policymakers, investors, and contractors to anticipate macroeconomic fluctuations and pricing shocks months in advance. The primary goal of this study is to determine the causal relationships between business/consumer surveys and critical construction sector indicators (production and cost indexes). To achieve these objectives, this research utilizes PCMCI (Peter-Clark and Momentary Conditional Independence) algorithm. This study demonstrates genuine causal relationships—from the business surveys to production and cost indexes in the construction industry—through the application of the PCMCI framework. The results will yield data-driven early warning signals, allowing sector stakeholders, investors, and regulators to precisely anticipate developments in the construction industry based on the most statistically robust survey indicators.

Keywords: Construction industry; business surveys; production in construction; construction costs.

1 Introduction

The construction industry has substantial significance for the global economy. Global research indicates that the sector represents a significant portion of Gross Domestic Product (GDP). An analysis of European Union statistics reveals that the construction sector's gross value added is approximately 5.5 percent [1]. The high level of added value naturally places the sector among those that countries consider to be of great importance. An additional reason for the sector's significance arises from its connections with other sectors [2], [3]. For example, a building construction project promotes the construction material industry. Upon the sale of the finished residences, industries including furnishings, household appliances, and finance have heightened activity. This connection is also reflected in employment. This industry is inherently labor-intensive. Labor constitutes a fundamental element of project resources. According to Eurostat data, approximately 8.6% of total employment is directly in the construction sector [4].

Another consideration that requires monitoring of the construction-related business is the magnitude of expenses within the sector. Business operations in this sector necessitate a robust capital framework and consistent liquidity over time. Unexpected fluctuations in material and energy prices have a direct impact on project costs [5]. Therefore, analyzing and forecasting the prices of inputs of construction activities is crucial for achieving the project's financial

objectives. Since construction projects are normally long-term, it is important to monitor not only the costs, but also the risks of domestic and global crises. The construction industry is very sensitive to crises (e.g. COVID-19 pandemic or the war of Ukraine and Russia). These crises decrease the predictability of the sector [6]. This induces a decrease of the production [7].

The dynamic industry structure of today's world requires data-driven decisions and not intuitive ones. By monitoring the production and costs at the macro level with the help of various indicators, decision-makers and policymakers can formulate data-driven strategies and reduce risks, while efficiently planning long-term investment decisions. The paper analyses the relation between sectoral indices (cost and production indices) and construction business surveys. The rest of the paper is organized as follows. In section "2. Importance of Business Surveys", the importance of business surveys specific to each industry, produced and disseminated by statistical agencies, is discussed. The variables and the analytical approach are discussed in the "3. Methodology" section. In "4. Findings & Discussion", the results are presented and discussed in relation to existing literature. Finally, the findings are summarized in section "5. Conclusion".

2 Importance of Business Surveys

Qualitative business surveys have been regarded as significant resources for sectoral and economic assessment, policy development, and macroeconomic forecasting [8], [9]. One of the most significant advantages of business surveys is that they are published earlier than other sectoral indicators [10]. On the other hand, the results of business surveys are generally published shortly after the end of the relevant period [11]. Thus, business surveys serve as early indicators for decision-makers.

A further characteristic that enhances the significance of business surveys is their direct representation of the observations and insights of industry experts. The surveys offer a comprehensive insight into various fields from diverse viewpoints such as current situation and expectations via industry experts [8]. For example, while the "Construction Confidence Index" and "Evolution of the Current Overall Order Books" are indicators that provide an analysis of the current situation, "Employment Expectations over the next 3 months," "Building Activity Development over the past 3 months," and "Price Expectations over the next 3 months" are indicators that reflect future expectations. In contrast to macroeconomic measures, these indicators enable us to monitor qualitative aspects related to the sector.

Business surveys provide substantial insights to the literature, especially within the realm of econometrics. Survey indicators perform particularly effectively in forecasting short-term GDP growth and industrial production [12-13]. The studies show that the "production expectations for the next three months" of enterprises are the most effective leading indicator for forecasting GDP growth [14]. In addition, consumer and confidence indices also stand out as key variables in GDP forecasts [15]. The studies also show that order book levels, export orders, finished goods inventories, and employment expectations are frequently used in econometric forecasts ([13], [16]).

Business surveys are also employed in inflation forecasting models. A study performed in Germany indicates that the "IFO Price Expectations" indicator is a crucial factor in predicting both producer and consumer inflation (CPI) [17]. Furthermore, the literature has found that price-based surveys alone are not sufficient to explain CPI inflation; survey questions regarding capacity constraints, real economic activity, and the labor market also have a very strong additional explanatory power for CPI inflation. It is believed that inquiries concerning the evaluation of the prevailing economic conditions are factors that substantially improve the accuracy of CPI estimates [12].

The literature confirms that business surveys make significant contributions to forecasting models. Nonetheless, the relationship between business surveys and industry-specific indicators

in the construction sector remains untested. This study aims to identify potential variables for forecasting models by examining the relationships between the construction sector business surveys—which are published by statistical offices—and, in particular, production and cost indices.

3 Methodology

3.1 Data

Data employed in this paper has been obtained from the official database of the European Union's statistical office (EUROSTAT) [18]. The statistical agencies of European Union nations perform several business surveys on a monthly basis and submit the findings to Eurostat. Eurostat, thereafter, publishes the data following the verification process. The key business surveys and sectoral indicators examined in this study are presented in Table 1.

Table 1. Construction Sector Business Surveys and Industrial Indicators

Variables	**Reference**
Construction Confidence Index (CONF)	[19]
Evolution of the Current Overall Order Books (Construction) (ECOOB)	
Employment Expectations over the next 3 months (Construction) (EE)	
Building Activity Development over the past 3 months (BAD)	
Price Expectations over the next 3 months (Construction) (PE)	
Factors Limiting Building Activity – None (FLBA-N)	
Factors Limiting Building Activity – Insufficient Demand (FLBA-ID)	
Factors Limiting Building Activity – Weather Conditions (FLBA-WC)	
Factors Limiting Building Activity – Shortage of Labour (FLBA-SOL)	
Factors Limiting Building Activity – Shortage of Material and/or Equipment (FLBA-SOM)	
Factors Limiting Building Activity – Other (FLBA-O)	
Construction Cost Index (CCI)	[20]
Production in Construction (PiC)	[21]

Business surveys are fundamentally structured as balance-type questionnaires. In balance-type surveys, participants can respond to the questions in three ways: increased/positive, unchanged/stable, and decreased/negative [22]. Surveys measure current conditions and future expectations. FLBA-N signifies the absence of impediments to construction efforts, whereas FLBA-O denotes the presence of additional difficulties beyond those indicated. Survey statistics are derived by computing a difference between the proportion of positive responses, and the proportion of negative responses [22]. The investigation covered countries that have fully reported all variables from 2000 to 2026; in this regard, Austria, Finland, and the Netherlands were included as part of the study.

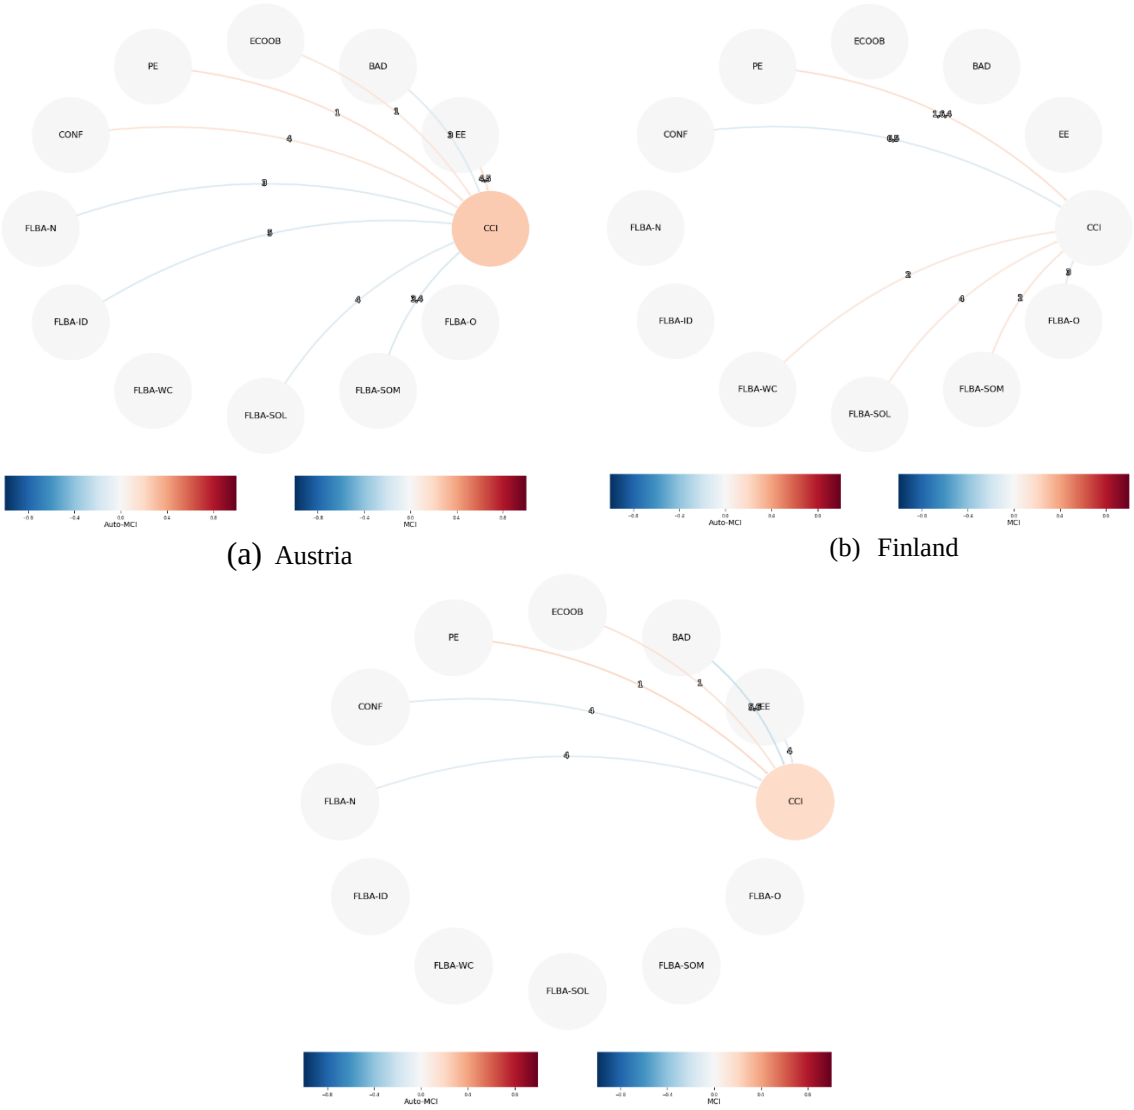
3.2 Peter-Clark and Momentary Conditional Independence (PCMCI)Algorithm

The PCMCI algorithm [23] is a causal inference method designed to detect underlying causal relationships and lagged interactions in multivariate time series [24]. In contrast to econometric causality models, the algorithm is highly effective at controlling for autocorrelations and potential confusing correlations in multidimensional time-series data [25].

The algorithm consists of two stages: PC and MCI. In the PC phase, potential variables are identified from the time series. At this stage, an independence test is conducted for each variable up to the designated lag value [24]. The MCI (Momentary Conditional Independence) phase performs more focused tests using the set of candidate parent-child pairs obtained from the PC phase. The primary goal here is to eliminate all remaining false relationships [26].

In this study, the approach was used to explore the causal relationships between all job surveys and the CCI and PiC variables. Prior to identifying causal relationships between the variables, all variables were standardized utilizing Z-scores. Subsequently, the relationships up to a 6-month lag in the surveys were examined.

4 Findings & Discussion



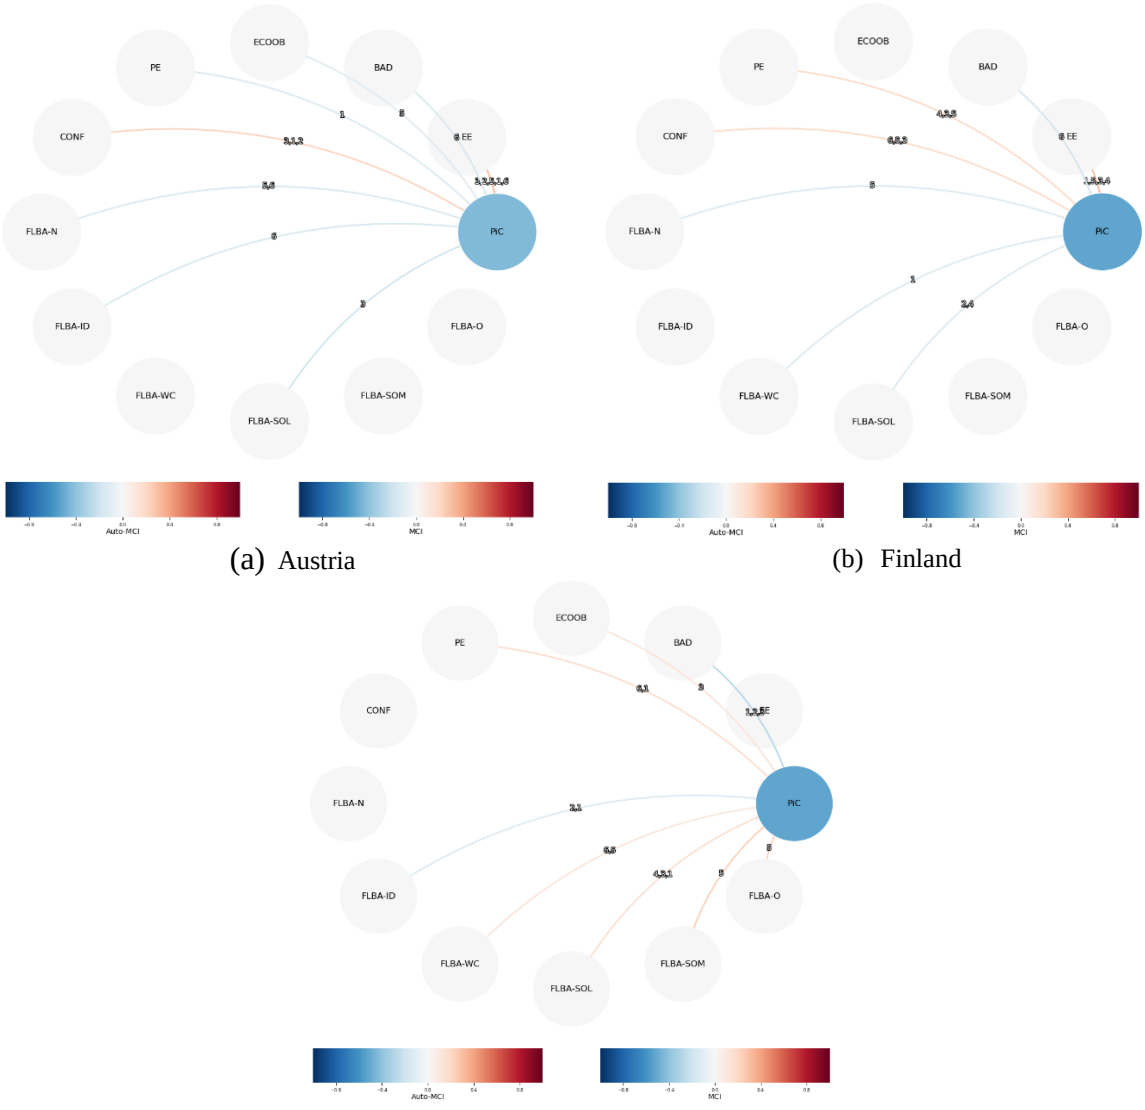
The measures of central tendency for the variables analyzed in this study are presented in Table 2.

Table 2. Mean and Std. Deviations of Variables

Variables	Austria		Finland		Netherlands	
	Mean	Std. Dev.	Mean	Std. Dev.	Mean	Std. Dev.
CONF	-8.93	18.35	-10.42	19.47	1.03	20.71
ECOOB	-14.72	19.70	-16.75	19.73	-2.87	22.94
EE	-3.13	25.50	-4.09	25.42	4.92	19.25
BAD	3.90	24.90	1.54	21.73	1.82	17.65
PE	6.34	21.02	-3.68	26.84	25.61	25.18
FLBA-N	48.78	15.44	33.74	12.34	62.06	12.29
FLBA-ID	16.25	9.23	39.04	18.64	15.60	12.81
FLBA-WC	11.64	13.78	3.98	5.02	5.51	8.11
FLBA-SOL	15.40	12.38	23.30	14.43	9.33	9.86
FLBA-SOM	3.17	7.34	4.97	5.40	4.42	7.53
FLBA-O	2.69	5.18	7.19	5.85	9.07	7.26
CCI (%)	0.26	0.63	0.18	0.37	0.23	0.48
PiC	2.92	19.64	1.78	15.80	6.40	42.43

According to comparing the cost and production indices of countries, Austria exhibits the highest volatility in costs, whereas the Netherlands has the greatest volatility in its production index. Surveys generally show a pessimistic outlook concerning order books. For the CONF, EE, BAD, and PE variables, it is noted that perspectives fluctuate over time; thus, the survey means tend to be low, followed by larger standard deviations. It is also evident that participants in all three countries generally stated that there were no factors limiting construction activity.

The analysis results show that many business surveys explain the change in the CCI (Fig. 1). The results show that, despite not being strong, there is a statistically significant causal relationship between survey data and the CCI in each country. In Austria, the EE and PE surveys were identified as exerting the most influence on the CCI (Fig. 1(a)). The effect coefficients of EE (lag 4) and PE (lag 1) on the CCI were determined to be 0.192 (p-value: 0.001) and 0.169 (p-value: 0.004) respectively. In Finland, similarly, the PE (lag 1) variable stands out as the variable with the highest explanatory power for the CCI, with a MCI coefficient of 0.171 (p-value: 0.003) (Fig. 1(b)). In the case of the Netherlands, the BAD (lag 6) and PE (lag 1) variables are the most significant variables, with MCI coefficients of -0.222 (p-value: 0.000) and 0.213 (p-value: 0.000), respectively (Fig. 1(c)). The results show that there is a significant causal relationship between the price expectation survey and cost index in all three countries. The notable relationship between a price expectations and the cost index suggests that the prior period's price expectations survey has the potential to be regarded as a predictive indicator. In addition, it has been found that the employment survey in Austria and the construction activity survey in the Netherlands show causal relationships with cost index. The findings indicate, in particular, that the PE variable has the potential to contribute to CCI forecasts.



(a) Austria (b) Finland

(c) Netherlands

Fig. 1. PCMCI Results on CCI

In the second phase of the study, the causal relationships between the survey data and the construction production index were explored. The causal relationships between the business surveys and PiC are shown in Fig. 2. The findings indicate that the surveys show much stronger relationship with PiC. In Austria, the strongest causal relationships with PiC are EE (lag 3) and EE (lag 2) (Fig. 2(a)). The MCI coefficients for these two variables with respect to PiC are 0.313 (p-value: 0.000) and 0.300 (p-value: 0.000), respectively. On the other hand, there is a relatively weaker but still significant causal relationship between CONF (lag 3) and PiC (MCI: 0.222, p-value: 0.000). The data from Finland also confirms that there is a strong causal relationship between the EE (lag 1) variable and PiC with MCI: 0.309 (p-value: 0.000) (Fig. 2(b)). The findings indicate that the most appropriate business survey indicator for identifying changes in production in the construction sector in Austria and Finland is employment expectations. However, the findings have not been confirmed in the Netherlands. Unlike in other countries, the variables BAD (lag 1, 2 and 3) stand out as having a significant and strong causal relationship with the PiC variable. Interestingly, while a negative MCI coefficient (-0.283, p-value: 0.000) was observed between BAD (lag 1) and PiC, positive causal relationships were identified between BAD (lag 2 and 3) and PiC, with coefficients of 0.195 and 0.187, respectively (p-value: 0.001). It is believed that this situation indicates that, particularly with

the development of new projects, a decline in production was observed in the short term as a result of the shift in the workforce, but that the decline recovered in later periods and production increased. Finally, a moderate causal relationship was found in the Netherlands between the FLBA-SOM (lag 5) variable and PiC (MCI: 0.239, p-value: 0.000). This shows that the increase in production was reflected in a rise in demand for machinery and materials.

(c) Netherlands

Fig. 22. PCMCI Results on PiC

5 Conclusion

This study was conducted to investigate the potential of business survey time-series data in construction project management. The study identified causal relationships between the construction cost and production indices and the construction business surveys published monthly by statistical offices. The time-series data were obtained from the Eurostat database. Causal relationships between the lagged values of each survey and the sector indices were identified using the PCMCI algorithm. The results indicate that there exist notable relationships among the variables, even in the absence of strong connections. The EE and PE variables have a causal relationship with the CCI. In one of the three countries, it was found that the BAD variable also has a causal relationship with the CCI. Analysis of the causal relationships

between the surveys and production revealed that the EE and BAD variables have a significant causal relationship with PiC.

The research findings provide important insights for future CCI and PiC forecasting studies. The integration of the specified variables into forecasting models possesses the ability to aid in model advancement. However, validation of the results across different economies would strengthen the findings.

Artificial Intelligence Adoption in Construction Management: A Bibliometric Analysis of Emerging Trends, Opportunities, and Future Directions

Özge ALBOĞA*
0000-0002-2848-8373, Independent Scholar, Adana, Türkiye
*albogaozge@gmail.com

Abstract. In recent years, the acceleration of digital transformation has led to a notable increase in academic research on the application of artificial intelligence (AI) technologies in construction management. Machine learning, deep learning, and AI-enabled decision making systems, in particular, have been increasingly applied in many construction management applications, such as project management, risk management, process optimization, and resource planning. This study aims to investigate research trends, development patterns, and future directions for the integration of artificial intelligence in construction management through bibliometric analysis. A total of 249 academic publications published between 2020 and 2026 and indexed in the Web of Science Core Collection were examined. VOSviewer software was used for bibliometric mapping and visualization. The analyses included keyword co-occurrence analysis, overlay visualization, and density analysis. The results show that artificial intelligence has emerged as a central research focus in the construction management literature. Recent studies have expanded from earlier research concentrating on machine learning-based risk prediction and safety management applications toward AI-supported construction project management, integrated decision-support systems, and intelligent project management approaches. A significant increase in publication volume has been observed since 2024. The findings are expected to contribute to understanding the current state of research on artificial intelligence adoption in construction management and to provide guidance for future studies.

Keywords: Artificial intelligence, construction management, bibliometric analysis, project management, VOSviewer.

1 Introduction

Construction projects are, by their very nature, socio-technical production systems in which numerous stakeholders work simultaneously and where site conditions, the supply chain, contractual relationships, and project objectives constantly interact. Project data is generated from various sources, including BIM models, work schedules, cost records, contracts, progress reports, images, sensors, and enterprise information databases [1]–[3]. In addition to increasing the amount of data, this diversity calls for the fast, accurate, and context-sensitive interpretation of data in a variety of formats and levels of detail in order to support choices about cost, schedule, safety, quality, and resource management. The sector's project-based, multi-stakeholder structure and low digitalization level further complicate translating this data into timely decisions. However, today’s advancing Artificial Intelligence (AI) technologies offer

capabilities such as classification, prediction, optimization, natural language processing, and computer vision that can support this decision-making burden [3]–[5].

Therefore, the maturation of the field depends not only on model accuracy but also on the integration of these components within project workflows. Previous studies have shown that AI has expanded through methods such as genetic algorithms, neural networks, machine learning (ML), natural language processing, and computer vision; the primary application contexts are project planning, optimization, progress tracking, and risk management [4]–[6]. Pan and Zhang [3] categorized the roles of AI in civil engineering and management in terms of data generation, knowledge extraction and decision-making/action processes. Taboada et al. [7] studied automation and decision support in project management and, as shown by Datta et al. [2] the application of AI/ML is mostly on planning and construction phases within the whole project life cycle. Recent reviews also indicate that cost, schedule, and safety management form a common, data-intensive, and interdependent axis of project management [8]. On the other hand, Aladağ et al. [9] used a scope-definition method to classify AI's contribution to construction project management processes in terms of planning, scheduling, cost estimation, and quality control; Savaş [10], expanded these findings to include organizational, cultural, and strategic dimensions, emphasizing that factors such as resistance to change and skill gaps can often take precedence over technical performance.

Technical model success, however, does not automatically lead to organizational adoption. Implementing AI in construction requires simultaneously managing technological suitability, data quality, business-process alignment, cost, competence, trust, and regulatory responsibilities. Watfa et al. [11] associated the adoption of automation with the on-site feasibility and low-cost proof-of-concept demonstrations, whereas Igwe et al. [12] reported that digital instruments are adopted unevenly in the area of cost management. Wider reviews find that barriers like data access, interoperability, upfront costs, skills gap, explainability, privacy and resistance to change slow down the scalability [13], [14]. The emergence of generative AI and Large Language Models (LLMs) offers opportunities in education, information access and contextual decision support, but has also brought issues such as accuracy, source reliability, hallucination and accountability into sharper focus [15]–[19].

Previous bibliometric studies have focused mostly on machine learning methods or AI-Building Information Modeling (BIM) integration [1], [4], [6]. In contrast, during the 2024–2026 period, there are only a limited number of studies that directly address the rapidly growing literature on generative AI, LLMs, explainable AI, and decision support within the context of construction management by updating it with record-level compliance checks and normalized author keywords. This study offers three complementary contributions: quantitatively determining the current publication momentum, analyzing the field's conceptual structure through eight thematic clusters and the relationships between them, and synthesizing the findings in terms of applicability and the requirements for responsible use. The study focuses on three research questions: (RQ1) How has publication output changed during the 2020–2026 period? (RQ2) Around which core concepts and thematic clusters are author keywords organized? (RQ3) What do temporal trends reveal about the opportunities, limitations, and future research agenda of AI in construction management?

2 Materials and Methods

The study is based on a three-phase design consisting of bibliometric performance analysis, keyword-based science mapping, and contextual thematic interpretation. As part of the performance analysis, changes in the number of publications over the years were examined; the

relationships between keywords and the resulting clusters were evaluated through science mapping. In the contextual thematic interpretation phase, the identified patterns were discussed within the framework of construction management functions, debates regarding the adoption of artificial intelligence, and potential future research directions. This approach allows bibliometric findings to be evaluated not only through numerical distributions but also within the scope of the relevant literature.

2.1. Data source, search, and selection

The data were obtained in August 2026 from the Web of Science Core Collection database, within the scope of accessible indexes. The search query used in the "Topic" field is as follows: ("artificial intelligence" OR "AI" OR "machine learning") AND ("construction management" OR "construction project management"). The search results were limited to studies published between 2020 and 2026, with the document types "Article" and "Review Article," and published in English. The Web of Science was selected because it presents bibliographic records in a standardized format and allows author keywords and citation information to be imported into the VOSviewer software. The initial search yielded 299 records. Since the presence of search terms in the title, abstract, or keywords does not necessarily mean that each record is directly relevant to the scope of the study, the titles and abstracts of the studies were also reviewed. Studies were included if AI/ML served as a method or decision-support tool for cost, time, risk, safety, quality, contracts, planning, training, or asset management.

Conversely, 48 studies were excluded from the scope because the terms "construction" or "management" appeared only in a limited or indirect manner; these studies focused primarily on materials science, medicine, urban planning, or cultural heritage and did not establish a sufficient connection to construction management. Additionally, two retracted publications were not included in the analysis set. The review revealed no duplicate Web of Science entries, and the final analysis set consisted of 249 publications. Since data for 2026 included only publications indexed in Web of Science through August 2026, the number of publications for that year was evaluated with caution when compared directly to complete years.

2.2. Bibliometric analysis

Bibliometric analysis enables the examination of development and relationship patterns within large sets of publications through performance indicators and science mapping [20], [21]. VOSviewer is one of the tools widely used in the literature for bibliometric analysis [22]. Therefore, VOSviewer 1.6.20 was used in this study as well. Author keywords were selected as the unit of analysis because they directly reflect the conceptual focus highlighted by the authors of the studies. In the full count, the presence of a keyword in each record is weighted equally. Node size represents the number of occurrences (Occurrence-O); a link indicates the co-occurrence of two terms in the same record; and Total Link Strength (TLS) represents the sum of all co-occurrence links for a term in the network. In the "Overlay" view, colors represent the occurrence-weighted average publication year, while in the "Density" view, they represent local neighborhood density weighted by term weight [21], [23].

The author keyword is present in 239 of the 249 records. The 843 unique terms in the raw data were normalized using a canonical thesaurus file to prevent plural/singular forms, abbreviations, and spelling variants from fragmenting the network. This involved (i) merging spelling/abbreviation variants (e.g., AI, ML, BIM, LLM), (ii) standardizing singular/plural forms, and (iii) removing generic methodological terms (e.g., "systematic literature review"). The minimum occurrence threshold was set at three, and all 50 terms meeting this threshold were included in the analysis. The software's default settings were retained for clustering and

visualization. Cluster names were not automatically assigned by VOSviewer; instead, they were carefully assigned by the researchers based on term composition and reported in Table 1 along with representative terms.

3 Results and Discussion

3.1. The Chronological Development of Publications

The annual distribution of the final 249 publications is as follows: 11 in 2020, 16 in 2021, 25 in 2022, 17 in 2023, 37 in 2024, 62 in 2025, and 81 in 2026 (Fig. 1). Following a temporary decline in 2023, a marked acceleration occurred during the 2024–2026 period. These three years' account for 72.3% of total publications, while 2025–2026 alone accounts for 57.4%. When comparing full years, the number of publications in 2025 is 5.64 times that of 2020. Although the 2026 data covers only records indexed through August 5, it has already surpassed the 2025 level. However, due to the partial year, indexing delays, and the query's sensitivity to specific terms, this value should be interpreted not as a growth estimate but as a descriptive indicator of the field's current research intensity.

This acceleration is consistent with the association of AI with project management, BIM-based digital ecosystems, text analytics, and generative AI applications, beyond individual prediction problems [1], [17], [24], [25]. The broadening of the research focus brings to the forefront the combined use of images, text, and structured data within the same project problem, as well as the integration of prediction outputs into workflows such as decision support and automated reporting [19], [26], [27].

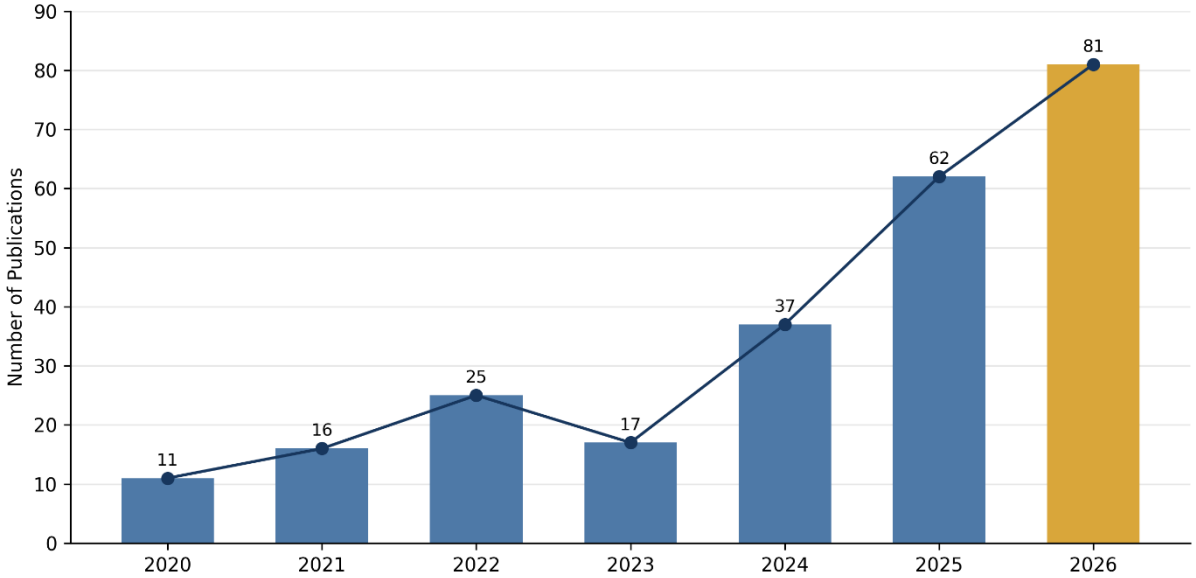

Fig. 1. Number of publications by year in the final sample

3.2. The Core of the Keyword Network and Thematic Clusters

Visualizations of the network based on author keywords, temporal overlap, and density are presented in Figure 2. In Figure 2a, "construction management" (O=85; TLS=157) is the largest node; "artificial intelligence" (O=75; TLS=153) and "machine learning" (O=68; TLS=111) follow. Building information modeling (O=24; TLS=53), deep learning (O=22; TLS=49), construction project management (O=21; TLS=30), and project management (O=16; TLS=42) are other prominent terms. The strongest relationships were found between construction management and machine learning (29), artificial intelligence and construction management

(26), artificial intelligence and building information modeling (14), and artificial intelligence and machine learning (11).

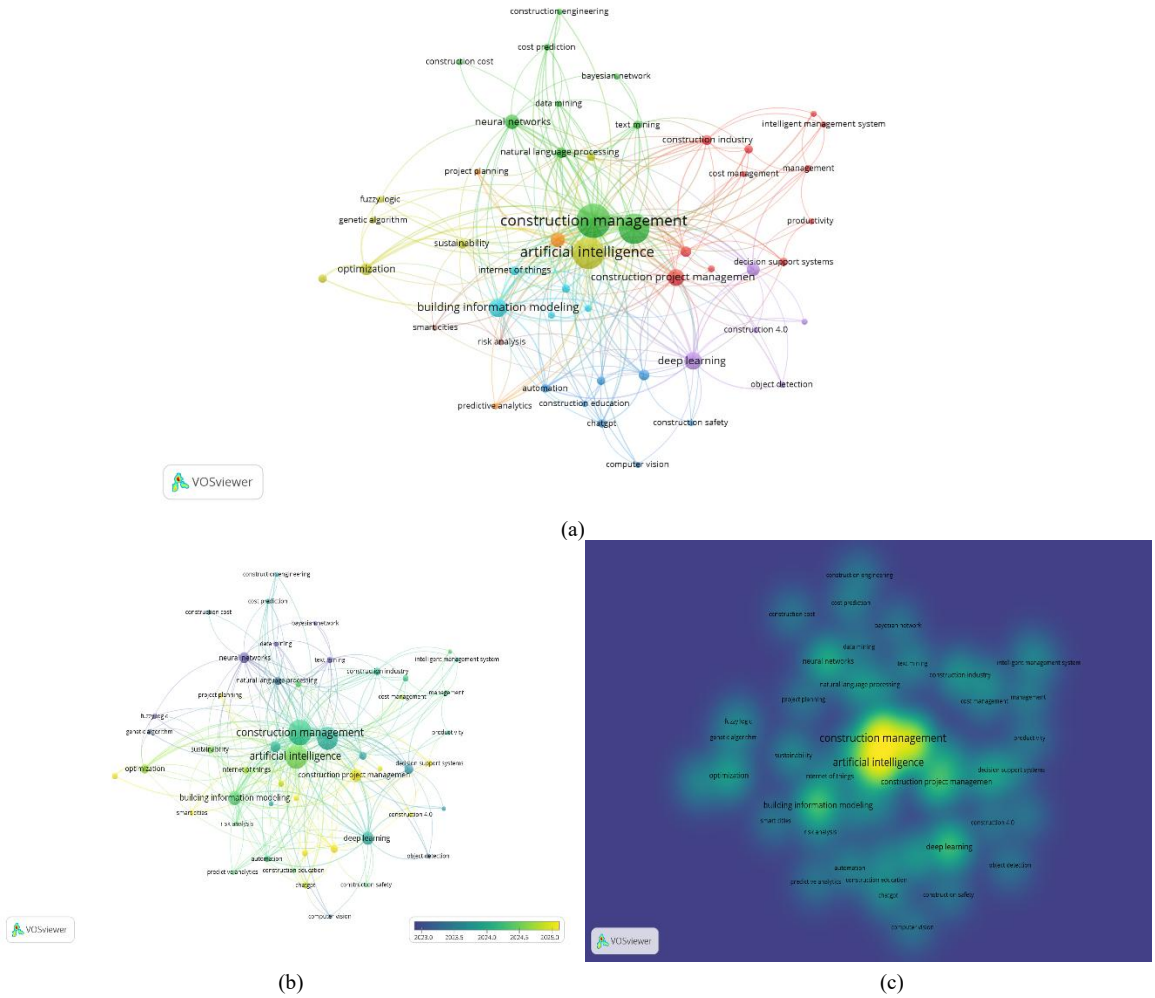

Fig. 2. Visualizations of author keywords showing (a) network, (b) temporal overlap, and (c) density

Tablo 1. Thematic Summary of VOSviewer Keyword Clusters

Cluster	Proposed theme	n	Representative terms (O; TLS)
1	Project management and decision support	11	construction project management (21; 30); risk management (9; 23); decision support systems (5; 9)
2	Machine learning and text/data analytics	10	construction management (85; 157); machine learning (68; 111); neural networks (15; 36)
3	Generative AI, automation, education, and safety	7	large language models (9; 19); automation (5; 21); ChatGPT (5; 15)
4	AI-supported optimization and sustainability	7	artificial intelligence (75; 153); optimization (11; 23); sustainability (6; 21)
5	Deep learning and visual/technical prediction	5	deep learning (22; 49); construction (12; 25); object detection (3; 7)
6	BIM-integrated connected and smart construction	5	building information modeling (24; 53); internet of things (6; 20); smart construction (5; 18)
7	Project planning and predictive analytics	3	project management (16; 42); predictive analytics (3; 8); project planning (3; 6)
8	Risk analysis in the smart city context	2	risk analysis (3; 14); smart cities (3; 8)

Note: O = occurrences; TLS = total link strength.

The keyword network presented in Figure 2a, when evaluated in conjunction with Table 1, shows that the eight-cluster solution space does not consist of a single technical axis. Cluster K2 forms the methodological core by combining machine learning with text/data analytics in construction management, while Cluster K4 forms the performance and objective functions layer through the integration of AI, optimization, and sustainability. In Figure 2a, the closeness of these two clusters to the center of the network, and their dense interconnection, indicates that methodological and managerial themes are not developing independently of each other. Prediction and information extraction are often related to the optimization of resources, time, cost, or environmental performance, as can be seen by the fact that the total inter-cluster connection strength between these two clusters is 69, the largest value in the network. The co-occurrence of construction project management, risk management, cost management and decision support systems in K1 indicates that AI has shifted from a technical model to managerial decision support [3], [7], [28]. The combination of project management, predictive analytics and project planning in K7 represents a more limited but management-oriented subfield, where foresight is brought into the planning and control cycle.

Terms such as deep learning, object detection and cost estimation in K5 are indicative of technical applications based on automatic feature extraction from images and high-dimensional data. As shown in Figure 2a, the fact that K5 operates within a more limited but distinct subnetwork in the deep learning environment suggests that these applications, while connected to the main network, are more specialized. This approach has shown promise for applications such as site monitoring, quality defect detection and cost estimation, but it is sensitive to issues like data volume, class imbalance and explainability [5], [29], [30]. The convergence of BIM, Internet of Things (IoT), smart construction, digital transformation and digital twins in K6, in contrast, is indicative of the interconnected data infrastructure that powers these models [1], [24]. The connections between K5 and K6 on the network map indicate that sensing and prediction methods are considered in conjunction with technologies that provide digital representation and data flow.

In K3, LLMs, ChatGPT, generative AI, automation, construction training, and safety are grouped under the same theme. The fact that the terms “large language models,” “ChatGPT,” and “generative artificial intelligence” appear in more contemporary color tones in Figure 2b indicates that this cluster represents one of the trends that gained prominence in the final years of the period under review. The occurrence-weighted average year for the cluster is 2024.79, making K3 one of the network’s most recent trends [16], [17]. Empirical studies show that progress is not merely conceptual but is highly dependent on the task and dataset. Lee et al. [15] found that RAG and fine-tuned models provided improvements of 21.5% and 26%, respectively, over the general-purpose GPT-4 in accessing construction safety information; Zhou et al. [27] reported that a multimodal knowledge graph incorporating domain-specific knowledge increased the accuracy of general-purpose LLMs in project management question-answering by an average of 30%. Xiao et al. [30] validated the use of ChatGPT with computer vision for the automatic generation of daily reports at a real construction site over the course of one month. Ray et al. [31], Smetana et al. [32] and Al Omari et al. [33] reported similarly high performance in extracting and classifying accident-narrative text at scale. These findings support the potential of LLMs for information retrieval, reporting, and safety analytics, but also indicate that performance depends on domain knowledge, verified sources, task design, and human supervision. The fact that K8 appears in Figure 2a as a small, peripheral cluster consisting of only two terms suggests that risk analysis within the framework of smart cities is underrepresented in the dataset under examination. When assessed together, the field can be divided into three high-level strata. The first layer is the data/representation infrastructure, such

as BIM, IoT, digital twins, images, and text. The second layer generates predictions, classifications, and options through machine learning, deep learning, natural language processing, and optimization.

These results provide evidence of the potential of LLMs in information retrieval, reporting and safety analytics, but also show that performance is dependent on domain knowledge, verified sources, task design and human supervision. The fact that K8 appears in Figure 2a as a small, peripheral cluster with only two terms suggests that risk analysis in the setting of smart cities is underrepresented in the dataset under examination. When assessed together, the field can be divided into three high-level strata. The first layer is the data/representation infrastructure, such as BIM, IoT, digital twins, images and text. The second layer generates predictions, classifications and options through machine learning, deep learning, natural language processing and optimization. The third layer bridges analytical results with human decision-making and organizational workflows using project management, decision support systems, explainable AI, and LLM interfaces. Concepts associated with the top-two layers are more prevalent in the literature, as demonstrated by the unique core around "construction management," "artificial intelligence," and "machine learning" in the density visualization of Figure 2c. The link between data infrastructure, technical analysis, and management tasks is instead reflected by the secondary density clusters around "BIM," "deep learning," and "construction project management." The presence of "generative AI," "explainable AI," and "decision support" in the more recent color tones of Figure 2b also suggests that research on the third layer has been more prevalent in recent years.

3.3. Temporal orientation, intensity, and research agenda

Theoretically, the findings indicate that AI research in construction management has expanded from an algorithm-centered approach toward a system- and human-centered integration. From a managerial perspective, the findings indicate that AI investments should be managed as a phased implementation portfolio rather than a single-step transformation beginning with technology procurement. This should proceed in phases: evaluating data ownership and quality; selecting bounded use cases with clear success metrics (e.g., cost estimation, reporting, contract screening); and embedding human approval, explanation, and audit trails into the workflow. The decision to scale up should only be made after external validation has been achieved using project performance indicators such as accuracy, time savings, error costs, decision quality, user trust, and field safety. This approach can reduce the risk of early and uncontrolled deployment of high-visibility technologies into processes with low readiness levels [11], [13], [28].

4 Conclusion

This study examined the development, conceptual structure, and current trends of 249 Web of Science (WoS) publications on the adoption of AI in construction management during the 2020–2026 period. The fact that 72.3% of the publications were published in the last three years and that 2026 reached the highest number of publications demonstrates the rapid expansion of this research field. The keyword network generated 50 terms, 8 clusters, 265 connections, and 550 TLS; "construction management," "artificial intelligence," and "machine learning" formed the core of the field. The eight clusters revealed a multi-layered research structure in which AI extends from machine learning and forecasting to optimization, sustainability, BIM-IoT-digital twin integration, project planning, decision support, and generative AI. The strongest inter-cluster link—between machine learning/text analytics and AI-supported optimization/sustainability—indicates that technical methods are increasingly being linked to managerial objectives and performance metrics.

The study's key contribution lies in presenting both classical technical methods and new managerial and generative AI themes within the same contemporary framework and maintaining a clear distinction between bibliometric visibility and actual organizational adoption. Going forward, producing more models will not be sufficient; reliable data infrastructure, explainable outputs, human oversight, and measurable field impact must be addressed collectively. Success should therefore be measured not only by prediction accuracy but also by decision quality, accountability, and contribution to project performance. This approach offers a more realistic research and application framework for the transition of AI in construction management from experimental tools to reliable and institutionalized decision support. Since this study covers co-occurrence analysis based solely on articles and reviews published in English and indexed in the Web of Science Core Collection, the results are sensitive to the choice of database, language, and keywords. For future studies, it is recommended to include different databases such as Scopus and to conduct sensitivity analyses using alternative thresholds and clustering settings. Furthermore, it may be beneficial to support the bibliometric findings with surveys, case studies, and field validation research that examine the actual use of artificial intelligence at the project and organizational levels.

Abstract. The effective use of project management software capable of supporting planning, coordination, resource management, and real-time decision-making processes can support the successful execution of construction and engineering projects. However, selecting the most appropriate software remains a challenging problem because decision makers must evaluate multiple technical, operational, and organizational criteria simultaneously. This study develops an integrated multi-criteria decision-making model based on decision-making trial and evaluation laboratory (DEMATEL), TODIM (Portuguese acronym for interactive multi-criteria decision-making), and combinative distance-based assessment (CODAS) methods for project management software selection. The DEMATEL method is first applied to identify the interdependencies among evaluation criteria and determine their significance weights. Subsequently, TODIM is used to rank software alternatives by considering the behavioral tendencies and preferences of decision makers. In the final phase, the CODAS method is employed to validate and re-rank alternatives according to their distance from the negative ideal solution. The study adopts a group decision-making approach involving five academicians and five project managers. The evaluation criteria are established through the integration of literature findings and expert judgments, including emerging considerations such as artificial intelligence functionalities, automation features, and field usability performance. The findings show that functionality (K1) received the highest DEMATEL weight (0.1121), TODIM ranked MS Project first, and CODAS ranked Asana first, indicating that the final recommendation depends on the decision logic adopted.

Keywords: Project management software selection; Multi-criteria decision-making; DEMATEL; TODIM; CODAS.

1 Introduction

A project is a set of activities conducted to achieve planned objectives by delivering a unique product or service within a specified timeframe [1]. Project management is the planning, execution, monitoring, and control of a project within defined scope, time, cost, and quality constraints to achieve project objectives [2]. Activities such as cost estimation, resource planning, budget control, team management, documentation, and reporting, carried out from project design to final delivery, generate a large volume of data. As a result, manually managing project processes becomes increasingly difficult. Today, engineers and project managers extensively use project management software to facilitate project processes and improve project performance [1,3].

Project management software plays a critical role in effectively managing project scope within predefined time and budget constraints [4]. Accordingly, selecting the most appropriate software is an important process that directly contributes to project success [5,6]. However, the wide range of software products available on the market, with different functionalities and costs, makes selecting the most appropriate software a challenging task for project managers and requires the simultaneous evaluation of multiple factors [1,7]. Consequently, selecting software that satisfies the requirements of engineers, project managers, and experts becomes a multi-criteria decision-making (MCDM) problem [1]. Although various MCDM techniques have been applied to the project management software selection problem, studies addressing this problem remain limited in the existing literature [4,7].

In this study, MS Project, Primavera, and Asana were ranked using TODIM and CODAS according to ten DEMATEL-weighted criteria under a group decision-making approach.

2 Literature Review

Studies on the selection of enterprise and project management software and tools using MCDM methods have been examined in the literature. These studies can be classified into two groups: studies employing individual MCDM methods and studies adopting integrated MCDM frameworks.

Studies based on individual MCDM methods have employed techniques such as AHP, ANP, and MARCOS for software selection problems. Puska et al. [6] evaluated 4 software alternatives (MS Project, Asana, Primavera, and Basecamp) using the MARCOS method based on 6 criteria and identified Smartsheet as the best software alternative. Akbar et al. [4] applied the ANP method using 3 main criteria and 18 sub-criteria to evaluate OpenProject, Redmine, and MS Project, identifying Redmine as the most appropriate software. Kutlu et al. [5] evaluated three software alternatives (HP-PPM, MS Project, and Primavera) using the AHP method based on 4 main criteria and 17 sub-criteria. Based on expert evaluations from 3 sectors, HP-PPM was identified as the most appropriate alternative.

Studies based on integrated MCDM frameworks have combined different MCDM methods within a single decision-making framework. Ömürbek et al. [1] applied the AHP and TOPSIS methods using 4 main and 13 sub-criteria to evaluate 4 enterprise project management software alternatives, identifying Alternative A as the most suitable software. Ünal and Çetin [8] addressed CRM software selection using the Delphi technique together with the DEMATEL and TODIM methods based on 6 criteria and identified Alternative 5 as the most suitable CRM software. Karaatlı et al. [9] evaluated 23 Turkish sugar factories using the DEMATEL and Fuzzy TOPSIS methods based on 7 criteria. The criteria weights were determined by DEMATEL, and Ereğli, Ilgın, and Eskişehir were identified as the best-performing alternatives.

The existing literature indicates that software selection studies have mainly focused on traditional MCDM methods, whereas integrated decision-making frameworks and the consideration of interrelationships among criteria remain limited. Furthermore, recent technological developments and AI-related evaluation criteria have not been adequately considered. Therefore, this study proposes a hybrid framework in which the criteria are weighted using DEMATEL and the software alternatives are ranked using TODIM and CODAS. Since TODIM and CODAS are based on different decision-making principles, they were employed together to provide behavioural-based and distance-based evaluations of the software alternatives.

3 Methodology

In this section, the application procedures of the DEMATEL, TODIM, and CODAS methods employed in this study are presented with the corresponding mathematical formulation.

3.1 DEMATEL

DEMATEL is one of the MCDM methods developed to analyze and solve complex problems [9]. The method analyzes the cause-and-effect relationships among interdependent criteria and ranks them according to their relative importance [8,9]. By revealing the strength of the relationships among the criteria, DEMATEL enables the calculation of criterion weights [9]. The application steps of the DEMATEL method are presented below.

Step 1. Construction of the direct-relation matrix. In the first step, the influence of each criterion on the others is evaluated by the experts using the scale presented in Table 1. Based on the evaluations provided by the expert group, an $n \times n$ matrix is constructed for each expert. The direct-relation matrix (**A**) is then obtained from these matrices using Eq. (1), as shown in Eq. (2).

$$a_{ij} = \frac{1}{H}\sum_{k=1}^{H} x_{ij}^{ex} \quad i,\ j \in \{1, 2, 3, \ldots, n\} \tag{1}$$

in which, H denotes the number of experts participating in the study; x_{ij}^{ex} denotes the evaluation score assigned by the ex^{th} expert to represent the influence of criterion (i) on criterion (j); and a_{ij} denotes the average of the expert evaluations.

$$\mathbf{A} = \begin{bmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ a_{n1} & \cdots & a_{nn} \end{bmatrix} \tag{2}$$

where, n denotes the number of criteria. Since the influence of a criterion on itself is not evaluated, the diagonal elements of matrix **A** are equal to zero.

Table 1. The measurement scale for DEMATEL (Karaatlı et al. [9]).

Numerical Value	Description
0	No influence
1	Low influence
2	Medium influence
3	High influence
4	Very high influence

Step 2. Normalization of the direct-relation matrix. In the second step, the normalized direct-relation matrix (**M**) is obtained from matrix **A** using Eqs. (3) and (4)

$$\mathbf{M} = k \times \mathbf{A} \tag{3}$$

$$k = min\left[\frac{1}{\max\limits_{1 \le i \le n} \sum_{j=1}^{n} |a_{ij}|}, \frac{1}{\max\limits_{1 \le i \le n} \sum_{j=1}^{n} |a_{ij}|}\right] \tag{4}$$

where, k denotes the normalization factor determined based on the maximum row and column sums of the direct-relation matrix.

Step 3. Construction of the total-relation matrix. In the third step, the identity matrix (**I**) is first constructed. Matrix **M** is then subtracted from identity matrix **I** and the total-relation matrix (**S**) is obtained using Eq. (5).

$$\mathbf{S} = \mathbf{M} \times (\mathbf{I} - \mathbf{M})^{-1} \tag{5}$$

Step 4. Determination of the cause-and-effect groups. In the fourth step, the cause-and-effect groups are determined using Eqs. (6) and (7). The row sums and column sums of the **S** are denoted by, respectively. The $D - R$ value indicates whether a criterion belongs to the cause or effect group. Criteria with positive $D - R$ values are classified as the cause group, whereas those with negative values belong to the effect group. The $D + R$ value represents the total level of interaction of each criterion within the system.
where $\mathbf{S} = [S_{i,j}]_{\mathrm{n}\times\mathrm{n}}$; $i, j \in \{1, 2, 3, \ldots, n\}$

$$D = \left[\sum_{j=1}^{n} S_{i,j}\right]_{n*1} \tag{6}$$

$$R = \left[\sum_{i=1}^{n} S_{i,j}\right]_{1*n} \tag{7}$$

An influence diagram is constructed using the obtained values. In the diagram, the horizontal axis represents the $D + R$ values, whereas the vertical axis represents the $D - R$ values.

Step 5. Calculation of the criterion weights. In the final step, the relative weight (w_i) representing the relative importance of each criterion within the system and the normalized weight (W_i) of each criterion are calculated using the $D + R$ and $D - R$ values through Eqs. (8) and (9).

$$w_i = \{(D_i + R_i)^2 + (D_i - R_i)^2\}^{1/2} \tag{8}$$

$$W_i = \frac{w_i}{\sum_{i=1}^{n} w_i} \tag{9}$$

3.2 TODIM

TODIM is a multi-criteria decision-making method based on Prospect Theory, proposed by Kahneman and Tversky in the 1970s, which explains how individuals make decisions under risk [8,10]. In this method, the alternatives are evaluated by considering the decision makers' behavior toward gains and losses [8,10]. For this purpose, the dominance values between the alternatives are calculated with respect to a criterion selected as reference, and the total dominance of each alternative over the other alternatives is determined [8,10]. The alternatives are ranked according to the obtained overall performance values [10]. The application steps of the TODIM method are presented below.

Step 1. Construction of the decision matrix. In the first step, the performance values of the alternatives under each criterion are determined by the decision makers, and the decision matrix (**X**) given in Eq. (10) is constructed.

$$\mathbf{X} = [x_{uc}]_{q\times p} = \begin{bmatrix} x_{11} & \cdots & x_{1p} \\ \vdots & \ddots & \vdots \\ x_{q1} & \cdots & x_{qp} \end{bmatrix} \tag{10}$$

where, q denotes the number of alternatives; p denotes the number of criteria; and x_{uc} denotes the performance value of alternative A_u with respect to criterion C_c.

Step 2. Construction of the normalized decision matrix. In the second step, the values of the **X** are normalized according to the benefit and cost type criteria using Eq. (11) and the normalized decision matrix $\mathbf{P} = [p_{uc}]_{q\times p}$ is obtained.

$$p_{uc} = \begin{cases} \frac{x_{uc} - min_u\, x_{uc}}{max_u\, x_{uc} - \min_u x_{uc}} & c \in C^+ \\ \frac{\max_u x_{uc} - x_{uc}}{\max_u x_{uc} - \min_u x_{uc}} & c \in C^- \end{cases} \quad (11)$$

in which, p_{uc} denotes the normalized performance value, whereas $C^+$and C^- denote the benefit and cost criteria, respectively.

Step 3. Calculation of the relative criteria weights. In the third step, a reference criterion is selected by the decision maker by considering the criterion weights obtained using DEMATEL. The criterion with the highest weight may be selected as the reference criterion [8]. The relative weights of the criteria with respect to the reference criterion are calculated using Eq. (12).

$$w_{cr} = \frac{w_c}{w_r} \quad (12)$$

here, w_c denotes the criterion weight; $w_r = \max\{ w_c | \, c = 1,2, \dots, p\}$ denotes the weight of the reference criterion; and w_{cr} denotes the relative criterion weight.

Step 4. Calculation of the dominance performances of the alternatives. In the fourth step, the dominance value of alternative A_u over alternative A_v with respect to criteria C_c is obtained using Eq. (13).

$$\phi(A_u, A_v) = \begin{cases} \sqrt{\frac{w_{cr}(P_{uc} - P_{vc})}{\sum_{c=1}^{p} w_{cr}}} & \text{if } P_{uc} - P_{vc} > 0 \\ 0 & \text{if } P_{uc} - P_{vc} = 0 \\ \frac{-1}{\theta} \sqrt{\frac{(\sum_{c=1}^{p} w_{cr})(P_{vc} - P_{uc})}{w_{cr}}} & \text{if } P_{uc} - P_{vc} < 0 \end{cases} \quad (13)$$

where θ is the attenuation factor of losses. When $\theta = 1$, losses affect the result in proportion to their actual values [10]. Accordingly, θ was set to 1 in this study.

The total dominance value of alternative A_u over alternative A_v across all criteria C_c is obtained using Eq. (14).

$$\delta(A_u, A_v) = \sum_{c=1}^{p} \phi_c\,(A_u, A_v) \quad (14)$$

Step 5. Calculation of the overall performances of the alternatives. In the final step, the dominance performance is normalized using Eq. (15) and the overall performance value is calculated.

$$\xi_u = \frac{\sum_{v=1}^{q} \delta(A_u, A_v) - min_u\{\sum_{v=1}^{q} \delta(A_u, A_v)\}}{max_u\{\sum_{v=1}^{q} \delta(A_u, A_v)\} - min_u\{\sum_{v=1}^{q} \delta(A_u, A_v)\}} \quad (15)$$

The alternatives (A_u) are ranked by ordering the overall performance values (ξ_u) from highest to lowest.

3.3 CODAS

CODAS is a distance-based multi-criteria decision-making method introduced by Ghorabaee et al. [11]. The method primarily uses the Euclidean distance [11,12]. When the Euclidean distances of the alternatives are close to each other, the Taxicab distance is additionally considered [11,12]. Accordingly, alternatives farther from the negative ideal solution are ranked higher [11,12]. Since CODAS evaluates alternatives based on their distances from the negative

ideal solution, it provides an additional perspective for assessing the software alternatives in this study. The application steps of the CODAS method are presented below.

Step 1. Construction of the decision matrix. In the first step, the performance values of the alternatives under each criterion are determined by the decision makers, and the decision matrix (**X**) given in Eq. (10) is constructed.

Step 2. Construction of the normalized decision matrix. In the second step, the values of **X** are normalized according to the benefit and cost type criteria using Eq. (16) and the normalized decision matrix $\mathbf{N} = [n_{uc}]_{q\times p}$ is obtained.

$$n_{uc} = \begin{cases} \dfrac{x_{uc}}{max_u\, x_{uc}} & c \in C^+ \\ \dfrac{\min_u x_{uc}}{x_{uc}} & c \in C^- \end{cases} \tag{16}$$

here, n_{uc} denotes the normalized performance value, whereas C^+ and C^- denote the benefit and cost criteria, respectively.

Step 3. Construction of the weighted normalized decision matrix. In the third step, the normalized values are multiplied by the criterion weights obtained using DEMATEL, as shown in Eq. (17), to obtain the weighted normalized decision matrix $\mathbf{R} = [r_{uc}]_{q\times p}$.

$$r_{uc} = w_c \times n_{uc} \tag{17}$$

in which, w_c denotes the criterion weight; r_{uc} denotes the weighted normalized value.

Step 4. Determination of the negative ideal solution. In the fourth step, the negative-ideal solution vector is obtained by selecting the minimum value in each column of the weighted normalized decision matrix using Eq. (18).

$$s_c^- = \min_u (r_{uc}) \tag{18}$$

where, s_c^- denotes the negative-ideal solution value for criterion C_c.

Step 5. Calculation of the Euclidean and Taxicab distances. In the fifth step, the distances of the alternatives from the negative ideal solution are calculated using Eqs. (19) and (20).

$$E_u = \sqrt{\sum_{c=1}^{p}(r_{uc} - s_c^-)^2} \tag{19}$$

$$T_u = \sum_{c=1}^{p}|r_{uc} - s_c^-| \tag{20}$$

here, E_u denotes the Euclidean distance of alternative A_u from the negative-ideal solution, whereas T_u denotes its Taxicab distance.

Step 6. Construction of the relative assessment matrix. In the sixth step, the relative assessment matrix ($\boldsymbol{R_a}$) is obtained using Eq. (21).

$$\mathbf{R_a} = [h_{uv}]_{q\times q} \tag{21}$$

$$h_{uv} = (E_u - E_v) + [\psi(E_u - E_v) \times (T_u - T_v)] \tag{22}$$

where, h_{uv}, obtained using Eq. (22), denotes the relative assessment value of alternative A_u with respect to alternative A_v. Eq. (23) defines the threshold function ψ for considering the Taxicab distance based on the difference between the Euclidean distances of the alternatives.

$$\psi(x) = \begin{cases} 0 & if \quad |x| < \tau \\ 1 & if \quad |x| \geq \tau \end{cases} \tag{23}$$

here, τ denotes the threshold parameter of the CODAS method used to determine whether the Taxicab distance should be taken into consideration based on the difference between the Euclidean distances. Its value ranges from 0.01 to 0.05 [11]. In this study, τ = 0.02.

Step 7. Calculation of the assessment scores. In the final step, the assessment scores (H_u) obtained using Eq. (24) are ranked from highest to lowest, and the alternative with the highest assessment score is selected as the best alternative.

$$H_u = \sum_{v=1}^{q} h_{uv} \tag{24}$$

4 Application and Results

In this study, an integrated DEMATEL, TODIM, and CODAS model was developed to determine the most suitable project management software for construction projects. Ten evaluation criteria identified through the literature review and expert opinions are presented in Table 2. Among these criteria, Mobility and Field Usability and AI and Automation were included based on expert opinions to reflect current industry needs and recent technological developments. Based on the literature review and expert evaluations, MS Project, Primavera, and Asana were selected. The expert group consisted of five academicians specializing in construction management with at least 10 years of academic experience and five project managers with at least 7 years of professional experience in different engineering companies. Before the evaluation, the criteria and software alternatives were explained to the experts. For the DEMATEL, a common direct-relation matrix was constructed by calculating the arithmetic mean of the experts' evaluations. For the TODIM and CODAS, the experts evaluated the alternatives using a nine-point scale (1 = worst, 9 = best), and a common decision matrix was obtained by calculating the arithmetic mean of their evaluations. All calculations were performed using Microsoft Excel; the main intermediate matrices should be provided as supplementary material to support reproducibility.

Table 2. List of criteria used in this study.

Code	Criteria	Description
K1	Functionality	Support for project planning, monitoring, reporting and control functions
K2	Installation and Maintenance	Ease of installation, maintenance, software updates and sustainability
K3	Cost	License, subscription and total cost of ownership (USD)
K4	Reliability	System stability, data security, fault tolerance and operational continuity
K5	Vendor Evaluation	Vendor experience, support capability, market position and references
K6	User-Friendly Interface	Ease of use, learnability and interface simplicity
K7	Compatibility and Integration	Integration with CAD, office software and other systems
K8	Service and Support	Technical support, training, online assistance and consulting services

K9	Mobility and Field Usability (Expert Opinion)	Mobile access, field usability, offline operation and field data transfer
K10	AI and Automation (Expert Opinion)	AI-based forecasting, automated reporting and resource optimization support

The $D + R$, $D - R$ and criterion weights obtained from the DEMATEL analysis are presented in Table 3. According to the results, K1 had the highest $D + R$ value and was identified as the most important criterion, indicating the greatest level of interaction within the system, while its W_i value represents its normalized criterion weight. In contrast, K4 had the lowest $D - R$ value and was identified as the main effect criterion, indicating that it is influenced more by the other criteria than it influences them. As shown in Figure 1, K1, K6, K9, and K10 belong to the cause group, whereas K2, K3, K4, K5, K7, and K8 belong to the effect group.

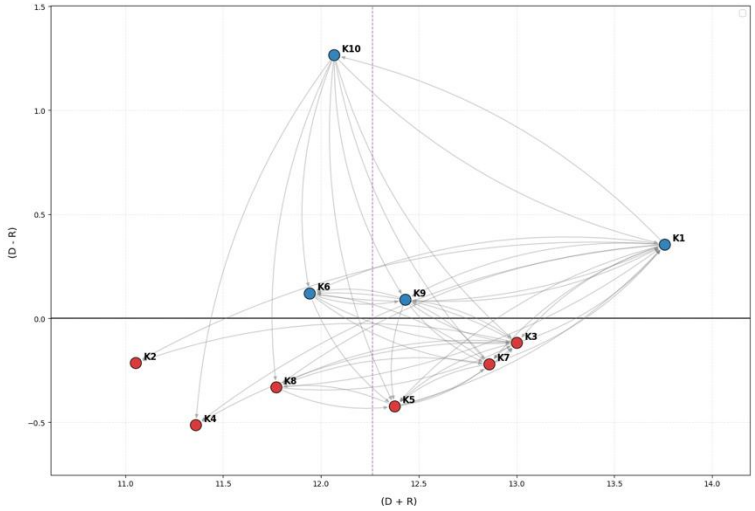

Fig. 1. DEMATEL cause-effect diagram

Table 3. DEMATEL results.

Criteria	**D + R**	**D - R**	W_i
K1	13,7583	0,3537	0,1121
K2	11,0538	-0,2154	0,0901
K3	13,0019	-0,1184	0,1059
K4	11,3607	-0,5140	0,0927
K5	12,3777	-0,4240	0,1009
K6	11,9430	0,1186	0,0973
K7	12,8614	-0,2215	0,1048
K8	11,7722	-0,3323	0,0960
K9	12,4320	0,0888	0,1013
K10	12,0680	1,2645	0,0989

The software rankings obtained using the TODIM and CODAS methods are presented in Table 4. The results show that the two methods produced different ranking results. According

to the results, MS Project ranked first in TODIM (score = 1.0000), whereas Asana ranked first in CODAS (score = 0.0488). The CODAS scores of Asana and MS Project were very close, indicating that the CODAS evaluation distinguished only a small performance difference between these two software alternatives.

Table 4. Comparison of TODIM and CODAS results.

Alternative	TODIM Score(ξ_u)	TODIM Rank	CODAS Score(H_u)	CODAS Rank
MS Project	1,0000	1	0,0439	2
Primavera	0,4720	2	-0,0927	3
Asana	0,0000	3	0,0488	1

5 Discussion

The TODIM and CODAS methods produced different software rankings: TODIM ranked MS Project first, whereas CODAS ranked Asana first. The different rankings obtained from the two methods can be attributed to their different decision-making mechanisms. While TODIM evaluates the alternatives based on their relative dominance by considering the behavioral preferences of decision makers, CODAS ranks the alternatives according to their distances from the negative-ideal solution. These findings indicate that the final choice is sensitive to the decision logic embedded in the selected MCDM method. Therefore, considering the results obtained from different MCDM methods enables decision makers to evaluate software alternatives from different decision-making perspectives.

Since studies integrating the DEMATEL, TODIM, and CODAS methods for project management software selection remain limited, the proposed hybrid framework is expected to contribute to the existing literature. Future studies may increase the number of software alternatives, include a larger and more diverse expert group, perform sensitivity analysis, and integrate additional MCDM methods.

6 Conclusion

This study developed and demonstrated an integrated DEMATEL–TODIM–CODAS decision-making framework for project management software selection, showing that different MCDM methods may lead to different software selection outcomes. In this study, project management software selection was carried out in three main stages. First, the evaluation criteria and software alternatives were identified based on the literature review and expert opinions. Second, the criterion weights were calculated using the DEMATEL method, which identified Functionality (K1) as the most important criterion with a criterion weight of 0.1121. Finally, the software alternatives were ranked using the TODIM and CODAS methods, where MS Project ranked first with a TODIM score of 1.0000, whereas Asana ranked first with a CODAS score of 0.0488. The proposed integrated decision-making framework provides a systematic approach for evaluating project management software from different decision-making perspectives.

Abstract. This study proposes a multi-stage framework for automatic brick wall quantity estimation from real construction site images using YOLO-based object detection and multiple linear regression. First, individual bricks are detected using a YOLO-based object detection model. Instead of directly using the detected brick count for quantity estimation, the detection outputs are transformed into physically meaningful quantity variables based on brick count, bounding box geometry, equivalent brick count, and area representations. Based on these variables, eleven parametric quantity estimation approaches are developed and comparatively evaluated. The best parametric approach achieved a Mean Absolute Percentage Error (MAPE) of 7.00%. To further improve estimation accuracy, the outputs of the eleven parametric approaches were integrated into a multiple linear regression model. Variable reduction was performed to obtain a compact regression model while maintaining high prediction accuracy. The final regression model achieved a MAPE of 5.19%, a Mean Absolute Error (MAE) of 0.1408 m², and an adjusted R^2 of 0.9796. The proposed framework demonstrates that combining YOLO-based object detection with parametric quantity estimation and regression provides an accurate, interpretable, and practical solution for automated brick wall quantity estimation from construction site images.

Keywords: Brick wall quantity estimation; YOLO; object detection; regression analysis; automated quantity takeoff.

1 Introduction

The rapid advancement of digital technologies has accelerated the adoption of data-driven approaches in the architecture, engineering, and construction (AEC) industry. Among these technologies, computer vision and deep learning have become increasingly important for automating construction site monitoring, progress assessment, and quantity surveying. Compared with traditional manual measurements, image-based methods offer significant advantages in terms of efficiency, repeatability, and reduced labor requirements, particularly under dynamic construction site conditions.

Recent studies have successfully applied deep learning-based object detection methods to various construction applications, including worker and equipment monitoring (Nath and Behzadan, 2020), personal protective equipment detection (Kurniawan et al., 2025), and automated material recognition and counting (Li et al., 2021). In addition, advances in YOLO architectures have further improved the accuracy and efficiency of real-time object detection for construction-related tasks (Ding et al., 2025). Despite these developments, research on automated quantity takeoff from construction site images remains limited. Existing studies

primarily rely on image segmentation or pixel-based measurements, while object detection outputs are generally used only for counting detected objects. One of the few studies addressing brick wall quantity estimation was conducted by Başağa and Hacıefendioğlu (2024), who estimated wall areas using a U-Net-based image segmentation approach. However, the direct use of object detection outputs for quantity estimation has received limited attention.

To address this gap, this study proposes a multi-stage framework for automatic brick wall quantity estimation from real construction site images using YOLO-based object detection and multiple linear regression. First, individual bricks are detected using a YOLO model. Subsequently, the detection outputs are transformed into physically meaningful quantity variables through eleven parametric quantity estimation approaches developed under different assumptions regarding brick visibility and bounding box geometry. Finally, the outputs of these parametric approaches are integrated into a multiple linear regression model to improve wall quantity estimation accuracy.

The main contributions of this study are as follows:

- A YOLO-based object detection model is developed for automatic brick detection using images collected from real construction sites.
- Eleven parametric quantity estimation approaches are proposed to estimate brick wall quantities under different geometric assumptions.
- A multiple linear regression model is developed by integrating the outputs of the parametric approaches to improve estimation accuracy.
- The proposed framework is validated using independent test images, demonstrating its applicability for automated brick wall quantity estimation under real construction site conditions.

2. Methodology

2.1. Overall Framework

This study proposes a multi-stage framework for automatic brick wall quantity estimation from real construction site images. The proposed framework consists of five main stages: image acquisition, brick annotation, YOLO-based brick detection, parametric quantity estimation, and regression-based quantity prediction. Rather than directly using the detected number of bricks as the final quantity estimate, the proposed framework transforms the detection outputs into different parametric quantity estimates, which are subsequently integrated through a multiple linear regression model to improve estimation accuracy. The overall workflow of the proposed framework is illustrated in Fig. 1.

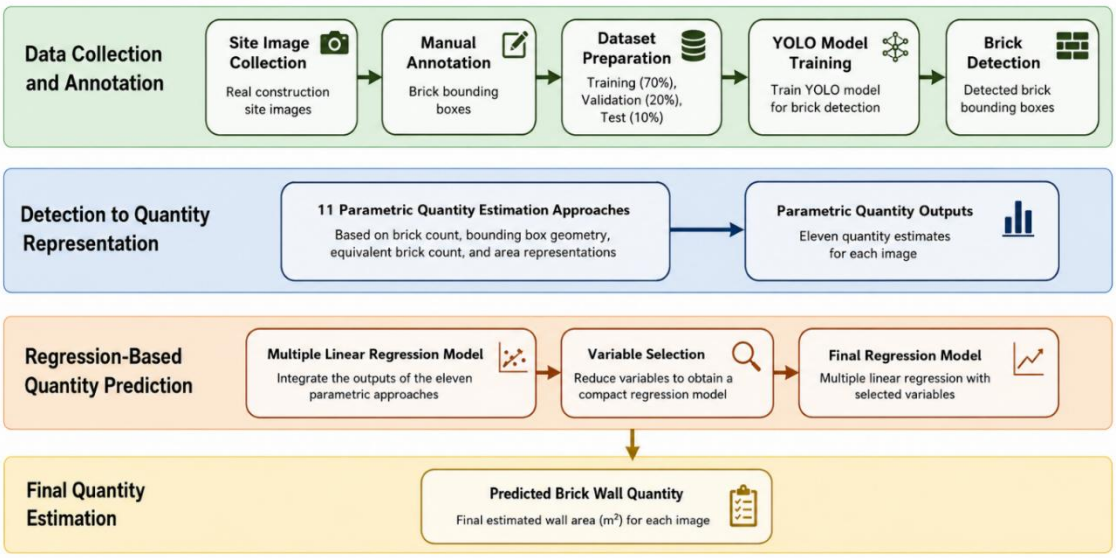

Fig. 1. Overall workflow of the proposed multi-stage brick wall quantity estimation framework

2.2. Data Collection and Annotation

Brick wall images were collected from active construction sites, primarily representing interior masonry works. To ensure that the proposed framework reflects realistic construction environments, images were captured under different lighting conditions, viewing angles, shooting distances, and wall configurations using a smartphone without any stabilizing equipment. The dataset includes flat walls, walls with openings, and walls adjacent to sloped ceilings. All images have a resolution of 2160 × 3840 pixels.

The dataset consists of 300 images, which were divided into training (70%), validation (20%), and test (10%) subsets for object detection.

Representative examples of the collected images are shown in Fig. 2.

Fig. 2. Representative samples of brick wall images collected from real construction sites under varying conditions

All brick instances were manually annotated using the Roboflow platform. Each brick was assigned to a single object class (*brick*) by drawing a bounding box around the visible brick region. Approximately 40,000 brick instances were annotated. To improve the robustness of the detection model, rotational data augmentation (±20°) was applied while preserving the corresponding annotation coordinates.

An example of the annotated images is presented in Fig. 3.

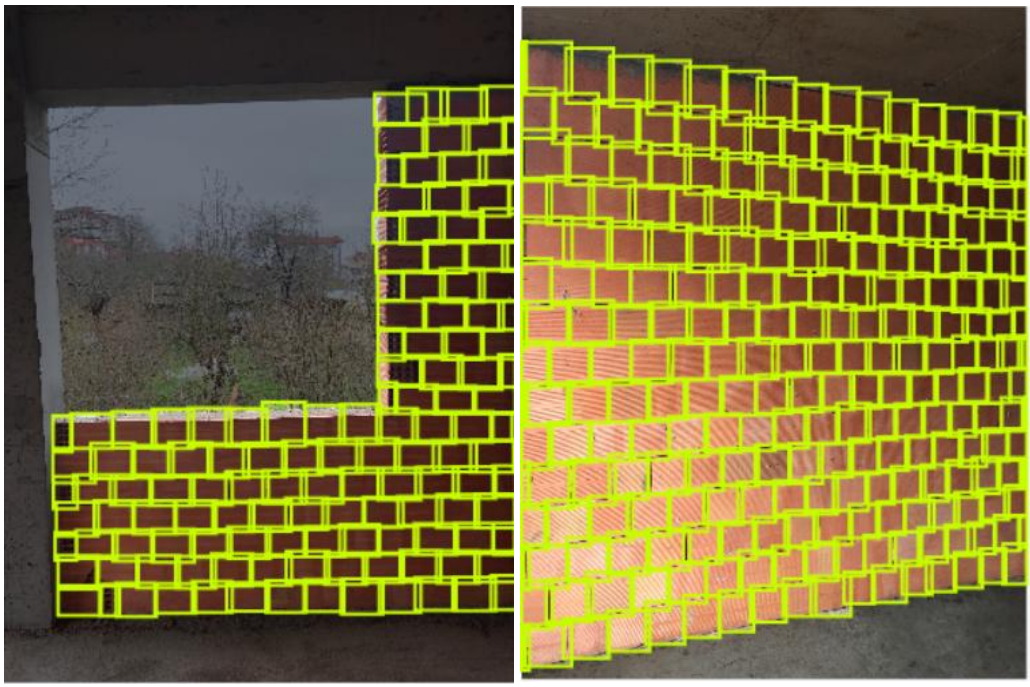

Fig. 3. Example of annotated brick wall images with bounding boxes used for YOLO training

2.3. YOLO-Based Brick Detection

Brick detection was performed using a YOLO-based object detection model trained on the annotated dataset. The trained model predicts the location of each brick by generating bounding boxes, which subsequently provide the geometric information required for quantity estimation. Model training was carried out using the Google Colab platform with NVIDIA T4 GPU acceleration.

Unlike conventional counting approaches, the proposed framework does not directly convert the detected brick count into wall quantities. Instead, the detection outputs serve as the basis for generating multiple quantity estimation scenarios.

2.4. Parametric Quantity Estimation

To estimate brick wall quantities from YOLO detections, four groups of parametric quantity estimation approaches were developed. These approaches progressively consider different assumptions regarding brick visibility and bounding-box geometry. In total, eleven quantity estimation scenarios were generated, including one full-brick approach, four threshold-based partial-brick approaches, one multi-level area-based approach, and five area-reduction approaches.

2.4.1. Full-Brick Assumption

In the first approach, all detected bricks are assumed to be complete bricks. The estimated wall area is calculated as

$$Q = N \times A_{brick} \tag{1}$$

where Q denotes the estimated wall area, N is the number of detected bricks, and A_{brick} is the physical area of a single brick.

2.4.2. Threshold-Based Partial-Brick Estimation

This approach classifies detected bricks as either full or partial according to their bounding-box areas relative to the average bounding-box area. The estimated wall area is computed as

$$Q = N_{full}A_{brick} + N_{partial}(A_{brick}\alpha) \tag{2}$$

where α represents the partial-brick coefficient. Four different coefficient values (0.50, 0.40, 0.30, and 0.20) were evaluated to investigate the influence of partially visible bricks on quantity estimation.

2.4.3. Multi-Level Area-Based Estimation

Instead of using a binary classification, this approach assigns each detected brick to one of four area categories according to the ratio between its bounding-box area and the average bounding-box area:

$$r_i = \frac{A_i}{A_{average}} \tag{3}$$

The estimated wall area is then calculated as

$$Q = \sum_{k=1}^{4} N_k \, A_{brick} \omega_k \tag{4}$$

where ω represents the weighting factor assigned to each area category (0,25, 0,50, 0,75, and 1,00).

2.4.4. Area Reduction-Based Estimation

In the final approach, all detected bricks are considered complete, while reduction coefficients are introduced to compensate for overestimation caused by partial brick visibility and geometric uncertainties.

The estimated wall area is calculated as

$$Q = NA_{brick}\beta \tag{5}$$

where β denotes the reduction coefficient. Five reduction coefficients (0.95, 0.90, 0.85, 0.80, and 0.75) were comparatively evaluated.

2.5. Regression Model

The eleven quantity estimation outputs obtained from the parametric approaches were used as independent variables in a multiple linear regression model to improve wall quantity estimation. The regression model can be expressed as

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_{11} x_{11} + \varepsilon \tag{6}$$

where y represents the measured wall area, x_1–x_{11} denote the outputs of the eleven parametric quantity estimation approaches, β represents the regression coefficients, and ε is the error term. A multiple linear regression model was developed using the outputs of the eleven parametric quantity estimation approaches as independent variables. Stepwise variable elimination was then performed to identify a simpler model while maintaining prediction accuracy. The final regression model was evaluated using an independent test dataset, and its performance was assessed using Mean Absolute Error (MAE), Root Mean Square Error (RMSE), Mean Absolute Percentage Error (MAPE), adjusted coefficient of determination (Adjusted R^2), and bias.

3. Results and Discussion

3.1. YOLO Detection Performance

The performance of the trained YOLO model was evaluated using the independent test dataset. Detection performance was assessed in terms of precision, recall, F1-score, and mAP, which are widely used metrics for object detection tasks. The confusion matrix of the final model is presented in Fig. 4, while the corresponding performance metrics are summarized in Table 1.

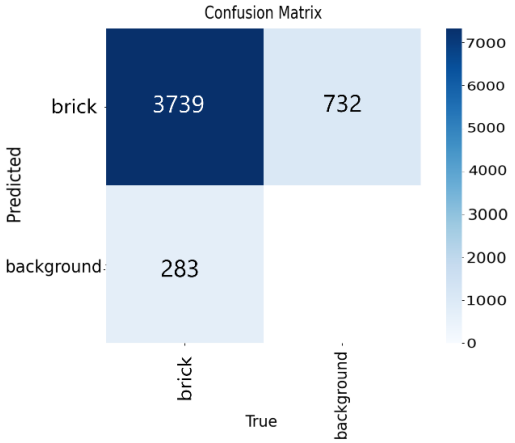

Fig. 4. Confusion matrix results

Table 1. Model metrics

Precision	0,8758
Recall	0,9114
F1 Score	0,8932
mAP@50	0,9260

The results indicate that the proposed model successfully detected individual bricks under varying construction site conditions, including different viewing angles, illumination levels, and wall geometries. Accurate brick localization provides the foundation for the subsequent quantity estimation process, as the detected bounding boxes are directly used to generate the parametric quantity estimation outputs.

3.2. Performance of Parametric Quantity Estimation Approaches

The eleven parametric quantity estimation approaches developed from the YOLO detection outputs were compared using the measured wall areas as reference values. The average error of each approach is illustrated in Fig. 5.

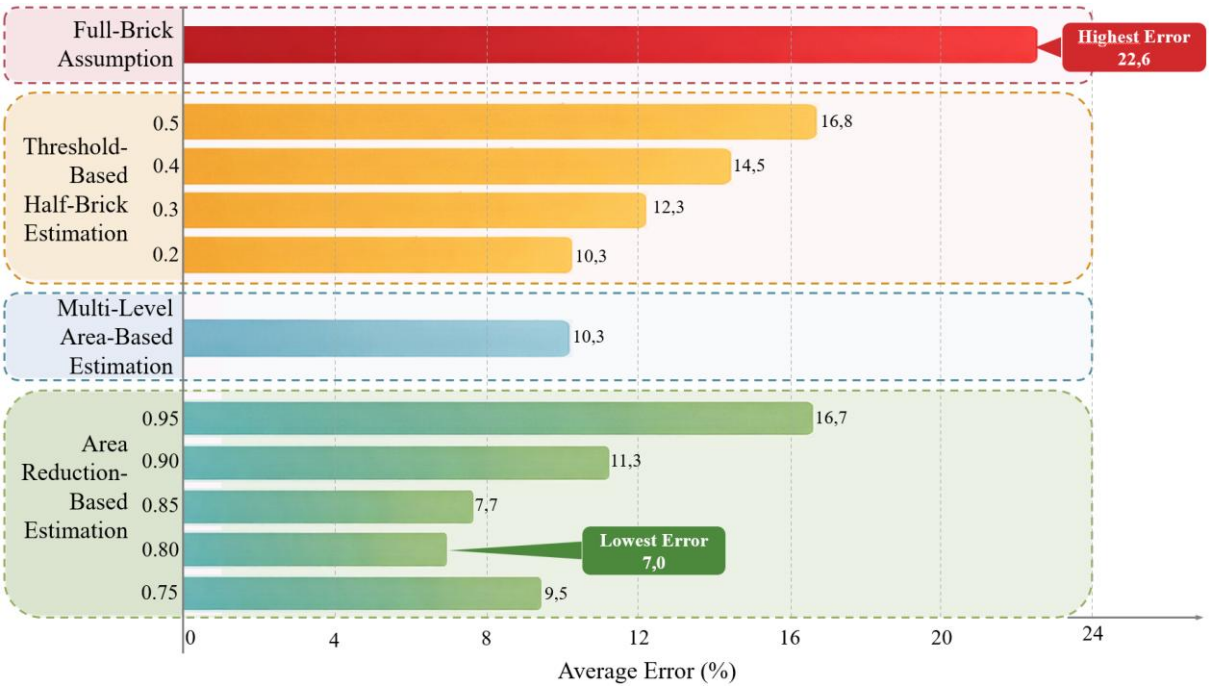

Fig. 5. Comparison of average error rates for different parametric quantity estimation approaches

The full-brick assumption produced the largest estimation error because all detected bricks were considered complete, resulting in systematic overestimation of the wall area. Introducing partial-brick assumptions substantially reduced the estimation error by accounting for partially visible bricks. The performance of the threshold-based approaches varied depending on the selected partial-brick coefficient.

The multi-level area-based approach provided more balanced estimations by assigning different weighting factors according to the relative bounding-box area of each detected brick. However, the lowest estimation errors were obtained using the area reduction approaches. In particular, reduction coefficients between 0,80 and 0,85 yielded the most accurate quantity estimates among all parametric approaches.

These findings demonstrate that incorporating geometric information derived from the detected bounding boxes significantly improves quantity estimation compared with simple object counting.

3.3. Regression Results

To improve the accuracy of wall quantity estimation, a multiple linear regression model was developed using the outputs of the eleven parametric quantity estimation approaches. The initial model, which included all variables, achieved an R^2 value of 0.9835, indicating a strong relationship between the parametric estimates and the measured wall area. To reduce model complexity, a stepwise variable elimination procedure was performed. At each step, the least significant variable was removed, and the resulting models were evaluated using R^2, Adjusted R^2, MAE, MAPE, and Bias. The performance of the regression models during the variable elimination process is summarized in Table 2.

Following the variable elimination process, the regression performance improved compared with the initial model. As shown in Table 2, the initial model containing all eleven variables achieved a MAPE of 6.58% and an MAE of 0.1716, whereas the reduced models yielded lower prediction errors. The lowest error was obtained using the eight-variable model (MAPE = 5.19%, MAE = 0.1408). A similar performance was achieved with the seven-variable model, while reducing the number of variables below seven resulted in a gradual increase in prediction error. Therefore, the seven-variable model was selected as the final regression model because it provided comparable accuracy with a simpler model structure.
The bias values remained close to zero for all regression models, indicating the absence of significant systematic prediction errors. Although a slight increase in bias was observed as the number of variables decreased, the overall prediction performance remained stable. The final regression equation is given below.

$$y = 0{,}0558 - 0{,}0906x_1 - 0{,}5491x_2 + 1{,}0956x_3 - 0{,}7018x_5 + 1{,}9199x_6 + 49{,}1126x_9 - 47{,}1925x_{10} \quad (7)$$

The final regression model achieved a MAPE of 5.19%, an MAE of 0.1408 m², and an Adjusted R^2 of 0.9796. These results demonstrate that integrating the outputs of the eleven parametric quantity estimation approaches through multiple linear regression significantly improves wall quantity estimation compared with individual parametric approaches. The proposed regression model provides an effective balance between prediction accuracy and model simplicity, making it suitable for automated brick wall quantity estimation from real construction site images.

Table 2. Stepwise variable elimination results and performance metrics of regression models

Removed	Remaining Features	R^2	Adj. R^2	MAPE	MAE	Bias

4. Discussion

This study proposed a multi-stage framework for automatic brick wall quantity estimation from real construction site images by integrating YOLO-based object detection, parametric quantity estimation, and multiple linear regression. Unlike conventional object counting approaches, the proposed framework transforms YOLO detection outputs into physically meaningful quantity estimates using different assumptions regarding brick visibility and bounding-box geometry. This detection-to-quantity strategy enables a more reliable estimation of wall quantities under real construction site conditions.

The results demonstrate that directly converting detected brick counts into wall quantities is insufficient for accurate quantity estimation. The full-brick assumption produced the highest estimation error (22,6%), indicating that partial brick visibility, openings, and geometric variations significantly affect quantity estimation. Incorporating geometric corrections through the proposed parametric approaches substantially reduced the estimation error, with the best parametric approach achieving a MAPE of 7.00%. These findings confirm that bounding-box geometry provides valuable information beyond simple object counting.

Further improvements were achieved by integrating the outputs of the eleven parametric quantity estimation approaches into a multiple linear regression model. The final regression model reduced the prediction error to a MAPE of 5.19% while maintaining a high Adjusted R^2 of 0.9796, demonstrating that combining complementary parametric estimates provides more accurate wall quantity predictions than any individual approach.

Compared with the segmentation-based approach proposed by Başağa and Hacıefendioğlu (2024), the proposed framework eliminates the need for pixel-level segmentation and reference area measurements by directly utilizing object detection outputs for quantity estimation. This demonstrates the feasibility of object detection as an alternative framework for automated brick wall quantity estimation from construction site images.

Despite these promising results, the proposed framework has several limitations. The regression model was developed and evaluated using a limited number of wall images with measured reference areas, and its generalization to different masonry types and construction environments requires further investigation. In addition, the estimation accuracy depends on the quality of YOLO detections, particularly in images containing occlusions, irregular brick arrangements, or inaccurate bounding boxes. Future studies should evaluate the proposed framework using larger datasets collected from different construction sites and investigate its applicability to other masonry materials and building components.

5. Conclusions

This study presented a multi-stage framework for automatic brick wall quantity estimation from real construction site images by integrating YOLO-based object detection, parametric quantity estimation, and multiple linear regression. Rather than directly converting detected brick counts into wall quantities, the proposed framework transforms object detection outputs into physically meaningful quantity estimates using eleven parametric approaches developed under different geometric assumptions.

The experimental results showed that the full-brick assumption resulted in the highest estimation error (22.6%), whereas the best parametric approach reduced the error to a MAPE of 7.00%. By combining the outputs of the eleven parametric approaches, the proposed multiple linear regression model further improved the estimation accuracy, achieving a MAPE of 5.19%, an MAE of 0.1408 m^2, and an Adjusted R^2 of 0.9796.

Overall, the proposed framework demonstrates that transforming YOLO detection outputs into physically meaningful quantity estimates provides an effective and interpretable solution for automated brick wall quantity estimation. The proposed methodology has the potential to support digital quantity surveying and construction site management and may be extended to other masonry elements and image-based quantity estimation applications in future studies.

Abstract. On a global scale, the construction industry struggles with chronic issues such as project delays, cost overruns, and productivity losses due to its intrinsic dynamic nature, multi-stakeholder organizational structures, and high-uncertainty factors. International literature and field practices demonstrate that these chronic problems are fundamentally rooted in disruptions in on-site information flow, labor mismatches, and operational wastes (muda). Although the Lean Construction approach offers a robust methodological framework for waste elimination and continuous improvement (kaizen), the lack of practical, accessible, and guiding digital tools to ensure the sustainable implementation of these principles, particularly in the field environment, is felt as a global problem. Existing construction management tools and Building Information Modeling (BIM) solutions primarily remain at descriptive ("What happened?") or diagnostic ("Why did it happen?") analysis layers in terms of their data processing capacities. However, in dynamic and chaotic jobsite environments where field crews must make decisions within seconds, the need for a prescriptive guidance mechanism to answer the question "What should I do now?" stands as a critical gap in the literature.

This study adopts Systematic Literature Review (SLR) and conceptual analysis methods to systematically examine operational efficiency barriers and information flow interruptions in the global construction industry. Accordingly, a large-scale review covering the years 2020-2026 was conducted across the Scopus, IEEE Xplore, and ScienceDirect databases, through which 138 qualified academic publications screened within the framework of determined criteria were analyzed in depth. By synthesizing these theoretical and practical findings in the international literature, coordination problems in the field, interruptions in real-time information flow, and delays in decision-making processes were identified as the primary global structural impediments to lean efficiency. Unlike traditional data storage systems, this study demonstrates the conceptual and theoretical necessity of an interactive decision support structure capable of directly interacting with field personnel, interpreting signals from the jobsite, and generating prescriptive action recommendations. Consequently, through an in-depth literature analysis and theoretical modeling, this research constructs the theoretical infrastructure for a novel mechanism that will enable the proactive forecasting of field wastes and convert complex field data into instant action planning. The proposed approach contributes theoretically and methodologically to the global sectoral digitalization vision by arguing that digital tools in construction management must transform

from passive archiving centers into dynamic "decision partners" that think alongside project managers.

Keywords: Lean Construction, Operational Efficiency, Decision Support Systems, Prescriptive Analytics, Construction Management.

1 Introduction

The global construction industry frequently experiences chronic issues such as budget overruns, delays, and stagnant productivity due to its fragmented nature, multi-stakeholder organizational structures, and complex project dynamics (Kissi et al., 2022). International literature and field practices demonstrate that these failures generally stem from the accumulation of daily micro-disruptions -such as disconnections in information flow, spatial conflicts, and operational inefficiencies- rather than a single major event (Görsch et al., 2024).

To eliminate these non-value-adding activities (Ohno, 1988), termed as "muda" (waste) in production theory, and to ensure "kaizen" (continuous improvement), the Lean Construction approach adapted from the Toyota Production System was developed (Koskela, 1992). Lean tools such as the Last Planner System (LPS), Value Stream Mapping (VSM), and Just-in-Time (JIT) delivery possess the potential to stabilize workflows (Ballard, 2000; Bamana et al., 2019). However, the disconnect between high-level planning and the volatile dynamics in the field hampers the sustainable implementation of these principles. This bottleneck originates from the lack of dynamic, accessible, and prescriptive digital tools tailored to real-time field conditions, thereby causing jobsite management to remain reactive rather than proactive (Dave et al., 2016; Görsch et al., 2024).

Today, the construction industry is undergoing a profound digital transformation led by Building Information Modeling (BIM), the Internet of Things (IoT), and sensor technologies (Dave et al., 2016). Nevertheless, while these technologies enhance visualization and data collection capacities, they fall short in dynamic and short-interval decision-making processes on site; they generally function as passive administrative archives that report what has already occurred in the past (Salhab et al., 2026). Yet, in fast-paced and chaotic jobsite environments, managers and engineers urgently require not only descriptive or diagnostic analyses but also actionable, instantaneous, and prescriptive guidance that answers the question, "What should I do now?"

In this context, it is a critical requirement on a global scale for digital systems to evolve from passive data repositories into proactive "decision partners" that think alongside managers. Utilizing a comprehensive literature review and conceptual analysis method, this study systematically examines the operational efficiency barriers and real-time information flow interruptions in the global construction industry. By addressing the integration of lean construction philosophy with modern data analytics solutions, the research aims to establish the conceptual framework for more advanced and holistic models that will enable the proactive management of operational wastes in the field.

2 Systematic Literature Review Methodology

This study adopts Systematic Literature Review (SLR) and conceptual analysis methods to reveal the barriers to operational efficiency in the global construction industry and to demonstrate the need for prescriptive digital tools in overcoming these barriers. Moving beyond a random literature review, the objective is to filter and categorize the global body of knowledge regarding the research question in accordance with specified criteria, and to establish a conceptual and theoretical foundation for future digital tools.

2.1 Data Collection and Screening Strategy

In this study, an initial search conducted across the relevant databases (Scopus, IEEE Xplore, ScienceDirect) based on the determined keywords yielded a total of 1,280 academic publications. During the search process, combinations of keywords including "Lean Construction," "Muda," "BIM," "Decision Support Systems," and "Industry 4.0" were utilized to capture the intersection of operational efficiency, digitalization, and lean principles in construction management. Studies belonging to disciplines outside of construction management that did not directly align with the focus of the research, as well as duplicate records across different databases, were systematically excluded from the pool.

Following the initial screening stage, 659 publications that maintained relevance to the topic were subjected to a second evaluation based on title, publication year, and contextual suitability criteria. At this stage, articles failing to meet the recency and scoping limitations of the research were eliminated, reducing the number of publications to be reviewed to 531.

In the final stage, all of the remaining 531 publications were analyzed in depth using the full-text analysis method. Studies that did not provide a direct theoretical or practical contribution to the intersection of lean construction philosophy, jobsite digitalization, and prescriptive decision support systems were excluded. As a result of this rigorous and multi-stage methodological elimination process, 138 references were ultimately included in the analysis to construct the conceptual framework of the study and to substantiate its theoretical foundation.

This large-scale literature pool has allowed for the mapping of a universal, rather than merely regional, landscape of operational efficiency barriers in the global construction industry. The distribution of the relevant publications according to their databases, methodologies, and thematic focuses is comprehensively summarized in Table 1. The methodological synthesis of the analyzed ~140 studies clearly validates the global necessity for prescriptive digital mechanisms that will allow the industry to break away from static archiving processes and function as dynamic "decision partners."

Table 1. Database and Thematic Distribution of the Analyzed Literature

Database	**Reviewed Period**	**Number of Articles (N)**	**Most Frequently Encountered Methods**	**Dominant Thematic Focus Areas**
Scopus	2020–2025	~65	Structural Equation Modeling (SEM), Quantitative Survey Analyses, Bibliometric and Critical Reviews, Conceptual Model Development	Lean construction implementation barriers, awareness and knowledge obstacles, process improvement in mega projects, Industry 4.0, and operational efficiency.
IEEE Xplore	2021–2025	~45	Discrete Event Simulation (DES), Algorithm Modeling, Knowledge Graphs, Statistical Analyses (ANOVA, RII), Case Studies	Digital twin and 4D/5D BIM applications, smart supply chain constraint management, intelligent communication, and visual jobsite management mechanisms.
ScienceDirect	2020–2026	~30	Delphi Technique, Systematic Literature	Decision support systems, computer vision-based

			Reviews (SLR), Fuzzy Systems, Computer Vision, Interviews	proactive site/field management, lean construction knowledge (LCK) frameworks, and sustainability integration.
TOTAL	2020–2026	~140		General Trend: Shift from root causes of operational inefficiencies toward prescriptive and dynamic decision support systems.

2.2 Synthesis of Literature Findings and Operational Barriers

The global construction industry suffers from chronic inefficiencies due to its highly fragmented structure, multi-stakeholder organizational charts, dynamic field conditions, and high-uncertainty factors (Ghassemi & Becerik-Gerber, 2011; Ibrahim et al., 2026). These systematic inefficiencies lead to significant project delays, budget overruns, and stagnant productivity rates (Pourrahimian et al., 2026). Systematically classifying these barriers and determining the need for "prescriptive" digital tools to overcome them constitutes one of the most critical areas of study in the construction management literature. Listed below are the barriers compiled within the framework of available references through the Systematic Literature Review (SLR) and Conceptual Analysis methods, along with the necessity of prescriptive tools.

According to the literature, operational barriers in the sector can be grouped into four main categories: organizational, process-based, spatial, and technological-information-driven.

2.2.1. Organizational and Behavioral Barriers

Managerial and Cultural Resistance: The preservation of traditional "command and control" oriented hierarchical structures and the failure to adopt a Lean Construction culture (Ibrahim et al., 2026). Resistance to change and the inability to decentralize decision-making authority on site slow down decision-making processes (Bidhendi et al., 2026; Ghassemi & Becerik-Gerber, 2011).

Fragmented Contractual and Project Delivery Models: Temporary, transactional, and adversarial short-term relationships among designers, main contractors, and subcontractors lead to a "silo mentality" (Ghassemi & Becerik-Gerber, 2011). This fragmentation creates a governance gap where risks and responsibilities are inequitably distributed among stakeholders (Ibrahim et al., 2026).

2.2.2. Process and Supply Chain Barriers

Workflow Unreliability and Volatility: Uncertainties in the material supply chain, unplanned downtimes, and the inability to manage interdependencies between sequential activities disrupt the continuity of workflow (Babanagar et al., 2024).

Retrospective Performance Tracking: The industry's heavy reliance on the static Critical Path Method (CPM) and retrospective (post-mortem) progress reports prevents the instantaneous resolution of micro-disruptions emerging in real time on site, such as material delays or handover cleanups (Aboelmagd, 2020; Salhab et al., 2026).

2.2.3. Spatiotemporal and Spatial Barriers

Workspace Conflicts and Congestion: Distinct subcontractor crews attempting to utilize the same physical space within the same time frame constitutes a severe spatial constraint

(Salhab et al., 2026). Studies indicate that congested and uncoordinated workspaces reduce labor productivity by up to 65% and lead to project delays of up to 30% (Salhab et al., 2026). This barrier is further exacerbated by the inability of static 2D layout plans to capture dynamic field realities.

2.2.4. Technological and Information-Driven Barriers

Lack of Digital Literacy and Integration: The insufficiency of field technical personnel and foremen in utilizing complex digital tools (digital literacy gap) and the non-user-friendly nature of software applications (Bidhendi et al., 2026).

Data and Communication Disconnection: The inability to integrate systems such as Building Information Modeling (BIM), computer vision (CV), and the Internet of Things (IoT) with on-site decision support systems (DSS), which causes data to remain isolated in silos and leads to information loss (Salhab et al., 2026).

2.3. The Need for Prescriptive Digital Decision Support Tools

The majority of digital tools in construction management currently operate solely at the descriptive ("What happened?") and diagnostic ("Why did it happen?") layers of data analytics (Pourrahimian et al., 2026). These tools do not go beyond being passive digital archives that report retrospective data. However, chaotic and fast-changing jobsite environments require managers and field crews to make decisions within seconds. This situation renders the transition to prescriptive analytics ("What should I do now?") a theoretical and practical necessity (Salhab et al., 2026).

By processing unstructured field data (site logs, voice recordings, etc.) via natural language processing (NLP) and machine learning, prescriptive systems forecast lean wastes such as waiting and rework before they even occur, and simulate alternative scenarios to prevent them (Maciel et al., 2026; Pourrahimian et al., 2026). Digital twins and artificial intelligence-based decision support systems transform from being passive displays for managers into proactive "decision partners" that think alongside them (Liu & Liu, 2026). These systems generate optimized, context-specific, and actionable operational plans to resolve instantaneous constraints on site. In this manner, complex office planning is successfully translated into short-interval visual work instructions that foremen and craftsmen working directly in the field can easily understand (Görsch et al., 2026). Consequently, a bidirectional, real-time feedback loop is established between the workers and the decision engine, triggering continuous improvement (kaizen) directly at the point of production.

2.4. Conceptual Analysis

When the "future research directions" obtained from the systematic literature review were examined, it was observed that the literature clearly points toward decision support structures and the lean integration of advanced technologies. Pioneers in the literature emphasize the necessity of simulation-based virtual test environments and decision support tools (Sreram & Thomas, 2023) to detect non-value-adding (NVA) activities and accelerate process improvement, knowledge graph-based intelligent evaluation systems, or the integration of computer vision with fuzzy logic (Salhab et al., 2026). Accordingly, the ultimate methodological output of this study is to establish the philosophical and theoretical foundation for the vision of utilizing novel digital tools capable of proactivity forecasting wastes by processing heterogeneous data from the field, thereby closing the gaps identified in the literature (static archiving, reactive management, and information barriers). The research aims to

systematically define the conceptual boundaries upon which future dynamic decision mechanisms will be built.

3 Prescriptive Digital Tools in Lean Construction Management

3.1. Analytical Layers and Limitations of Existing Digital Systems

The transition from labor-intensive traditional processes to technological solutions in the construction industry fundamentally shapes operational control mechanisms. This transformation process evolves from the stage of digitization, where manual practices are replaced by integrated digital systems, toward the level of digitalization, where data analytics, artificial intelligence, and cyber-physical systems are utilized to optimize decision-making processes (Salhab et al., 2026). Today, digital technologies used in construction management are divided into five main functional categories: data collection, analytical processes, visualization, communication, and design and execution automation (Chen et al., 2022). However, the major operational limitation of existing digital systems is that, due to their information-centric building blocks, they do not allow project teams to communicate effectively at the field level and coordinate activities instantaneously (Guerriero et al., 2017).

Widely used lean production control mechanisms, such as the Last Planner System (LPS), primarily ensure coordination at the team or workgroup level, yet they cannot directly respond to the daily and dynamic decision-making needs (TP&C) of workers in the field (Görsch et al., 2026). Existing digital visual management (DVM) tools also support the general planning level rather than situational reality (Görsch et al., 2026). The fragmented nature of digital applications on jobsites prevents these data from being processed in an integrated manner despite the generation of large volumes of data, thereby hindering the creation of a proactive "situation picture" (Görsch et al., 2026).

3.2. The Need for Prescriptive Analytics in the Jobsite Environment

In chaotic, fast-changing, and high-uncertainty jobsite environments, lagging performance reporting or static critical path methods (CPM) impede proactive decision-making (Salhab et al., 2026). To increase the reliability and predictability of the workflow, leading metrics such as "tasks made ready" (TMR) must be continuously tracked during the lookahead planning process and predicted using machine learning algorithms (Hamzeh et al., 2015). Reducing non-value-adding activities and preventing wastes (muda) on site is only possible if field personnel attain a high level of situational awareness. This necessitates delivering structured information in the correct format to the relevant person in the field at the right time (Görsch et al., 2026).

Visual management (VM) tools compress time and reduce process volatility by making information transparent. However, the vast majority of existing systems remain stuck in the descriptive ("What happened?") and diagnostic ("Why did it happen?") layers. For jobsite management to break away from a reactive structure, it is a necessity to move beyond being passive databases and transition to the prescriptive analytics layer that offers dynamic operational recommendations to the field (Salhab et al., 2026). Prescriptive tools that can generate instantaneous answers to the question "What should be done now?" are required so that craftsmen and foremen in the field can proactively manage immediate spatial conflicts, material delays, or labor mismatches (Görsch et al., 2026).

4 Discussion

The systematic literature analysis reveals that digital management tools must undergo a philosophical and functional paradigm shift to overcome the chronic inefficiencies, budget overruns, and productivity losses in the global construction industry. Although traditional project management approaches and existing Building Information Modeling (BIM) solutions have enhanced data collection and visualization capacities, they are inherently information-centric. As frequently criticized in the literature, these static tools remain stuck in descriptive and diagnostic layers that mostly seek answers to "What happened?" and "Why did it happen?". In jobsite environments requiring simultaneous operations in chaotic, multi-stakeholder, and space-constrained areas, this reactive structure fails to prevent micro-disruptions from accumulating and leading to macro-level schedule deviations. Rather than storing real-time data from the field as passive administrative archives, the proposed AI-Assisted Decision Making (AADM) and interactive decision-support mechanisms convert this data into real-time prescriptive action-planning outputs, thereby transforming jobsite management into a proactive execution force.

Although traditional Lean Construction tools provide tactical planning stability, particularly at the Last Planner System (LPS) level, they remain limited to coordination at the crew level; they cannot directly guide the instantaneous, minute-by-minute operational decisions of workers in the field. Literature findings prove that to prevent spatial conflicts, material supply disruptions, or labor mismatches from turning into non-value-adding waste (muda), the decision-making chain (DMC) length must be shortened, and information must be delivered directly to the executors in the field (foremen and craftsmen).

However, the adoption of prescriptive digital tools on the jobsite depends not only on algorithmic success but also on a dynamic trust relationship between the human and technology layers. The digital literacy gap and employee resistance, which are highlighted in the global literature as the major structural barriers to the digitalization vision, can be overcome if the developed systems can think alongside jobsite personnel as a proactive "decision partner." Prescriptive tools capable of generating instantaneous, simple, and visual answers to the question "What should be done now?" will break the operational delays caused by hierarchical approval processes and provide task transfer resilience in the field.

5 Conclusion

This study has examined the operational efficiency losses and on-site information flow interruptions in the global construction industry through a systematic literature review (SLR) and conceptual analysis method covering ~140 qualified publications. The findings demonstrate that the digital transformation in the industry must inevitably evolve from passive data recording and archiving layers toward proactive decision-support structures that offer directly applicable mitigating strategies to field crews. It has been validated that existing BIM, IoT, and computer vision integrations fall short of breaking the reactive structure in the jobsite environment, and transitioning to the prescriptive analytics layer is theoretically imperative for the sustainability of lean principles.

This research aimed to map out the philosophical framework into which digital tools in construction management must transform by identifying existing technological gaps in the literature. In this context, for future academic studies, it is of paramount importance to develop deep reinforcement learning and game theory-based decision models capable of proactively forecasting wastes by processing heterogeneous data from the field. Finally, user-friendly, short-interval visual work instruction interfaces that optimize the participation of architects, engineers, foremen, and craftsmen in decisions should be developed, and empirical research

should be conducted on dynamic trust-calibration mechanisms between humans and artificial intelligence.

Abstract. Buildings are among the largest contributors to global energy consumption and greenhouse gas emissions, making the reduction of energy demand essential for sustainable development. This study investigates the effects of night ventilation and thermal insulation on the cooling energy performance of an existing public building in Sakarya, Türkiye, using dynamic EnergyPlus simulations under typical meteorological year weather conditions. Four scenarios were evaluated: a baseline case, night ventilation only, wall and roof insulation, and the combined application of insulation and night ventilation. Annual cooling energy consumption and electricity-related carbon dioxide equivalent (CO_2-eq) emissions were analyzed to assess the energy and environmental performance of each passive strategy. Wall and roof insulation reduced annual cooling energy consumption from 18.98 to 10.99 kWh/m²/y, corresponding to energy savings of approximately 42.1% compared with the baseline. Night ventilation alone, implemented as a cost-free passive cooling strategy, reduced cooling energy consumption to 17.89 kWh/m²/y, achieving approximately 5.7% energy savings without additional operational energy consumption. The combined strategy further reduced cooling energy consumption to 9.42 kWh/m²/y, increasing total energy savings to approximately 50.4%. Likewise, CO_2-eq emissions declined from 39.92 to 37.63, 23.11, and 19.81 tCO_2-eq for the night ventilation, insulation, and combined scenarios, respectively. These findings demonstrate that integrating night ventilation with conventional building envelope improvements can substantially reduce cooling energy demand and greenhouse gas emissions in existing public buildings.

Keywords: Cooling Energy Consumption; Passive Cooling Strategy; Building Energy Performance; EnergyPlus

1 Introduction

The rapid growth in global energy demand has become one of the defining challenges of the 21st century, driven by economic expansion, population increase, urbanization, and improvements in living standards. According to the International Energy Agency, global primary energy consumption has increased substantially since 1990 and is expected to continue rising in the coming decades if current trends persist [1]. This increase is particularly pronounced in developing economies, where industrialization and urban growth significantly accelerate energy use [2]. As a result, the relationship between energy consumption, energy security, and climate change has become increasingly complex. Indeed, a large share of global greenhouse gas emissions is directly linked to energy production and consumption, highlighting the urgent need for more efficient and sustainable energy use [3], [4].

Within this context, the building sector plays a critical role due to its substantial share in total energy consumption and emissions. Buildings account for a considerable portion of global final

energy use, primarily driven by heating, cooling, ventilation, and lighting [5]. In addition to energy consumption, buildings are responsible for a significant fraction of global carbon emissions, both directly and indirectly [6]. These figures underline the importance of improving energy performance in buildings as part of broader climate mitigation strategies.

Recent trends indicate that energy demand in buildings is not only increasing in magnitude but also changing in structure. In particular, cooling demand has emerged as one of the fastest-growing components of building energy use. Rising global temperatures and increasing expectations for indoor thermal comfort have intensified the need for space cooling, especially in urban environments. Projections suggest that cooling energy demand will continue to grow significantly in the coming decades, potentially doubling by mid-century [3], [4]. This trend is further reinforced by the anticipated expansion of cooled floor area, particularly in developing regions.

At the national level, Türkiye has experienced a steady increase in energy consumption over the past two decades, closely linked to economic growth, industrial development, and demographic changes. The residential and service sectors have shown a particularly strong upward trend, driven by urbanization, increased building stock, and wider adoption of electrical appliances [7]. Given these dynamics, improving energy efficiency in buildings has become a strategic priority for reducing both energy consumption and associated emissions.

In response to global and national challenges, various policy frameworks and international agreements have been established to promote energy efficiency and emission reduction. Agreements such as the Kyoto Protocol and the Paris Agreement have set global targets for limiting greenhouse gas emissions, while regional initiatives, including the European Green Deal, emphasize the transformation of the building sector toward low-carbon performance [8], [9]. Türkiye has also aligned with these efforts by adopting a carbon neutrality target for 2053 and implementing regulatory measures such as the Energy Performance of Buildings Regulation [10], [11].

In this framework, passive energy strategies have emerged as practical and sustainable approaches for reducing building energy demand while improving indoor thermal conditions. Unlike active mechanical systems, passive measures enhance building performance by optimizing the thermal behavior of the building envelope and utilizing natural environmental conditions. Among these strategies, thermal insulation and night ventilation have attracted considerable attention due to their potential to reduce cooling energy demand, particularly in climates where daytime heat gains can be mitigated through improved envelope performance and nighttime heat dissipation.

Therefore, this study aims to evaluate the impact of thermal insulation and night ventilation on the annual cooling energy consumption of a representative public building located in Sakarya, Türkiye. A simulation-based approach using EnergyPlus is employed to quantify the individual and combined effects of these strategies. The findings are expected to contribute to the implementation of energy-efficient passive strategies for improving the cooling performance of existing public buildings.

2 Research Background

Night ventilation has been established as a highly effective passive strategy for reducing cooling energy demand and enhancing indoor environmental quality across various climates. Large-scale evaluations of residential buildings indicate that night ventilation can reduce initial cooling loads by 10% to 40%, with average energy savings of 12 kWh/m²/y and potential contributions as high as 40 kWh/m²/y in high-demand scenarios [12]. In ultra-low energy buildings and desert regions, optimized ventilation schemes have demonstrated the capacity to achieve annual energy savings between 6.67 kWh/m² and 11.96 kWh/m² [13]. Theoretical models further support these findings, suggesting that increasing a building's thermal time

constant through strategic mass utilization can reduce overall cooling loads by more than 60% [14].

Beyond energy savings, night ventilation significantly improves occupant comfort by lowering indoor temperatures and extending the duration of the thermal comfort zone [15]. Field measurements in extremely hot-arid climates show that nighttime ventilation can reduce indoor air temperatures by up to 3.80 °C and mitigate next-day peak temperatures by approximately 3.20 °C [15]. The efficacy of this technique is further amplified through innovative material integration; for instance, combining wall-attached jet ventilation with phase change material wallboards can enhance room air temperature reduction by 94.97% and extend comfort hours by 38.42% [16]. Strategic operational schedules, such as opening windows from late afternoon until the following morning (17:00–09:00), are essential for maximizing heat dissipation and offsetting the significant thermal gains associated with human activity [17].

3 Research Methodology

This study adopted a simulation-based methodology to investigate the effectiveness of passive cooling strategies in reducing the cooling energy demand of an existing public building located in Sakarya, Türkiye. The methodological framework combines dynamic building energy simulation with environmental impact assessment to quantify both energy savings and the associated reduction in carbon dioxide equivalent (CO_2-eq) emissions. The workflow consists of sequential stages including building energy model development, implementation of passive energy strategies, automated simulation of different scenarios, and evaluation of energy and environmental performance. The overall research procedure followed throughout the study is illustrated in Figure 1.

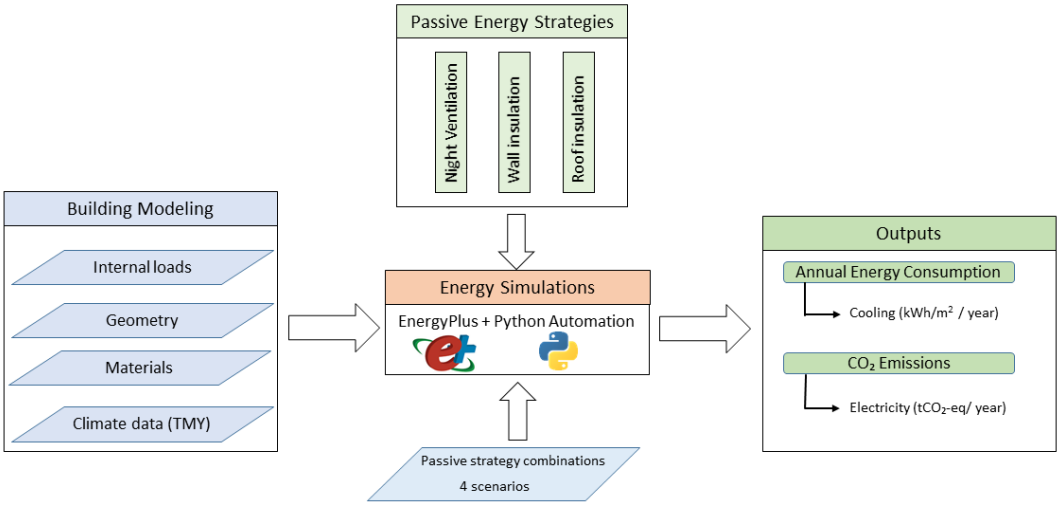

Fig. 1. Workflow of the research methodology

3.1 Building Description and Energy Model Development

The study was conducted using a representative four-storey office building located in Sakarya, Türkiye (Fig. 2). A dynamic building energy model was developed in EnergyPlus to evaluate the influence of passive cooling strategies on the building's cooling energy demand under local climatic conditions. The building model incorporated the architectural geometry, construction assemblies, occupancy schedules, internal heat gains, and HVAC system characteristics to represent the operational conditions of the existing building.

Fig. 2. Reference office building used in the simulations

The building envelope consisted of external walls, roof, ground floor slab, and ceiling assemblies with material properties defined according to the existing building characteristics. The construction assemblies and selected thermophysical properties of the building envelope used in the simulations are summarized in Table 1.

Table 1. Construction layers and thermal properties of the reference building envelope

Construction Element	Material Layer	Thickness (m)	Thermal Conductivity (W/m·K)
External wall	Cement plaster	0.03	1.60
	Insulation (EPS)	0.05	0.035
	Brick	0.19	0.50
	Gypsum plaster	0.03	0.70
Ground floor slab	Granite tiles	0.02	2.80
	Cement finish	0.05	1.40
	Reinforced concrete	0.12	2.50
	Lean concrete	0.10	1.65
	Stone chips	0.20	0.7
Ceiling	Granite	0.02	2.80
	Reinforced concrete	0.12	2.50
	Plaster ceiling panel	0.0125	0.17
Roof	Gravel	0.10	2.00
	Geotextile felt	0.005	0.04
	Insulation (XPS)	0-0.05	0.035
	Cement finish	0.05	1.40
	Lean concrete	0.10	1.65
	Reinforced concrete	0.12	2.50
	Gypsum plaster	0.003	0.7

Cooling energy simulations were performed using EnergyPlus under typical meteorological year weather data representing the climatic conditions of Sakarya. Mechanical cooling was modeled using electricity-driven air-conditioning systems with a cooling setpoint temperature of 25 °C, meaning that the cooling system was activated whenever the indoor air temperature exceeded the specified setpoint.

3.2 Passive Cooling Scenarios and Simulation

Four simulation scenarios were established to evaluate the individual and combined effects of night ventilation and thermal insulation on the building cooling performance. The baseline scenario represented the existing building without any passive improvement. The second scenario incorporated night ventilation only, while the third scenario considered the application of thermal insulation to the external walls and roof. The fourth scenario combined both night ventilation and thermal insulation to assess the cumulative effect of multiple passive cooling strategies.

Night ventilation was modeled as a natural ventilation strategy in EnergyPlus using an air change rate of 6 ACH. To represent realistic building operation, natural ventilation was scheduled to operate only during the cooling season, extending from May to September, and remained active between 20:00 and 08:00. In addition, the ventilation schedule was restricted to working days only, while weekends and public holidays were excluded from the operation schedule.

Thermal insulation was modeled by introducing a 5 cm expanded polystyrene (EPS) insulation layer to the external walls and a 5 cm extruded polystyrene (XPS) insulation layer to the roof. Apart from these passive strategy modifications, all simulation scenarios maintained identical building geometry, internal loads, occupancy schedules, HVAC settings, and weather conditions to ensure that differences in cooling energy demand resulted solely from the investigated passive measures.

EnergyPlus simulations for all scenarios were automatically generated and executed using Python-based automation. The automation procedure eliminated repetitive manual operations, ensured consistent simulation settings across all scenarios, and minimized the possibility of user-induced modeling errors.

3.3 Energy and Environmental Performance

The annual cooling energy consumption obtained from each simulation scenario was used to evaluate the effectiveness of the investigated passive cooling strategies. Since cooling operation was scheduled only during the period from May to September, the reported annual cooling energy consumption represents the cumulative electricity demand during the building's active cooling season. Following the energy simulations, electricity-related carbon dioxide equivalent (CO_2-eq) emissions were calculated using the annual cooling electricity consumption and the corresponding national electricity emission factor. Because the cooling system was modeled as an electricity-driven air-conditioning system, the electricity emission factor of 0.478 tCO_2-eq/MWh for the Turkish electricity generation and distribution system was adopted from the Ministry of Energy and Natural Resources [18]. The annual cooling-related CO_2-eq emissions were calculated using Eq. (1).

$$E_{CO_2\text{-eq}} = Q_{electricity} * EF_{electricity} \quad (1)$$

where $E_{CO_2\text{-eq}}$ denotes the annual carbon dioxide equivalent emissions (tCO_2-eq), $Q_{electricity}$ is the annual cooling electricity consumption and $EF_{electricity}$ represents the electricity emission factor. The calculated cooling energy consumption and corresponding CO_2-eq emissions were subsequently compared among the four simulation scenarios to quantify the energy-saving and environmental benefits of the investigated passive cooling strategies.

4 Results and Discussion

Table 2 presents the annual cooling energy consumption obtained for the four simulation scenarios. The baseline building (S1) exhibited an annual cooling energy demand of 18.98 kWh/m²/y. Implementing night ventilation alone (S2) reduced the cooling energy demand to 17.89 kWh/m²/y. Applying thermal insulation to the external walls and roof (S3) produced a substantially greater reduction, decreasing the annual cooling energy consumption to 10.99 kWh/m²/y. The lowest cooling energy demand was achieved when night ventilation was

combined with wall and roof insulation (S4), resulting in an annual cooling energy consumption of 9.42 kWh/m²/y. These results indicate that although thermal insulation provides the greatest individual contribution to reducing cooling demand, its effectiveness can be further enhanced when integrated with night ventilation.

Table 2. Annual cooling energy consumption under different simulation scenarios

Scenarios	Passive strategy	Cooling energy consumption(kWh/m²/y)
S1	Baseline	18.98
S2	Night ventilation	17.89
S3	Wall + roof insulation	10.99
S4	Night ventilation + wall + roof insulation	9.42

The comparative energy savings and corresponding electricity-related CO_2-eq emissions for each scenario are summarized in Table 3. Compared with the baseline scenario, night ventilation alone reduced cooling energy consumption by 1.09 kWh/m²/y, corresponding to an energy saving of 5.7%, while the associated CO_2-eq emissions decreased from 39.92 to 37.63 tCO_2-eq. The application of wall and roof insulation achieved a considerably larger reduction of 7.99 kWh/m²/y, representing an energy saving of 42.1%, and lowered annual emissions to 23.11 tCO_2-eq. The combined implementation of insulation and night ventilation produced the highest overall performance, reducing cooling energy consumption by 9.56 kWh/m²/y (50.4%) and decreasing annual CO_2-eq emissions to 19.81 tCO_2-eq.

Table 3. Energy performance and annual CO_2-eq emissions of the analyzed scenarios

Scenarios	Energy consumption (kWh/m²/y)	Energy savings (kWh/m²/y)	Energy savings (%)	Annual CO_2-eq emissions (tCO_2-eq/y)
S1	18.98	-	-	39.92
S2	17.89	1.09	5.7%	37.63
S3	10.99	7.99	42.1%	23.11
S4	9.42	9.56	50.4%	19.81

From a practical perspective, thermal insulation is a well-established passive strategy that effectively limits heat transfer through the building envelope and therefore provides substantial reductions in cooling energy demand. However, the results demonstrate that additional improvements can be achieved by integrating insulation with night ventilation. Unlike conventional insulation measures, natural night ventilation is essentially a free passive cooling strategy, utilizing cooler outdoor air during nighttime to dissipate the heat accumulated within the building without additional energy consumption. When combined with the thermal resistance provided by the insulated envelope, this approach results in greater reductions in both cooling energy consumption and CO_2-eq emissions than insulation alone. These findings highlight that combining conventional envelope improvements with free passive cooling strategies can provide a more effective approach to improving the energy and environmental performance of existing public buildings while supporting national and global energy efficiency and carbon reduction targets.

5 Conclusion

This research demonstrates the significant potential of integrated passive strategies in mitigating the cooling energy demand of public buildings in temperate climates such as Sakarya, Türkiye. The empirical findings reveal that while individual interventions, such as the application of wall and roof insulation, yield a substantial 42.1% reduction in cooling loads, the efficacy of these measures is optimized through the inclusion of night ventilation. The study highlights a critical synergy: the thermal resistance provided by an insulated envelope, when coupled with the heat dissipation capability of a cost-free night ventilation schedule, achieves a cumulative energy saving of 50.4%. By reducing the annual cooling consumption from 18.98

kWh/m²/y to 9.42 kWh/m²/y, this integrated approach proves that conventional envelope improvements can be significantly enhanced by strategic natural ventilation without incurring additional operational energy costs.

From an environmental and policy perspective, the implementation of these passive cooling interventions provides a robust pathway toward achieving broader decarbonization targets. The analysis indicates that the combined scenario effectively halves the building's carbon footprint, reducing annual electricity-related emissions from 39.92 to 19.81 tCO_2-eq. Such a drastic reduction aligns with Türkiye's national commitment to reach carbon neutrality by 2053 and adheres to the frameworks established by the Paris Agreement. Ultimately, this study underscores that prioritizing evidence-based passive design in the retrofitting of existing public building stocks is essential for reducing reliance on mechanical cooling systems and fostering sustainable urban development in the face of rising global temperatures.

Abstract. Bricklaying activities carried out at construction sites require close monitoring throughout all processes due to the intense physical exertion and dynamic working conditions involved. In this study, activity classification was performed using wearable inertial measurement unit (IMU) data collected from a worker assisting bricklayers by carrying materials and preparing mortar. Time-series data were gathered from tri-axial accelerometer, gyroscope, and magnetometer sensors; the worker's activities were categorized into three classes: material preparation, material transport, and idle. The classification problem was addressed using a Long Short-Term Memory (LSTM)-based deep learning approach, given its ability to model sequential dependencies. The proposed LSTM model achieved an activity classification accuracy of 85%. The findings indicate that multi-sensor IMU data is effective in distinguishing workers' primary tasks in the field, and that LSTM-based models could be considered a viable solution for real-time monitoring, workload analysis, and safety-focused decision support systems.

1 Introduction

The construction industry is a dynamic production environment in which numerous work tasks are carried out simultaneously, substantial physical effort is required, and working conditions continuously change. On construction sites, activities such as excavation, formwork, reinforcement, concrete pouring, material handling, assembly, and bricklaying expose workers to various postures, lifting, carrying, reaching, and repetitive movements. Due to these characteristics, construction operations are regarded as labor-intensive processes that require close monitoring in terms of both occupational health and safety and productivity [5, 6]. Within these processes, bricklaying work is one of the fundamental and widely performed activities in building production. It requires workers to carry out sequential and repetitive tasks such as transporting bricks or blocks, preparing and applying mortar, and aligning and placing bricklaying units. In particular, material handling and mortar preparation tasks that support bricklaying operations involve ergonomic risk factors, including prolonged standing, bending, twisting, lifting loads, and repetitive use of the upper extremities. These conditions increase workers' levels of physical strain and have direct implications for both work performance and occupational safety [1].

Construction sites are among the most physically demanding and hazardous occupational environments. Workers engaged in bricklaying support tasks — such as transporting materials and preparing mortar — perform highly repetitive motions that elevate the risk of

musculoskeletal disorders (MSDs), fatigue-related accidents, and reduced productivity [1, 3]. Continuous and objective monitoring of worker activities is therefore essential for proactive safety management and workload optimization.

Traditional activity monitoring approaches on construction sites rely on direct observation or video analysis, both of which are labour-intensive and prone to observer bias [10, 12]. Wearable inertial measurement unit (IMU) sensors offer a practical alternative: they are lightweight, unobtrusive, and capable of capturing rich kinematic information through tri-axial accelerometers, gyroscopes, and magnetometers [2, 14].

Deep learning approaches, and recurrent architectures in particular, have demonstrated strong performance on human activity recognition (HAR) tasks because they can model temporal dependencies within time-series sensor data. Long Short-Term Memory (LSTM) networks are specifically designed to address the vanishing gradient problem that limits standard recurrent networks, making them well-suited for recognising construction activities characterised by variable-length motion patterns [11, 16].

Several studies have investigated construction activity recognition using machine learning and deep learning methods based on motion sensor data. Kim and Cho (2020) [9] analyzed 14 fundamental construction activities in a quasi-experimental testbed and evaluated the influence of sensor number and body placement on recognition performance. Slaton et al. (2020) [13] collected data from construction equipment in a site environment and classified seven machine activities using CNN and ConvLSTM models. Zhao and Obonyo (2020) [15] employed ConvLSTM, CNN, and LSTM models to recognize eight worker stopping activities, while Bangaru et al. (2021) [2] classified 15 scaffolding erection activities using deep artificial neural networks. Jacobsen et al. (2023) [4] applied ConvLSTM to estimate direct work, indirect work, and waste activities. Karatas and Budak, on the other hand, sought to predict construction activities using both machine learning [8] and deep learning [7], based on data collected in a real construction site environment.

Despite this progress, relatively few studies focus on the activity patterns of support workers — those who supply and prepare materials for skilled tradespeople such as bricklayers. These workers perform distinct repetitive motion patterns that differ substantially from equipment operators and static workers, motivating the specialised dataset and classification approach developed in this paper.

This paper presents an LSTM-based activity classification system for bricklaying support workers equipped with a wrist-worn IMU sensor. The study contributes: (1) a labelled IMU dataset covering three construction-specific activity classes; (2) a sliding-window preprocessing pipeline; (3) an LSTM architecture tuned for on-site activity recognition; and (4) a classification evaluation achieving 85% accuracy across all three classes.

2 Methodology

Fig. 1 illustrates the methodology employed in this study. Accordingly, the data collection phase was first conducted by attaching a sensor to the arm of an assistant worker involved in bricklaying operations. The collected data were then subjected to preprocessing procedures to make them suitable for model development. Following model training and evaluation, the activities performed by the bricklaying assistant worker were predicted with a certain level of accuracy.

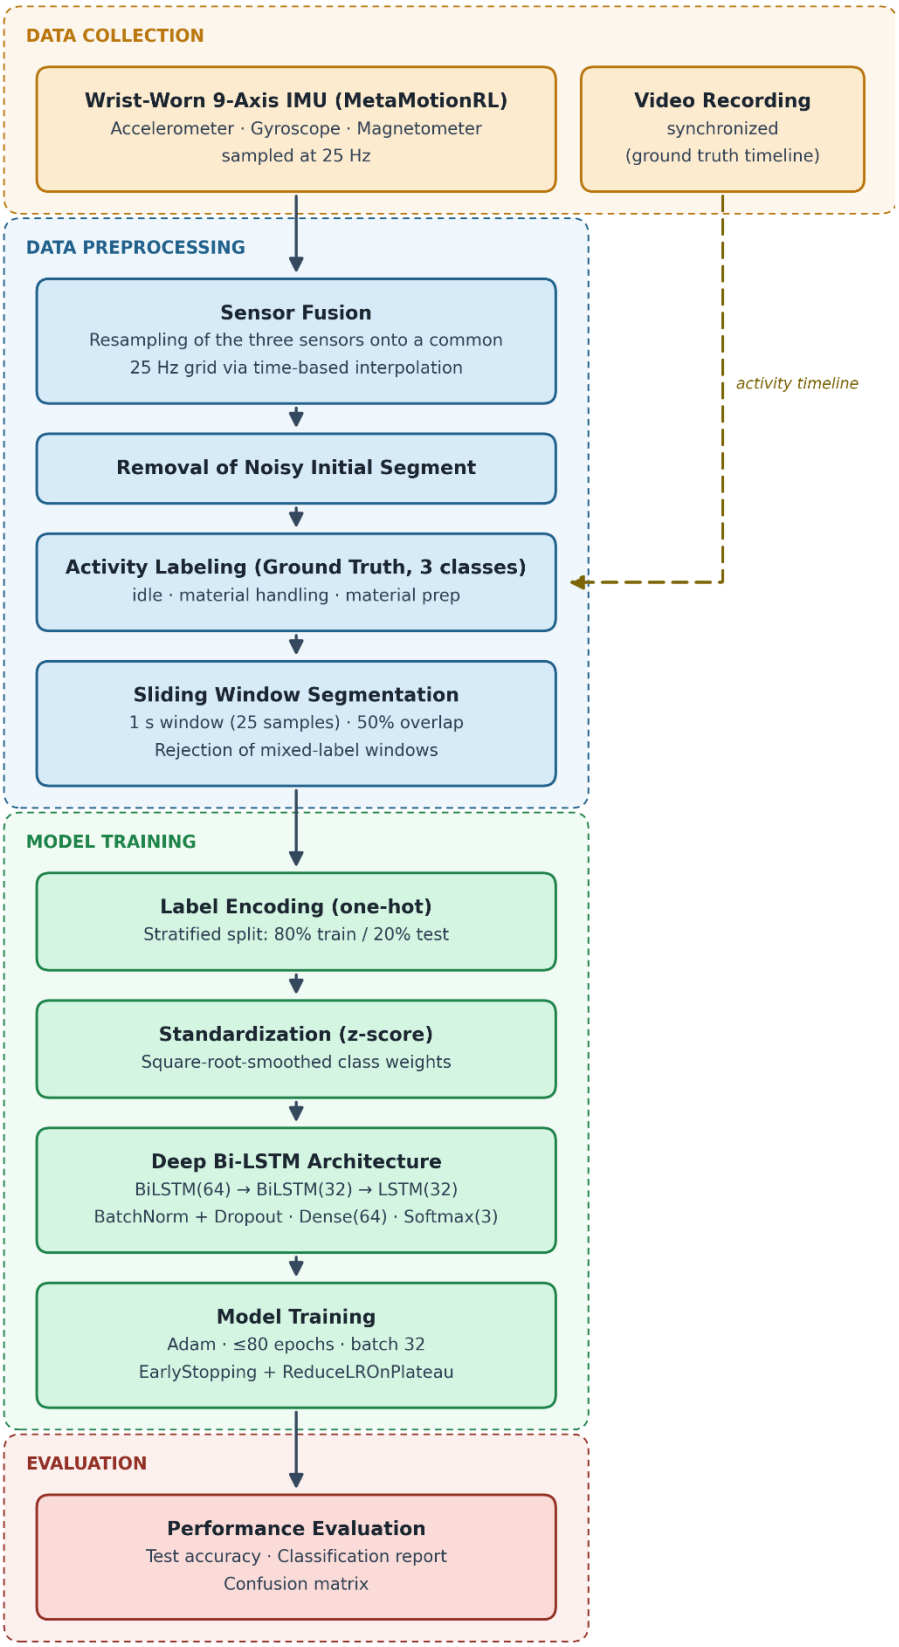

Fig. 1. Research Methodology Flowchart

2.1 Data Collection

IMU data were collected from one male construction worker assisting a bricklaying crew at an active residential construction site. An IMU sensor module with a sampling rate of 25 Hz was attached to the worker's dominant wrist. The module simultaneously recorded nine data

channels, including tri-axial accelerometer data (ax, ay, az), tri-axial gyroscope data (gx, gy, gz), and tri-axial magnetometer data (mx, my, mz). Activity labels were subsequently assigned based on video recordings captured while the worker was performing the tasks.

Based on site observations, three activity classes representing the main bricklaying support tasks were defined, as shown in Figure 2. (1) Material Preparation — mixing mortar at a stationary workstation; (2) Material Transport — carrying bricks or mortar buckets between the storage area and the active work face; and (3) Idle — rest periods, waiting, and brief tool adjustments. A total of 4.2 hours of labelled data were collected, comprising approximately 756,000 samples.

a) Material Preparation b) Material Transport

c) Idle

Fig. 2. Representative activity classes for Bricklaying support tasks

2.2 Data Preprocessing

Raw sensor signals were segmented using a sliding-window scheme with a window length of 2.56 seconds (128 samples at 50 Hz) and 50% overlap, yielding 11,718 windows across all

three activity classes. Each window produces a 128 × 9 input tensor for the LSTM model. Prior to segmentation, signals were normalised to zero mean and unit variance using statistics computed from the training set only, to prevent data leakage. The dataset was split into training (70%), validation (15%), and test (15%) subsets using stratified sampling. Class imbalance was addressed by applying class-weighted loss during training, as the idle class constituted only 18% of total windows.

2.3 LSTM Architecture

The classification model consists of two stacked LSTM layers followed by fully connected layers. The first LSTM layer contains 128 units and returns the full sequence; the second LSTM layer contains 64 units and returns only the final hidden state. Dropout with rate 0.3 is applied after each LSTM layer to reduce overfitting. A Dense layer with 32 ReLU units precedes the softmax output layer over three classes.

Table 1. LSTM model architecture.

Layer	Configuration	Output Shape
Input	128 time steps × 9 channels	(128, 9)
LSTM-1	128 units, return_sequences=True, Dropout 0.3	(128, 128)
LSTM-2	64 units, return_sequences=False, Dropout 0.3	(64,)
Dense	32 units, ReLU	(32,)
Output	3 units, Softmax	(3,)

2.4 Training Configuration

The model was implemented in Python using TensorFlow 2.x / Keras and trained for 50 epochs with a batch size of 64 using the Adam optimiser (learning rate: 0.001). Categorical cross-entropy with per-class weights was used as the loss function. Early stopping with patience of 10 epochs on validation loss was applied to prevent overfitting. All experiments were conducted on an NVIDIA RTX 3060 GPU.

3 Results and Discussion

3.1 Classification Performance

The proposed LSTM model achieved an overall accuracy of 85% on the held-out test set. Table 2 reports per-class results. Material Transport was recognised with the highest F1-score (0.88), benefiting from distinctive repetitive arm-swing patterns during load-carrying. Material Preparation showed slightly lower recall (0.81) due to partial overlap with idle postures during brief pauses in the mixing activity. The Idle class yielded the lowest F1-score (0.82), consistent with its heterogeneous nature.

Table 2. Per-class classification performance on the test set.

Activity Class	Precision	Recall	F1-Score	Support (windows)
Material Preparation	0.86	0.81	0.83	432
Material Transport	0.89	0.87	0.88	578
Idle	0.83	0.80	0.82	247
Macro avg.	**0.86**	**0.83**	**0.85**	**1,257**

Fig. 3 presents the training performance and confusion matrix of the activity recognition model. The training and validation accuracy curves show a steady increase across epochs, indicating that the model successfully learned the temporal patterns in the IMU data. The validation accuracy stabilizes at a high level, suggesting a satisfactory generalization performance. According to the confusion matrix, the model achieved strong classification

performance, particularly for the Idle and Material Preparation classes. However, some misclassifications were observed between Idle and Material Handling, which may be attributed to similarities in wrist movement patterns during these activities. Overall, the results indicate that the proposed IMU-based model can effectively recognize bricklaying support activities with promising accuracy.

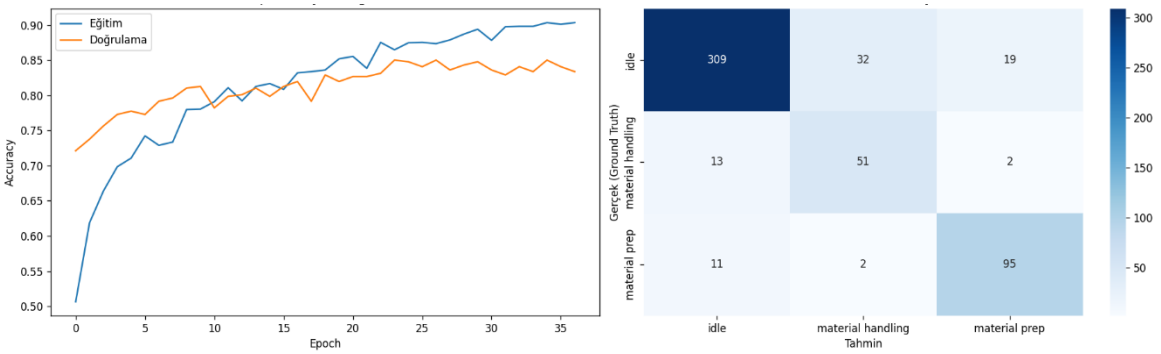

Fig. 3. Model evaluation results based on training curves and confusion matrix

3.2 Discussion

The 85% accuracy demonstrates that wrist-worn IMU sensors capture sufficient kinematic variation to distinguish the three bricklaying support activities under real construction conditions. Ablation tests removing the magnetometer channels reduced accuracy to 83%, suggesting that orientation information aids disambiguation of similar translational patterns. To contextualise the results, two baseline classifiers were trained on the same data: a Random Forest (RF), and a single-layer LSTM with 64 units. The two-layer LSTM outperformed both: the RF achieved 78% accuracy and the single-layer LSTM 82%. The gain over the RF confirms that temporal modelling of the raw sequence provides information not captured by aggregate statistical features. The primary limitation is the single-subject dataset. Variability in body size, carrying technique, and work pace across workers will likely reduce generalisation. Future work should collect data from a larger cohort and evaluate subject-independent performance.

4 Conclusion

This paper presented an LSTM-based activity classification system for bricklaying support workers using wrist-worn IMU sensors. A sliding-window dataset of 11,718 labelled windows was constructed from nine-channel IMU recordings collected on an active construction site. The two-layer LSTM model achieved 85% overall accuracy, outperforming a hand-crafted feature Random Forest baseline by 7 percentage points. The results confirm that wearable IMU sensors combined with LSTM-based deep learning are a viable approach for automatic activity monitoring of construction support workers.

Future research will address cross-worker generalisation through transfer learning, extend the activity taxonomy to include additional support tasks, and investigate edge deployment of the model on low-power microcontrollers for real-time on-body inference.

ABSTRACT

Artificial intelligence (AI) is increasingly used to support planning, monitoring, risk analysis, forecasting and other decision-intensive activities in construction management. Recent research demonstrates substantial progress in the technical capabilities of AI-based decision support systems (DSS), yet technical performance alone does not explain whether these systems improve managerial decisions in practice. This literature-based discussion examines the transition from AI capability to managerial decision quality by bringing together research on technical AI applications in construction, substantive system use, explainability and trust, and human-AI interaction. Recent construction studies combine predictive analytics with explainability, structured decision methods and expert involvement, while broader DSS research highlights the importance of system use, human judgement and appropriate reliance. The paper distinguishes organisational adoption from the substantive incorporation of AI capabilities into managerial work and uses this distinction to examine how technical capability may acquire practical decision value. The discussion identifies a need for construction-specific empirical research on how managers use, question and combine AI-generated information with professional judgement, and how these patterns of use relate to managerial decision quality.

Keywords: AI-based decision support systems; construction management; managerial decision quality; explainability; trust; substantive system use; human-AI interaction

1 Introduction

Construction management involves interdependent decisions concerning planning, scheduling, cost, resources, risk, safety and project control. These decisions are often made under uncertainty, time pressure and incomplete information. As construction projects generate increasing volumes of digital data, artificial intelligence (AI) has extended conventional decision support through prediction, pattern recognition, optimisation and real-time analysis [1-3,6].

Recent research demonstrates substantial growth in the technical capabilities of AI in construction. Machine learning, deep learning, computer vision and related techniques are increasingly applied to safety management, cost estimation, scheduling, monitoring and risk assessment [1-3]. Systematic reviews also show a growing role for AI-based decision support systems (DSS), although much of the literature remains concentrated on prediction and technically oriented applications [3,6]. Construction-specific systems illustrate this progress: Zorrilla et al. [7] combine machine learning and explainable AI (XAI) to support proactive risk identification, while Mlybari and Elgohary [8] integrate predictive analytics, multi-criteria decision-making and XAI within a construction value-management framework.

However, technical capability alone does not establish managerial value. Construction AI research continues to report problems related to fragmented implementation, data quality,

interoperability, interpretability and organisational readiness [3,4]. Construction decisions also depend on contextual knowledge, professional judgement and project-specific conditions that cannot always be represented completely by algorithmic models [3,9]. Predictive accuracy or analytical sophistication therefore does not by itself demonstrate that AI-generated information is understood, accepted or incorporated into managerial decisions.

This distinction directs attention to the difference between technology adoption and substantive system use. The Technology Acceptance Model (TAM) and Unified Theory of Acceptance and Use of Technology (UTAUT) explain important determinants of technology acceptance and behavioural intention [14,15]. Yet organisational adoption does not necessarily indicate how available system capabilities are used in practice. Drawing on the broader conceptualisation of system usage proposed by Burton-Jones and Straub [16], this paper uses substantive system use to refer to the extent to which available AI capabilities are incorporated into managerial decision processes.

A further issue concerns how managers interpret and evaluate AI-generated recommendations. Research on XAI and trust shows that high predictive performance may be insufficient when users cannot understand the basis of an output or do not consider it sufficiently reliable for use in a decision [10-13]. Recent AI-DSS research also indicates that transparency and trust can influence adoption and decision outcomes [19,20]. In construction, Mlybari and Elgohary [8] report improved decision consistency and greater stakeholder satisfaction with decision transparency when predictive analytics, structured decision methods and XAI are integrated in a construction decision-support environment.

Human-AI interaction therefore becomes central to AI-supported managerial decision-making. Research on hybrid intelligence and human-AI symbiosis emphasises complementary roles for computational analysis and human expertise [17,18]. Construction-specific work is beginning to reflect this perspective. Sarkheyli-Hagele et al. [9], for example, propose an expert-in-the-loop DSS for megaproject risk management in which AI-generated analysis is combined with domain knowledge and continuous human feedback.

The central question in this paper is therefore how technical AI capability becomes meaningful input to managerial decision-making. Construction research has begun to integrate technical AI capability, explainability and stakeholder-centred decision support in specific applications [7-9]. Nevertheless, the broader process through which organisational adoption becomes substantive system use, and how such use interacts with explainability, trust and human-AI interaction to shape managerial decision quality, remains insufficiently explained across construction management contexts. The purpose of this paper is not to propose or validate a causal model, but to clarify these conceptual connections and identify where further construction-specific empirical evidence is required. The contribution of this paper lies in reframing the managerial value of AI-based DSS as a transition from technical capability to substantive system use and, ultimately, managerial decision quality, while positioning explainability, trust and human-AI interaction as conditions shaping this transition.

2 Literature-Based Analytical Perspective

This study uses a narrative literature-based approach to examine how AI-based decision support moves from technical capability to managerial use in construction. The discussion draws on construction management, information systems and human-centred AI research because no single literature adequately captures this transition. Construction studies provide evidence on AI applications and implementation challenges [1-9], while information systems and human-centred AI research offers concepts for examining technology use, trust and the role of human judgement in decision support [10-23].

Sources were selected purposively for their relevance to the analytical relationships examined in this paper rather than through a systematic-review protocol. Priority was given to

construction-specific reviews and applications, complemented by established studies from information systems and human-centred AI where construction literature did not provide sufficient conceptual grounding. The selected studies are used to develop an analytical interpretation rather than an exhaustive classification of the literature. Particular attention is given to findings that help explain the gap between what an AI-based DSS is technically capable of doing and how its outputs become part of managerial decisions. The resulting discussion focuses on connections across the literature and on questions that remain insufficiently examined in construction-specific settings.

3 From Technical Capability to Managerial Decision Quality

3.1 Technical AI Capability in Construction Management

AI applications in construction management have expanded from relatively specific predictive tasks to a broader range of project functions. Machine learning, deep learning, computer vision and optimisation are now used in areas including cost estimation, scheduling, safety, progress monitoring and risk management [1-3]. AI is also increasingly integrated with digital environments such as BIM, enabling project data to support more responsive forms of analysis and decision support [5].

Recent reviews confirm both the scale of this development and its continuing technical orientation. Razi et al. [3], in a systematic review of 191 studies published between 2020 and 2025, identify risk and safety management, decision support, and monitoring and control among the main areas of AI application in construction management. Smith and Wong [6] similarly show that a substantial share of construction AI-DSS research has focused on prediction, particularly in early project stages. Together, these studies indicate a field with growing analytical capability but a strong emphasis on what AI systems can predict, detect or optimise.

More recent applications show a gradual move towards decision-oriented systems. Zorrilla et al. [7] combine machine learning with XAI to identify emerging construction risks and provide interpretable information for proactive intervention. Mlybari and Elgohary [8] go further by combining predictive analytics, multi-criteria decision-making and XAI in a construction value-management framework, reflecting the broader integration of machine learning and structured multi-criteria methods in intelligent DSS [23].

These developments also reveal a distinction that is sometimes blurred in discussions of AI in construction. Analytical performance describes the capability of the system; decision support describes what happens when that capability enters a managerial process. Construction projects involve changing site conditions, multiple stakeholders and forms of professional knowledge that cannot always be reduced to model inputs [3,4]. Technical performance is therefore an important starting point, but it cannot on its own indicate how much managerial value an AI-based DSS creates. The question then becomes whether useful analysis is actually incorporated into managerial work.

3.2 Adoption and Substantive System Use

The adoption of an AI-based DSS is an important organisational step, but it says relatively little about what happens afterwards. TAM and UTAUT explain technology acceptance through factors influencing behavioural intention and use [14,15]. For the present discussion, however, the more relevant question is not simply whether managers accept a system, but how they engage with its capabilities once it becomes available.

This distinction follows the broader information systems view that system usage should be understood in relation to the user, the technology and the task being performed [16]. Accordingly, substantive system use is used here to describe the extent to which available AI capabilities are incorporated into managerial decision processes. The term does not represent a

new measurement construct; it provides a way of distinguishing meaningful engagement with AI-based DSS from their organisational presence alone.

This is particularly relevant in construction because implementation remains uneven and project organisations differ substantially in digital maturity, data availability and managerial routines [3,4]. Conceptually, an organisation may introduce an AI-enabled system without its analytical functions becoming a regular part of project decisions. Conversely, substantive use implies that relevant outputs, such as forecasts, risk indicators or alternative scenarios, are considered when managers evaluate a problem or choose a course of action. The issue is therefore not the number of times a system is accessed, but the role its analytical capabilities play in the work being performed.

Evidence from the broader AI-DSS literature suggests that this role may also depend on how users evaluate the system. Bondac et al. [19] found that transparency and data quality were associated with trust and that trust influenced adoption intention. Their results also linked adoption intention with decision-making efficiency. Although these findings come from outside the construction context, they show that adoption-related attitudes towards AI-DSS are shaped by how users evaluate the system and the information it provides [19]. They do not, however, establish how extensively the system is subsequently incorporated into managerial work.

3.3 Explainability and Trust in AI-Based Decision Support

The increasing use of complex AI models introduces a practical problem for decision support: a useful prediction may still be difficult for a manager to evaluate. Explainable AI addresses this problem by providing information about how an output was produced, which factors influenced it or why a particular recommendation was generated [10,11]. In a DSS context, this matters because managers are not only recipients of predictions; they must decide whether those predictions are relevant and credible enough to influence action.

Explainability should therefore not be treated simply as an additional technical feature. Coussement et al. [11] argue that the strong emphasis on predictive performance in AI can come at the expense of explainability, creating difficulties for decision-makers who need to understand and evaluate model outputs. Kostopoulos et al. [10] similarly identify transparency and interpretability as central concerns in XAI-based DSS. The practical purpose of an explanation is not to expose every technical detail of a model, but to provide information that helps the user evaluate its output.

Trust is closely related to this process, but the two concepts are not interchangeable. Lee and See [12] argue that effective automation depends on appropriate reliance rather than simply increasing trust. Too little trust may lead users to disregard useful recommendations, whereas excessive trust can result in uncritical acceptance. Research on human trust in AI likewise shows that trust depends on system performance, transparency, user characteristics and the context in which the system is used [13]. Explainability may contribute to trust, but an explanation does not automatically make an AI recommendation trustworthy.

This distinction is especially relevant in construction, where managerial decisions often require information to be interpreted against site conditions, stakeholder requirements and professional experience. Mlybari and Elgohary [8] integrate XAI into an AI-supported value-management framework and report greater stakeholder satisfaction with decision transparency alongside improved decision consistency. Their findings suggest that explanations can have practical value when they are incorporated into a structured decision process rather than presented as isolated technical outputs. Explainability and trust therefore help clarify why the availability of an AI capability does not guarantee its substantive use.

3.4 Human-AI Interaction and Managerial Decision Quality

AI-based decision support does not remove the need for professional judgement. Research on hybrid intelligence and human–AI symbiosis suggests that computational and human capabilities can play complementary roles in decision-making [17,18]. AI can process large datasets, identify patterns and generate forecasts, while managers contribute contextual knowledge, experience and an understanding of constraints that may not be represented in the data.

This complementary view is particularly relevant to construction projects. Sarkheyli-Hagele et al. [9] propose an expert-in-the-loop approach to megaproject risk management in which AI analysis is combined with domain expertise and continuous feedback. Their framework allows experts to validate, correct and contextualise machine-generated insights, keeping the system aligned with human judgement and changing project conditions. Mlybari and Elgohary [8] similarly place AI-generated analysis within a structured construction decision process involving multiple criteria and stakeholder input.

Managerial decision quality should be distinguished from the technical quality of the information produced by an AI system. Earlier DSS research demonstrates that improvements in information quality do not necessarily translate directly into better decisions because the relationship also depends on the quality of the decision-making process [21]. Raghunathan [21], for example, shows that the effect of information quality on decision quality varies with decision-maker quality. This distinction is particularly important in construction, where forecasts and recommendations must be interpreted in relation to project conditions, stakeholder requirements and professional experience.

The contribution of a DSS may therefore extend beyond supplying information. Nemati et al. [22] argue that decision-support effectiveness can also be understood in terms of how well a system improves the decision-maker's knowledge, mental models and understanding, and thereby supports better decision-making. AI-based DSS should therefore not simply generate more accurate outputs; they should also help managers understand and evaluate those outputs within the decision context.

Construction-specific evidence provides some support for this view. Mlybari and Elgohary [8] report improved decision consistency when predictive analytics, multi-criteria evaluation and explainability are combined within an integrated decision-support process. Their case validation showed an increase in decision consistency from 0.67 to 0.82, alongside greater stakeholder satisfaction with decision transparency. These findings suggest that decision-support value can emerge from the combination of analytical capability, structured evaluation and transparent interaction rather than from predictive performance alone.

Evidence from human-centred AI-DSS research provides a similar indication. Zalfani et al. [20] compared an explainable, human-centred DSS with a functionally equivalent black-box system and reported improvements in trust, transparency, usability and decision accuracy. Their system also incorporated structured user feedback, human oversight and user-override functionality, allowing users to retain meaningful control over final decisions. This pattern is consistent with the principle of appropriate reliance [12]: effective decision support does not require managers to defer automatically to AI, but to judge when its output should be accepted, questioned or supplemented by professional judgement.

The managerial value of an AI-based DSS can therefore be located neither in the algorithm alone nor in human judgement alone. It emerges from the way analytical capability is brought into the decision process, interpreted by the user and combined with contextual knowledge. Fig. 1 summarises this analytical perspective. The figure is intended to organise the relationships discussed in the literature rather than to represent an empirically validated causal model [8,9,12,17,18,20-22].

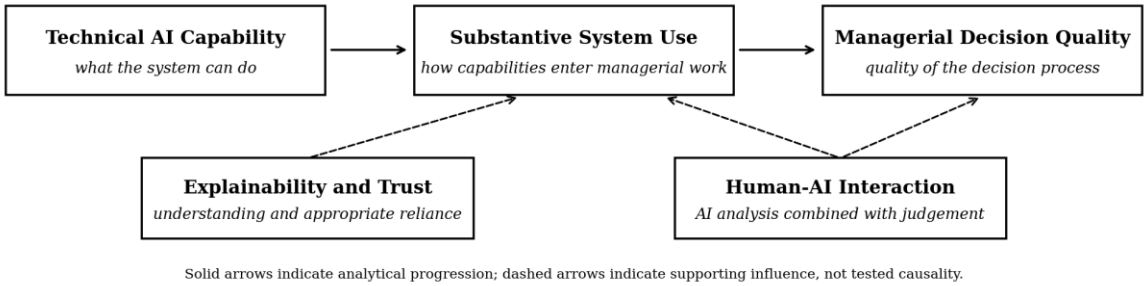

Fig. 1. Analytical perspective on AI-based decision support and managerial decision quality in construction management. Arrows indicate analytical relationships discussed in the literature rather than empirically established causal effects.

4 Research Gap and Future Research Direction

The literature reviewed here points to a broader issue than the limited adoption of AI in construction. Construction research has already demonstrated increasingly sophisticated AI applications and, more recently, has begun to combine predictive analysis with explainability, structured decision methods and human expertise [7-9]. These developments indicate that the field is moving beyond purely technical applications. However, the process through which technical AI capability becomes sustained and meaningful input to managerial decision-making remains insufficiently understood across construction contexts.

One part of this problem concerns the transition from adoption to substantive system use. Existing research provides considerable evidence on AI applications and implementation barriers [1-6], while recent reviews continue to report fragmented and inconsistent adoption in practice [3,4]. Organisational adoption, however, does not reveal which AI capabilities are actually incorporated into managerial work or how strongly they influence project decisions. The distinction between technology availability and substantive system use therefore requires greater attention in construction management research [16].

A related issue concerns explainability and trust. General AI-DSS research increasingly links transparency, explainability and trust with acceptance, reliance and decision outcomes [10-13,19,20]. Construction-specific studies also show growing interest in transparent and human-centred decision support [8,9]. Nevertheless, the literature reviewed here provides limited construction-specific empirical evidence on how explainability and appropriately calibrated trust affect managers' actual use of AI-generated information in managerial decision processes.

The literature reviewed here also provides limited evidence on the connection between substantive use and managerial decision quality. Construction applications demonstrate that AI, XAI and structured decision methods can improve particular aspects of decision support [7,8]. Broader DSS research, however, shows that better information does not automatically produce better decisions and that decision-maker quality and understanding remain important [21,22]. What is still unclear in construction is how AI-generated information is interpreted alongside professional judgement, project conditions and stakeholder requirements, and under what circumstances this interaction improves managerial decision quality.

These issues point to a research direction centred on the transition from technical capability to substantive system use and managerial decision quality, with explainability, trust and human-AI interaction shaping that transition. This perspective is analytical rather than causal. Future empirical research could examine which AI capabilities project managers actually use, how they assess and challenge AI-generated outputs, and whether different patterns of human-AI interaction are associated with differences in decision quality.

5 Conclusion

AI has substantially expanded the analytical capabilities available for decision support in construction management. Current applications demonstrate increasingly sophisticated uses in prediction, monitoring, risk analysis and structured decision-making [1-8]. However, the practical value of an AI-based DSS cannot be inferred from technical performance or organisational adoption alone. The central issue is how AI-generated information becomes part of managerial decision-making.

The literature reviewed in this paper suggests that substantive system use provides an important link between technical capability and managerial practice. Explainability and appropriately calibrated trust may affect whether AI-generated information is considered credible and usable, while human-AI interaction shapes how that information is interpreted alongside professional judgement [10-13,17-20]. More fundamentally, DSS research indicates that improvements in information quality do not necessarily translate directly into improvements in decision quality and that the knowledge and judgement of the decision-maker remain important [21,22]. Construction-specific studies are beginning to reflect this more interactive view of decision support [8,9], but evidence across project and organisational settings remains limited.

Future research should therefore examine AI-based DSS as part of the managerial decision process rather than evaluating them primarily through technical performance or adoption. Empirical studies are needed to establish which AI capabilities project managers actually use, how they evaluate and challenge AI-generated outputs, and how those outputs are combined with contextual knowledge and professional judgement. Such research would help clarify the conditions under which AI-based DSS contribute to higher-quality managerial decisions in construction management.

Abstract. This paper examines how restrictions on high-silica engineered stone are reshaping international trade for building and surface materials. Focusing on Australia as the most developed prohibition regime and comparing emerging approaches in the United States, Great Britain and New Zealand, the study evaluates how regulatory change affects import patterns, material substitution, customs classification and supplier competition. The analysis combines regulatory review with a descriptive assessment of Australian trade data for engineered-stone-associated product groups and natural stone. The findings indicate a clear contraction in trade categories linked to engineered stone, accompanied by stronger demand for natural stone and other alternatives, including porcelain, sintered surfaces and low-silica composite products. However, substitution is not certain and not evenly distributed among exporting countries. For Turkey, the changing market creates opportunities for natural stone exporters, particularly in higher-value finished and project-ready products. The paper concludes that engineered-stone restrictions can be perceived as a broader reshaping of the building materials market, in which regulatory compliance, product identity and supply-chain positioning increasingly shape international competitiveness.

Keywords: engineered stone; building material trade; natural stone; material substitution; Australia; Turkey; HS Code; market access

1 Introduction

Engineered stone is an industrially produced surface material that has become more and more popular over the last 20 years. It is made with the bonding of quartz and various types of aggregates through polymer resins, pigments and other additives. The success of the material in the global market can be attributed to wide range of uniform colour and pattern choices as well as the production cost efficiency along with the ability to mass produce granting competitive pricing [16]. Furthermore, the material has increasingly become a primary work safety concern in a few countries. As with other worktop materials engineered stones arrive at the area of construction as bulk slabs and are processed and cut to the shape desired. This situation causes silica in these materials to form tiny particles that can be inhaled by the workers [15].

Engineered stone commonly contains a substantially higher proportion of crystalline silica than most natural stones, with some products containing more than 90%, compared with much lower levels in marble and lower but variable levels in granite [15]. Cutting, grinding and polishing can release respirable particles that penetrate deep into the lungs and cause inflammation and irreversible fibrosis. Among engineered-stone workers, silicosis may develop after comparatively short and intense exposure histories and may continue to progress even after occupational exposure has ended. Advanced cases can result in severe respiratory impairment, lung transplantation or death, and no curative treatment is currently available [1,15,17]. The combination of high silica content, dust-intensive fabrication and rapidly

progressive disease helps explain why the regulatory response has moved beyond conventional workplace controls towards the elimination of particular products from the market.

The health effects associated with respirable crystalline silica generated during fabrication triggered the current regulatory response [1-4]. For trade analysis, the main development is that this response moved beyond workshop rules/basic safety measures. Australia removed a major category of slabs from domestic supply and then prohibited imports, converting an occupational health concern into a direct restriction on the trade and production of a building material. Other jurisdictions have not uniformly adopted a ban, but tighter rules, inspections and possible product restrictions are increasing compliance costs and regulatory uncertainty [5-11].

This paper analyses the extent of these regulations and how they have the potential to alter international trade for surface materials. It asks three questions: how a product restriction is transmitted to import flows; which substitute materials and supplier countries capture the displaced demand; and how Turkey can respond given its competitive advantage in natural stone. [14] The paper sees regulation as the initiator, while placing market substitution, customs classification, supplier competition and industrial adjustment at the centre of the analysis.

2 Engineered Stone in the Surface-Materials Market

Engineered stone occupies a specific segment between geologically formed natural stone and manufactured ceramic or sintered surfaces. Its industrial production permits large batches with controlled appearance, while the slab format allows the product to enter established worktop and interior design supply chains. The value chain extends from mineral aggregates, pigments and unsaturated polyester or other resins to slab producers, international distributors, local fabricators, installers and project contractors. A restriction at the slab stage therefore affects several upstream and downstream industries.

The relevant substitutes are not commercially identical. Natural marble, travertine, granite and quartzite offer variation and established premium or architectural identities, but may differ in weight, finishing requirements, maintenance and price. Resin-free porcelain and sintered surfaces can offer large formats and consistent appearance and are excluded from the Australian engineered-stone definition, while low-silica or silica-free composites attempt to preserve the standardisation advantages of engineered surfaces. Buyers can also move towards laminates, wood or stainless steel in specific price and design segments. Substitution is therefore a product range decision shaped by application, technical specification, consumer preference and the capabilities of local fabricators.

A restriction on silica heavy engineered stone redistributes demand. Importers replace prohibited or commercially risky product lines; retailers change catalogues and display ranges; architects revise material specifications; fabricators invest in new tooling or processing knowledge; and upstream suppliers reformulate products or seek other end uses. The final distribution of demand depends on relative prices, available colours and formats, fabrication costs, delivery times, warranty practices, brand recognition and access to contractors and designers. Regulatory status is one variable within this broader competition, but once market access is lost it can dominate the others.

3 Methodology and Limitations

Terminology in the manufactured-surface industry is not internationally uniform. In this paper, “engineered stone” is retained as the principal term because it is the terminology used in the Australian regulatory framework that forms the main case study. Commercial or regulatory expressions such as “quartz surface”, “engineered quartz” and “artificial stone” may overlap

with this category in other markets, but are not treated as legally interchangeable unless the relevant jurisdiction defines them as such.

The study uses a descriptive and comparative design updated through July 2026. It aims to depict the current issues and recent developments in the surface material trade through official regulations/stances and trade indicators. Primary sources include Safe Work Australia and Australian border-control materials, California legislation and Standards Board releases, British Health and Safety Executive guidance and enforcement communications, and New Zealand consultation documents. These sources are used only to establish the scope and timing of measures that can affect market access, product ranges and purchasing behaviour [2-12].

The trade component uses quarterly Australian import series compiled from ITC Trade Map [13]. Headings commonly associated with artificial, reconstituted or mineral stone products are combined as an engineered-stone proxy basket, while selected natural-stone groups are assessed separately. This approach reveals directional change but does not produce an exact measure of engineered-stone trade. Products can appear under headings such as 6810.11.90, 6810.99.90 and 6815.99, which also contain cement, concrete, other artificial-stone articles, mineral products and substitutes. A recovery in the engineered stone basket can consequently reflect alternative products rather than the return of prohibited slabs. The usage of the terms like countertops, worktops and benchtops vary between different geographies refer to the same function. Different terminology for engineered stone also may apply in different countries ie. in the US terms like quartz surfaces are widely used.

The analysis is not a causal estimate. Construction activity, exchange rates, prices, inventories and supplier strategy may also influence imports. Nor does a rise in natural-stone imports prove that all displaced engineered-stone demand moved to natural stone. The series is interpreted as evidence of a market break and subsequent reallocation across a wider building material product range.

4 Regulation and Market Access Shock

4.1 Australian Case of Ban

Australia provides the clearest trade case. From 1 July 2024, work involving the manufacture, supply, processing or installation of engineered-stone benchtops, panels and slabs was prohibited. For the purposes of the Australian model WHS Regulations, engineered stone is defined as at least 1% crystalline silica by weight, combines natural stone materials with chemical constituents such as resins or pigments, and is hardened into a product. Natural stone, concrete and cement products, ceramic tiles, resin-free sintered stone and resin-free porcelain are among the exclusions [2-4].

The decisive border measure followed on 1 January 2025, when engineered-stone benchtops, panels and slabs became prohibited imports under the Customs (Prohibited Imports) Regulations 1956 [4,5]. Safe Work Australia states that the import prohibition was designed to complement the domestic prohibition [4]. Commercially, this removed the principal route through which foreign slab producers supplied the Australian fabrication market. Importers and distributors had to replace affected stock-keeping units, verify whether alternatives fell outside the definition and redirect procurement towards natural stone, porcelain, sintered products or reformulated composites.

The 2025 review and January 2026 implementation plan show that the Australian market has entered a post-ban adjustment phase rather than returning to the pre-ban structure [6,7]. Questions concerning alternative materials, product classification, legacy stock and exemptions affect buyer confidence and the documentation expected from overseas suppliers. The result is

a lasting change in market organisation even where the immediate legal question appears settled.

4.2 Regulatory Diffusion and Market Behaviour

Outside Australia, regulation currently influences trade mainly through cost, uncertainty and anticipatory product range changes. California law prohibits dry methods for specified high-exposure tasks, requires effective wet methods and introduced annual training attestation from 1 July 2026 [8]. On 21 May 2026, the California Occupational Safety and Health Standards Board initiated a process towards a possible prohibition on artificial stone containing more than 1% crystalline silica [9]. This was not a final ban by 14 July 2026, but manufacturers, importers and retailers have an incentive to prepare for stricter market access before a final rule is adopted.

The regulatory pressure is supported by an increasingly severe public-health record. By 13 November 2025, the California Department of Public Health had confirmed 432 silicosis cases among countertop workers, including at least 25 deaths and 48 lung transplants. The median age at diagnosis was 46 and the median age at death was 48, while the identified workers were predominantly immigrant men from Mexico and Central America [17]. Enforcement evidence also indicates the practical limits of a control-only approach. An April 2026 Cal/OSHA evaluation reported that 94% of inspected fabrication shops had been cited for violations and that 20% had required emergency shutdown orders. The approximately 140 inspected shops represented only about one tenth of the estimated fabrication operations in the state [20]. These findings help explain why California has progressed from stricter fabrication rules towards consideration of a material-specific prohibition.

Great Britain has retained product availability but issued dedicated guidance, launched a nationwide inspection campaign and served prohibition notices on firms that failed inspections [10,11]. New Zealand has pursued consultation rather than a final ban [12]. These models differ legally, yet all can alter purchasing decisions by raising the expected cost of conventional engineered stone, increasing distributor caution and encouraging suppliers to introduce low-silica or alternative product lines.

The British debate is also supported by emerging clinical evidence. The first published UK case series documented eight male artificial-stone workers with a median age of only 34 and a median exposure history of 12.5 years; one of the patients had died by the time the cases were reported [18]. The relatively young age of the affected workers reinforced calls for intervention despite the continued availability of the product. New Zealand illustrates an earlier stage of the same policy process. Its consultation considered both an Australian-style prohibition and strengthened control-based approaches for work involving engineered stone and other crystalline-silica materials [12]. Consequently, the present trade effect in New Zealand is primarily anticipatory, whereas Australia has already created direct exclusion at the border and Great Britain is generating commercial pressure through enforcement.

Table 1. Regulatory models and principal trade effects as of July 2026

Jurisdiction		Market-access instrument	Principal trade and market effect
Australia		Domestic prohibition from July 2024 and import prohibition from January 2025.	Direct removal of conventional engineered-stone slabs from new supply; rapid substitution and border-classification requirements.
United States	California	Material-specific duties and rulemaking towards a possible >1% silica prohibition.	Higher compliance costs and anticipatory product supply shifts in a major U.S. building material market.
	Federal	Process-based silica rules and enforcement; no federal product ban.	Product remains tradable, but fabrication costs and liability concerns affect downstream demand.
Great Britain		Dedicated guidance, inspections and prohibition notices rather than a product ban.	Commercial pressure on fabricators and suppliers without formal exclusion from the market.
New Zealand		Consultation and policy development.	Regulatory uncertainty encourages suppliers and buyers to evaluate substitutes and lower-silica products.

5 Australian Trade Effects and Supplier Reallocation

The Australian import series shows a pronounced break before and after the prohibition. The engineered-stone basket averaged USD 50.6 million per quarter in 2023. Its average fell to USD 35.6 million in 2024, a decline of 29.7%. The basket then reached USD 18.4 million in the first quarter of 2025, 63.6% below the 2023 quarterly average. Although values recovered to USD 23.7 million in the second quarter and USD 30.3 million in the third, the mixed content of the HS headings means that this rebound cannot be interpreted as a return of prohibited engineered-stone slabs.

Natural-stone imports moved in the opposite direction. Their quarterly average rose from USD 49.4 million in 2023 to USD 58.1 million in 2024, an increase of 17.6%. Imports remained above USD 60 million in each of the first three quarters of 2025 and reached USD 71.0 million in the third quarter, 43.7% above the 2023 quarterly average. The timing and direction are compatible with substitution, particularly because the natural-stone series moved to a higher range from the second quarter of 2024. Nevertheless, the figures also incorporate construction demand, price effects and inventory decisions.

The increase was not uniform across natural-stone product groups. The principal upward movement was concentrated in processed marble and travertine products and in other worked monumental or building stone, while worked granite displayed a comparatively stable pattern and certain simply cut granite categories weakened. This composition suggests that the reallocation favoured finished or application-ready products rather than producing an equal expansion across all quarry-based exports. The product pattern is therefore consistent with demand emerging from worktop, surface and building applications, although the HS data cannot identify the final use of each imported product [13].

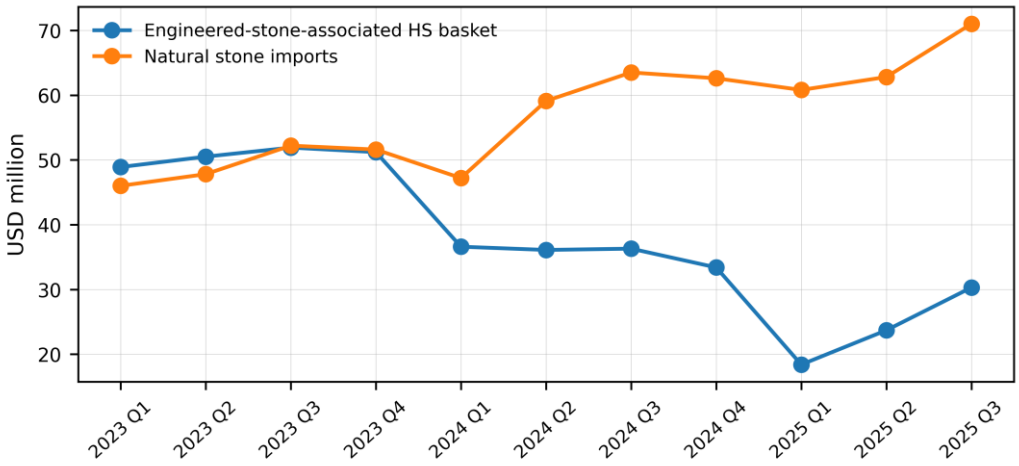

Fig. 1. Australian quarterly imports: engineered-stone-associated HS basket and natural-stone groups, 2023 - 2025. Source: ITC Trade Map [13].

Substitution demand is not distributed evenly among exporting countries as demonstrated by the data divided by natural stone exporters. In fact, it seems to be almost completely absorbed by China and Italy. China maintained a clear lead throughout the period and expanded its share of the four-country total from 50.7% in the fourth quarter of 2023 to 55.0% in the third quarter of 2025. Italy also strengthened its relative position, increasing its share from 22.4% to 25.7%. Turkey, by contrast, remained an established supplier but saw its share decline from 20.3% to 14.1%, as its import value remained broadly stable while Chinese and Italian exports expanded. The absolute import values make this divergence more visible. Between the fourth quarter of 2023 and the third quarter of 2025, Australian imports of the selected marble and granite products from China increased from USD 21.5 million to USD 31.9 million, while imports from Italy rose from USD 9.5 million to USD 14.9 million. Imports from Turkey remained broadly stable, moving from USD 8.6 million to USD 8.2 million, and imports from India changed only slightly, from USD 2.8 million to USD 3.0 million [13]. The additional demand observed in this comparison was therefore captured primarily by China and Italy, while Turkey maintained its market presence without participating proportionately in the expansion. These figures cover the four suppliers examined and should not be interpreted as their shares of Australia's total natural-stone imports.

It can be drawn out from product distinction that the relevant competitive unit is often not a quarry block or unfinished slab but a project-ready surface. Engineered stone was sold through a system built around predictable slab dimensions, colour continuity and rapid fabrication. Natural-stone exporters capture more of the displaced value when they can supply calibrated slabs, worktops, vanities, wall panels, edge finishing, packaging, technical support and reliable delivery. Otherwise, the substitution may favour Chinese processed stone, Italian premium products, porcelain, sintered surfaces or reformulated composites rather than raw or semi-processed natural stone.

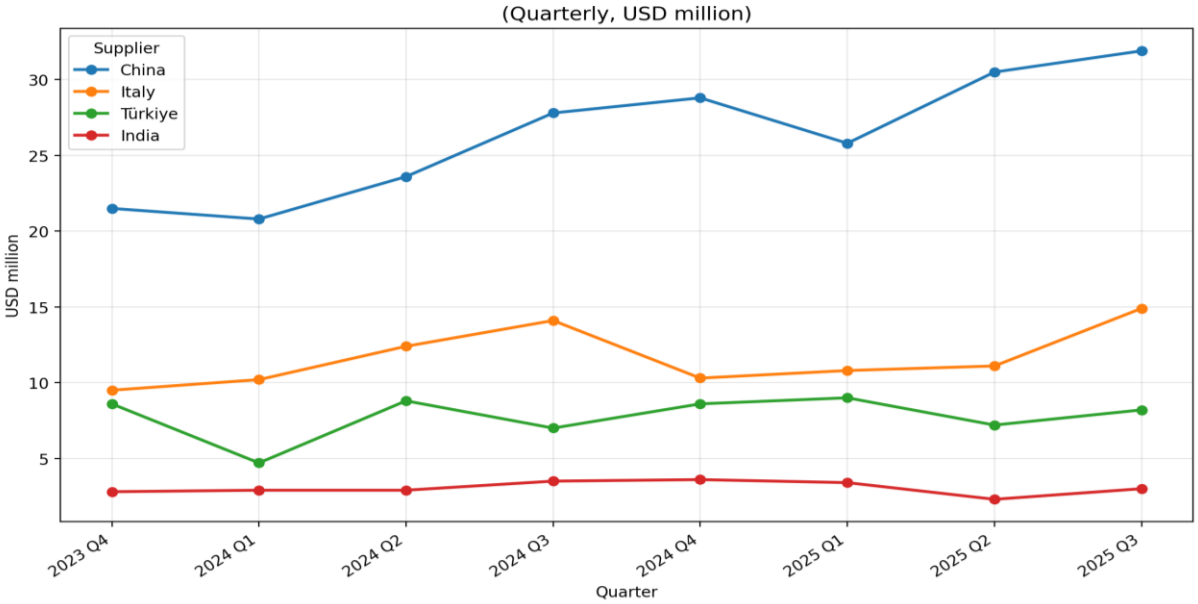

Fig. 2. Australian natural stone imports divided by exporter. Source: ITC Trade Map [13].

The same HS ambiguity that limits statistical analysis also creates commercial friction. Engineered stone is not represented by a single globally uniform code, while broad headings can contain prohibited slabs, excluded alternatives and unrelated mineral articles. Marketing expressions such as quartz surface, artificial stone, mineral surface or composite slab do not by themselves establish legal treatment. Importers may therefore request composition declarations, resin-status information, silica-content data, technical sheets and product photographs before shipment.

Documentary identity becomes part of the traded product. Natural-stone exporters must demonstrate that the material is geologically formed rather than reconstituted; producers of porcelain and sintered surfaces must document the absence of resin where this determines exclusion; and low-silica composite producers must show that the formulation meets relevant thresholds. Firms that standardise these documents can reduce customs delay and buyer hesitation, while vague classification increases the risk of rejected orders or lost specifications.

6 Wider Building Materials Trade Implications

The Australian case cannot only be read as a simple transfer from engineered stone to natural stone. A product prohibition changes the relative position of several materials at once. Natural stone gains access to where was left unoccupied by restrictions, however it is usually considered more expensive and less flexible than other substitutes. Porcelain and sintered surfaces compete for buyers that prioritise consistent design and manufactured specifications. Low and no-silica composites allow established engineered-surface firms to retain some of their technology, branding and distributor relationships. Lower-cost applications may move towards laminates or other non-stone surfaces. The recovery of the engineered stone associated HS coded products in the Fig.1 might be associated with more substitutes like silica free engineered stone, that is classified under these HS codes, being introduced to the market.

The shift also redistributes value within the supply chain. Conventional engineered-stone slab producers lose direct access to prohibition markets. Importers and wholesalers suffer the cost of replacing product lines. Fabricators may need different cutting, handling or installation methods. Kitchen and bathroom retailers must revise displays and warranties, while architects and contractors update specifications. At the upstream level, suppliers of quartz aggregate,

pigments, unsaturated polyester resins and other binders face reduced demand from affected formulations unless they diversify into new products or markets.

Regulatory hurdles favour firms with broad product ranges and strong documentation. A producer that can offer natural stone, porcelain or low-silica composites can redirect customers more easily than a single-product supplier. Larger firms may also absorb testing, certification and compliance costs more readily. The emerging trade pattern may consequently involve both material substitution and supplier consolidation, particularly where distributors prefer fewer vendors capable of serving multiple specifications.

7 Implications for Turkey

Turkey faces a dual exposure. Its natural-stone industry can benefit when engineered-stone demand shifts towards marble, travertine and other geological materials. A national or sectoral strategy should therefore avoid presenting the transition as an unqualified natural-stone gain.

Turkey's response can be considered through three separate trade and industrial channels. First, natural-stone producers can target direct exports of finished and project-ready products to Australia and other markets affected by restrictions. Second, block and slab exporters may benefit indirectly where processing centres, particularly China, capture a larger share of the additional demand for finished natural-stone products [13].

For natural stone, competing in the product forms that engineered stone previously supplied is the goal. This means moving beyond blocks and generic slabs towards calibrated and polished slabs, worktops, vanities, wall panels, edge profiles and project packages. The Australian supplier comparison indicates that Turkey is present but faces strong Chinese and Italian competition. Higher market share requires reliable delivery, consistent finishing, local distributor relationships and early involvement with architects, kitchen-bath designers and contractors.

Classification and technical documentation can also be a prime concern. Common templates should identify the geological material, commercial name, quarry origin, resin or mesh treatment where applicable, recommended HS classification, product dimensions and relevant composition information. This is important not because natural stone is part of the Australian prohibition, but because border authorities and buyers need to distinguish it quickly from reconstituted products and from resin-containing alternatives.

Finally, occupational compliance should be treated as a supporting market-access capability rather than the central commercial message. Buyers increasingly expect evidence of responsible fabrication and clear product information across all mineral surfaces. Turkish suppliers can meet that expectation through process documentation and credible supply-chain practices without reducing the trade strategy to a health-and-safety campaign.

8 Conclusion

Restrictions on engineered stone are reorganising international trade in a group of competing building materials. Australia converted the issue into a direct market-access shock by combining a domestic prohibition with an import prohibition. The engineered-stone import basket fell sharply, while natural-stone imports moved to a higher range. This provides strong descriptive evidence of market reallocation, although mixed HS headings and wider construction-market conditions prevent a one-to-one causal interpretation.

The commercial outcome is more than natural-stone substitution. Demand is being divided among natural stone, porcelain, sintered surfaces, low-silica composites and other materials. Supplier countries gain according to their ability to provide finished products, competitive prices, design compatibility, logistics, documentation and access to distribution and project

channels. Product restrictions also transmit upstream to aggregate and resin suppliers and downstream to importers, fabricators, retailers and contractors.

For Turkey, the appropriate response is a strategy that encapsulates the substitute market. The natural-stone sector should target higher-value finished applications and strengthen its position in architectural and distribution networks. Future research should extend the trade series through 2026, separate price and quantity changes, and compare the import performance of natural stone with porcelain, sintered surfaces and new composite formulations. The central transformation is the reallocation of a building material value chain under changing rules of market access.

Abstract. In the planning process of construction projects, determining and simultaneously evaluating the time, cost, and quality values of activities is one of the most important stages. In this process, the primary objective is to minimize time and cost while maximizing quality. However, alternative selection problems arise when criteria such as time-cost-quality (TCQ) take different values. To solve these problems, a holistic evaluation of the criteria is necessary. Decision Support Systems (DSS) stand out for evaluating all these criteria holistically and determining the best solution. In this study, a MATLAB-based Decision Support System (DSS) has been developed to solve TCQ trade-off problems and determine the best alternatives. In the developed MATLAB-based DSS, the Additive Ratio Assessment (ARAS) and Complex Proportional Assessment (COPRAS) methods, which are multi-criteria decision-making methods, are designed to work together with the Jaya, which is based on the principle of convergence to the best solution and divergence from the worst solution. By using multi-criteria decision-making methods, decision-makers are actively involved in the process by determining the criterion weights. The developed MATLAB-based DSS approach aims to introduce a new approach to the literature for the optimization of multi-criteria problems.

Keywords: DSS; Construction Project Planning; ARAS method; COPRAS method

1 Introduction

For construction projects to be successfully completed under multiple criteria such as TCQ, the planning process must be carried out systematically and in detail. Through the comprehensive work conducted during the planning phase, it is aimed to complete the project on time, keep the project cost to a minimum, and achieve the desired quality level. Decisions made during the planning phase of the project significantly affect the subsequent phases of the project [1].

Construction projects consist of multiple activities that are interconnected in a predetermined sequence. Each project activity has different values for criteria such as time, cost, and quality. The combination of these different values results in different TCQ values at the project level, presenting the decision-maker with numerous alternatives. The goal is to minimize the time and cost criteria and maximize the quality criterion. However, trade-off relationships exist among these criteria, and an improvement in one criterion may negatively affect the others. For example, reducing the cost criterion may lead to an increase in the time criterion and a decrease in the quality criterion. This makes it difficult to achieve the desired balance among the TCQ criteria simultaneously. Therefore, decision-makers have difficulty deciding among the alternatives [2]. In such trade-off problems, the criteria need to be evaluated holistically. In trade-off problems, DSS are utilized to determine the alternative that provides the most

appropriate balance among the criteria. DSS are computer-based systems used to support decision-makers in making more effective decisions in the solution of complex problems [3]. In the literature, multi-objective optimization (MOO) methods are used to solve such problems. There are two main approaches to solving multi-objective problems within the scope of MOO. One of these approaches is to reduce the objective functions to a single objective function or to incorporate the other objective functions into the model through certain constraints while one objective function is taken as the basis. The other approach is to determine the entire Pareto optimal solution set or a subset that represents this set. The Pareto optimal solution set consists of solutions that do not dominate one another and provides the decision-maker with a set of good solutions [4]. In the literature, another method used in solving decision problems by evaluating criteria holistically is Multi-Criteria Decision Making (MCDM). These methods help in evaluating alternatives according to multiple criteria and making the appropriate decision according to the objective of the decision problem.

When the literature is examined, there are also studies in which Pareto-based approaches and MCDM methods are addressed in a hybrid manner in construction projects. Zhan et al. [5] developed an MOO model including time-cost-safety-carbon emissions (TCSE). They obtained solution sets using the Nondominated Sorting Genetic Algorithm-II (NSGA-II) and Nondominated Sorting Genetic Algorithm-III (NSGA-III) methods. To determine the most appropriate solution from the solution set obtained by the NSGA-III method, they used the entropy-weighted VIKOR method. Bingöl et al. [6] developed an MOO model that holistically considers the cost-duration-quality-safety-environmental impact criteria for subcontractor selection in a construction project. In the study, subcontractor candidates were evaluated using the Grey Relational Analysis (GRA) method. NSGA-II was used to determine the Pareto set of the best subcontractor plans. The selection of the most appropriate subcontractor plan was carried out using the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) method.

Within the scope of this study, the trade-off relationship among TCQ criteria in the planning of a construction project consisting of 13 activities was analyzed through a DSS developed in the MATLAB environment. Within the developed system, ARAS and COPRAS, which are MCDM methods, were integrated into the system to work together with Jaya.

2 Problem formulation for time–cost–quality

In this study, the total project duration, project cost, and overall project quality were calculated in the MATLAB environment based on the approaches adopted by Mohammadi et al. [7]. The total project duration was determined using the Critical Path Method (CPM), developed by Kelley and Walker [8]. CPM is a method that calculates the project completion time by identifying the critical activities in the project. The total project cost was calculated using Equation (1), considering the direct cost, indirect cost, penalty cost and incentive cost. In calculating the overall project quality, quality indicators are used for each project activity. The quality of each activity is determined through these indicators, and the weighted total project quality is calculated by considering the quality weights of the activities within the overall project.

$$C = \sum_{i=1}^{N} DC_i^{(k)} + D \cdot ICR + u(D - D_{PD})(D - D_{PD})C_{pen} - u(D_{PD} - D)(D_{PD} - D)C_{inc} \quad (1)$$

In Equation (1), C represents the total project cost, $DC_i^{(k)}$ the direct cost of the i^{th} activity, N the number of activities, D the total project duration, ICR the indirect cost rate, D_{PD} the project deadline, and C_{pen} and C_{inc} the penalty cost and incentive cost of the project, respectively. In

addition, the function u(x) takes a value of 1 for positive x and 0 for negative x.

3 Description of Selected 13-Activity Construction Project

In this study, a 13-activity bridge construction project was investigated. This construction project example was first introduced by Zhang and Xing [13] and was subsequently used separately by ElBassuony [14] and Mohammadi et al. [7]. Zhang and Xing [13] expressed the TCQ values of the activities using fuzzy numbers. Subsequently, Mohammadi et al. [7] transformed the fuzzy numbers into expected TCQ values using Equations (2), (3), and (4), respectively. This bridge construction project consists of one preliminary work, three foundation excavations, three foundation piling, three pier concreting, two beam constructions, and one deck pavement. The activities, their corresponding numbers, and the precedence relationships among the activities are presented in Table 1. A maximum of three alternatives is available for the expected TCQ values of each activity. The expected TCQ values of the activities are presented in Tables 2, 3, and 4, respectively. The CPM network showing the precedence relationships among the activities is presented in Fig. 1.

$$T_e = \frac{T_o + 4T_m + T_p}{6} \tag{2}$$

$$C_e = \frac{C_{op} + 4C_{ml} + C_{pe}}{6} \tag{3}$$

$$Q_e = \frac{Q_{op} + 4Q_{ml} + Q_{pe}}{6} \tag{4}$$

4 Jaya-COPRAS and Jaya-ARAS Approaches

4.1 Jaya Algorithm

The Jaya algorithm, developed for solving constrained and unconstrained optimization problems, was first proposed by Rao. Only common control parameters are used in the Jaya algorithm. The flowchart of the algorithm is given in Figure 2. The basic approach of the algorithm is to update the obtained solutions in such a way that they approach the best solution while moving away from the worst solution [9]. The obtained solutions are updated using Equation (5) in the flowchart.

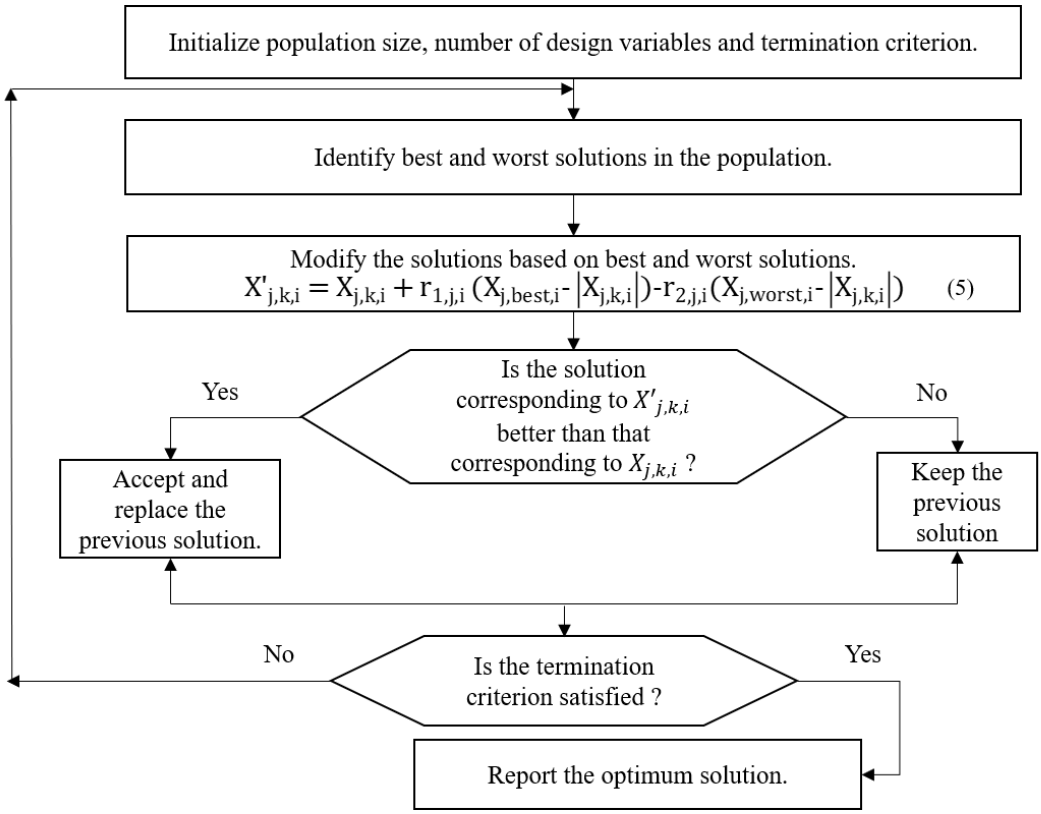

Fig. 2. The Jaya algorithm's flowchart [9]

In Equation (5), $X_{j,k,i}$ represents the value of the j^{th} variable for the k^{th} candidate in the i^{th} iteration. The new value obtained by updating this variable is represented by $X'_{j,k,i}$. $X_{j,best,i}$ and $X_{j,worst,i}$ represent the j^{th} variable values of the best and worst candidate solutions, respectively, in the i^{th} iteration. $r_{1,j,i}$ and $r_{2,j,i}$ are randomly generated numbers within the range [0,1].

4.2 COPRAS

First developed by Zavadskas and Kaklauskas, COPRAS is an MCDM method. The primary goal of COPRAS is to evaluate and rank alternative solutions by considering utility-oriented and cost-oriented criteria. This method uses the following steps to solve the problem [10-11].

Step 1: A decision matrix is created where columns correspond to criteria and rows correspond to alternatives.

Step 2: Each value in the decision matrix is divided by the sum of its respective columns to obtain the normalized decision matrix.

Step 3: The decision-maker assigns a weight value for each criterion. Then, the values in the normalized decision matrix are multiplied by their respective criterion weights to obtain the weighted normalized decision matrix.

Step 4: Using the values in the weighted normalized decision matrix, the sum of the utility-oriented criteria and the sum of the cost-oriented criteria are calculated separately for each alternative.

Step 5: The relative significance value of each alternative is calculated using the values obtained from the sums of the utility-oriented and cost-oriented criteria.

Step 6: The performance index value of each alternative is calculated by multiplying the ratio of its relative significance value to the highest relative significance value by 100. The alternative with the highest performance index value is considered the best option.

4.3 ARAS

The ARAS method was first developed by Zavadskas and Turskis. The main objective of this method is to determine the complex relative efficiency of each alternative by simultaneously considering the values and weights of the criteria. This method uses the following steps to solve the problem [12].

Step 1: First, the decision matrix is constructed. An optimal value is determined for each criterion and added to the decision matrix as a separate row. If the optimal value is unknown, the highest value among the alternatives is considered the optimal value for utility-oriented criteria, while the lowest value is considered the optimal value for cost-oriented criteria.

Step 2: The normalized decision matrix is constructed. To construct the normalized decision matrix, for utility-oriented criteria, each value is divided by the sum of all alternative values for the corresponding criterion. For cost-oriented criteria, the reciprocal of each value is first taken, and the resulting values are then divided by the total value in the column containing the corresponding criterion.

Step 3: A weight is assigned to each criterion by the decision-maker. The normalized values are then multiplied by their corresponding criterion weights to construct the weighted normalized decision matrix.

Step 4: The optimality function value for each alternative is calculated by summing the weighted normalized values of all criteria for that alternative. The alternative with a higher optimality function value is considered more effective.

Step 5: The optimality function value of each alternative is divided by the best optimality function value to determine the utility degrees of the alternatives. The utility degrees are ranked in ascending order, and the alternative with the highest utility degree is determined as the best alternative.

5 Analysis results

The selected bridge project was analyzed through the Jaya-COPRAS and Jaya-ARAS methods, with equal weights given to the criteria. The analysis was conducted using a population size of 50, 100 iterations, and 10 runs. The analysis results are presented in Table 5. In the analysis conducted using the Jaya-COPRAS method, two dominant solutions were identified. The first solution was obtained in 9 of the 10 runs, while the second solution was obtained only once. In the analysis conducted using the Jaya-ARAS method, a single optimal solution was obtained in all 10 runs.

Table 5. Analysis results

Jaya-COPRAS				
Solution	**Total time**	**Total cost**	**Total quality**	**Frequency**
(3,1,1,1,1,1,1,1,2,1,1,1,3)	235	2041	93.9333	9
(3,1,1,1,1,1,1,1,1,1,1,1,3)	241	2046	94.7333	1
Jaya-ARAS				
Solution	**Total time**	**Total cost**	**Total quality**	**Frequency**
(3,1,1,1,1,1,1,1,2,1,1,1,3)	235	2041	93.9333	10

6 Conclusion

The primary objective of this study is to comprehensively evaluate the TCQ trade-off in the planning of a 13-activity bridge construction project. To achieve this objective, a MATLAB-based computer program integrating the Jaya-COPRAS and Jaya-ARAS methods was

developed. The developed MATLAB-based DSS presents the decision-maker with the best alternatives among the available alternative solutions.

- In the analysis performed using the Jaya-COPRAS method, the solution (3,1,1,1,1,1,1,1,2,1,1,1,3) was repeated 9 times and became the most dominant alternative. The solution (3,1,1,1,1,1,1,1,1,1,1,1,3) was repeated 1 time.
- In the analysis performed using the Jaya-ARAS method, the solution (3,1,1,1,1,1,1,1,2,1,1,1,3) was obtained as the single best solution.
- Analysis results obtained using Jaya-COPRAS and Jaya-ARAS methods showed that solution (3,1,1,1,1,1,1,1,2,1,1,1,3) provided a more consistent and balanced result.

Abstract. Shell structures have excited architects and engineers with their astonishing aesthetics and fascinating structural behavior. Advances in 3D modeling techniques have allowed designers to expand their creativity with elegant free-form shell designs but a significant gap remains between the design and physical realization of such structures. One of the key barriers is the formwork requirement since they require a rigid, custom, and in most cases, geometry-specific formworks. This results in too much time, labor work and a tremendous amount of waste. A novel technology for the feasible construction of the shells is adaptive molding. In this technology, desired single or doubly curvature formwork can be obtained in a short time by deforming the surface with the help of the actuators. In this study, we analyze the manufacturing process of the concrete shell panels by focusing on an existing precast concrete panel facility. The major production processes are represented in the model using discrete-event simulation software Simio and validated based on the real production data. To investigate the adoption of the adaptive mold technology, we analyze the modified production process in a simulation model. The number of adaptive molds in the system emerged as a critical factor to fulfill the desired capacity for the panel production with this technology. The proposed methodology can be employed to determine this number and also can be utilized as a decision-support tool to test the viability of the integration of the emerging novel technologies and guide the decision-making process.
Keywords: Shell structures, adaptive mold, formwork, facility design, digital construction.

1. Introduction

Shell structures have excited architects and engineers with their astonishing aesthetics and fascinating structural behavior. They are special structures that can resist loads by virtue of their forms. That is why they are often called form-resistant structures. In recent years, advances in 3D modeling techniques of geometries have allowed designers to expand their creativity with elegant and appealing free-form shell designs. Today, curved and complex free-forms can be

easily created with the aid of modern CAD software, making innovative architectural designs more accessible than ever.

Despite development in design tools, there is still a significant gap between the design and physical realization of such structures [1]. The manufacturing of individual free-form shell components is a challenging task because of the lack of defined standardized methods that are applicable to the varying shapes of shell components. The conventional method in the industry requires a rigid formwork and, in most cases, formwork is specifically generated for only one shell geometry. This results in too much time, labor work and a tremendous amount of waste to construct the structural element mainly related to the formwork [2], [3]. The impractical and inefficient erection of this method is therefore one of the most important barriers against the extensive usage of shell concrete panels despite their aesthetics and engineering value.

Traditional formwork systems, despite being primarily designed for regular shapes, utilize rigid materials such as wood and metal to achieve curved surface. Wooden formwork is frequently employed in the construction of curved shells and arches, often requiring a skeleton frame to support the desired geometry, while steel formwork can be more efficient to produce curved surfaces due to multiple uses. However, the difficulty of shaping rigid materials has led to the development of flexible formwork systems, which offer a fundamentally different approach to casting non-standard shapes [4], [5]. Within this category, fabric formwork utilizes synthetic textile sheets that can be tensioned by external factors to create irregular forms. Additionally, digitally fabricated formwork leverages the methods—such as CNC milling of polystyrene blocks to realize concrete elements with full geometric freedom and high precision.

A novel technology for the feasible construction of the shells is adaptive molding. In this technology, desired single or doubly curvature formwork can be obtained in a short time by deforming the surface with the help of the actuators or pistons of the device, as demonstrated in Fig. 1. The construction sector, especially for free-form shell concrete panels, needs such cost-effective and time-saving technology for molding [6], [7] and necessary standards and guidelines should be established.

This study addresses the challenges in the production of geometrically complex concrete shell panels first by identifying production processes and then creating the facility model using Simio which is an object-based discrete-event simulation modeling framework [8], [9]. To enhance the efficiency of the production lines of the free-form shell components, it is essential to optimize operational efficiency, and ensure the cost-effective manufacturing by simulating the production process. The simulation model can serve as a crucial tool to understand and evaluate the integration of the novel technologies such as adaptive molds into the manufacturing line of existing facilities.

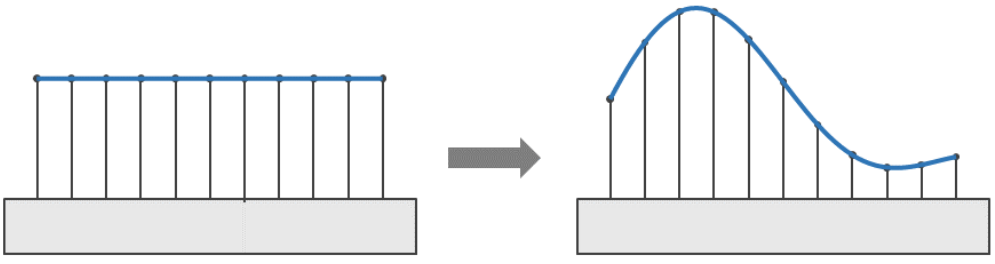

Fig. 1. Adaptive mold schematics.

1.1 Description of the Precast Concrete Panel Production Process

The production process of an existing precast concrete panel facility is examined to understand the production process of the existing plants. Accordingly, the workflow is classified into the phases while focusing on the manufacturing phase of the concrete panels, as shown in Fig. 2.

The first phase in the system is design and planning in which the type of formwork and manufacturing order of the panels are determined according to multiple factors, including the

geometric complexity of the product, the intended surface texture, and the number of repetitions required for the same mold and availability of the production line. The concrete panel manufacturing process starts with the production of the mold. The mold preparation stage plays a decisive role in determining the quality and efficiency of the manufacturing process. At the concrete facility investigated in this research, four primary mold types are utilized: wooden, polyester, styrofoam, and rubber molds. Each of these types has distinct properties and usage contexts.

Once a mold has been produced, the manufacturing process proceeds to the concrete casting stage where the concrete mixture is poured into the mold. After approximately one day, the panels are demolded and cured under controlled conditions. A typical curing period of seven to eight days is allocated to ensure proper strength development and to reduce the risk of cracking. If required, surface treatments such as sanding or polishing are carried out during post-processing. These operations are essential to meet aesthetic and functional requirements. The final stage of the production involves quality control inspection. Each panel is examined for dimensional accuracy, surface quality, and structural integrity. Based on the inspection results, the panels are either approved for shipment or returned for reprocessing.

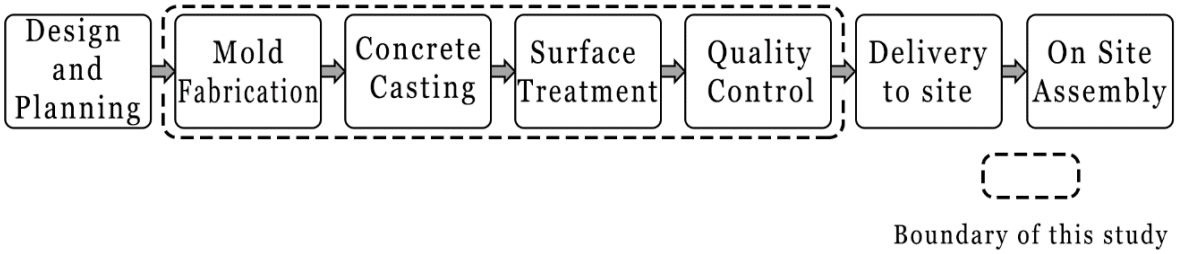

Fig. 2. Production phases in a concrete precast panel facility.

2. Methodology and Design of the Facility Model

1.2 Facility Design and Modeling in Simio

In the Simio model, each production process is represented as a separate server. The model is mainly composed of two parts that are the production of the molds and the concrete casting to represent the actual production line. Because of the insufficient data for the sub-processes of the mold production, they are modeled using a single aggregated server considering that it contains all of the sub-processes in the manufacturing process.

Figs. 3 and 4 illustrate the overview of the discrete-event simulation model. The production orders in the model are represented by *MoldEntity*. These entities first enter one of the mold production servers according to the specified selection weights. After erection of the molds, the mold entities proceed to the concreting and related processes as shown in Fig. 3. It is processed in the server *ConcreteCasting* that corresponds to the concreting process (either spraying or casting). The server *CuringOnMold* represents the curing time on the mold before reaching adequate hardening for removal from the formwork. Once curing is completed, the separator object, called *Demolding* in the model, removes the concrete panel from the mold. The *MoldEntity* returns back to *MoldRework* server for repairing and re-casting if the mold can be still used. The separator object, *Demolding*, creates a new entity, called as *Panel* in the model, and it goes to *Curing* server. After the panel entity passes through the servers *SurfaceTreatment*, *QualityControl*, and *Rework* if necessary, it leaves the production process at the server *Sink*. At this point, the panel is considered finished and ready for transportation to the construction site.

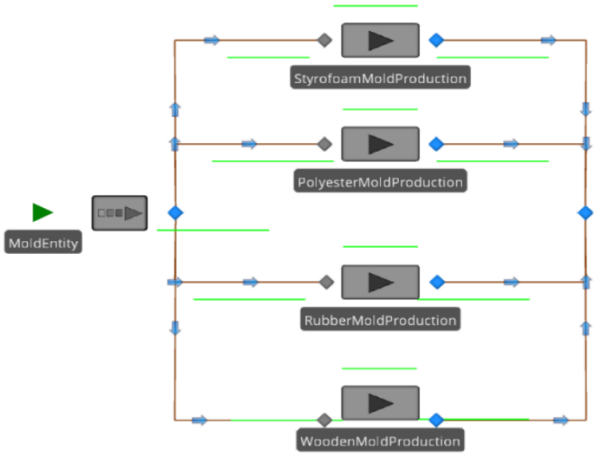

Fig. 3. Production of molds in Simio model.

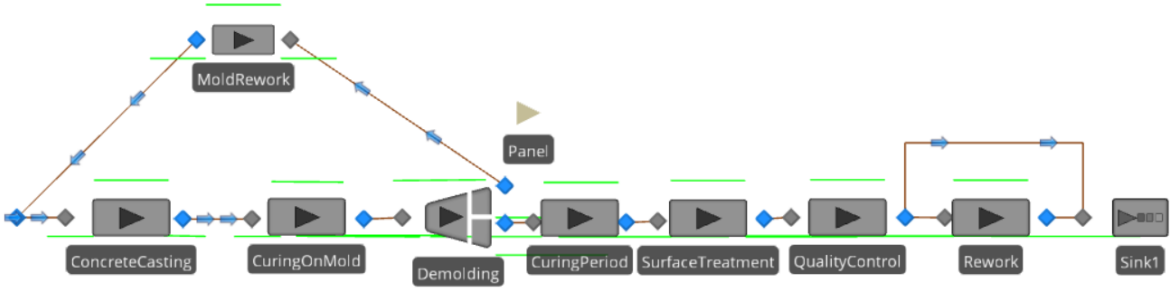

Fig. 4. Concreting and panel production in discrete-event simulation model.

1.3 Distribution Fitting and Data Analysis of the Processes

Production data are obtained from the Fibrobeton precast concrete panel facility and includes the mold production and concrete casting processes. The raw data were first cleaned by removing missing values, correcting inconsistencies and filtering outliers. Consequently, about 2750 and 4500 data were utilized for mold production and concrete casting processes, respectively. The mold production data consist of the observations of styrofoam (n=745), polyester (n=258), rubber (n=524), and wooden (n=1223). Then, the Chi-square method was used as the primary measure to fit the appropriate statistical distribution for each process. The resulting distributions were then incorporated into the simulation model developed in the Simio software. Furthermore, Q-Q plot of the fitted statistical distributions were presented as a diagnostic tool to evaluate the goodness-of-fit.

The triangular distribution was employed for the processes that do not have recorded data, namely *Demolding*, *CuringPeriod*, *SurfaceTreatment*, *Quality Control* and *Rework* processes. The minimum, median and maximum values of the triangular distributions were provided by the experts working in the facility.

1.4 Production System Specifications

The server capacities such as mold production and concrete casting processes were provided by facility's chief engineer and inserted into the model. Additionally, in order to reflect realistic mold usage in the model, a selection weight was assigned to the path between the source and mold production servers based on the one year period of production data.

In the production system, each mold can be used multiple times by repairing or modifying after the concrete panel is removed from the formwork. The company provided the median, maximum, and minimum allowable uses of each mold type. These parameters are employed to

assign maximum life span to each formwork applying triangular distributions. This approach considers the fact that not all molds are used until failure. They may be removed if they are not needed further or if they are critically damaged earlier.

The lifespan values are assigned to each mold entity when the entity exits the mold production server. Fig. 5 illustrates the add-on process to track the number of usage of the molds. Each time a mold returns to the *MoldRework* server (see Fig. 4), its count use is increased by one. In *Decide* stage, it checks whether the mold has reached its lifespan. If it does, the model destroys the entity and removes it from the model.

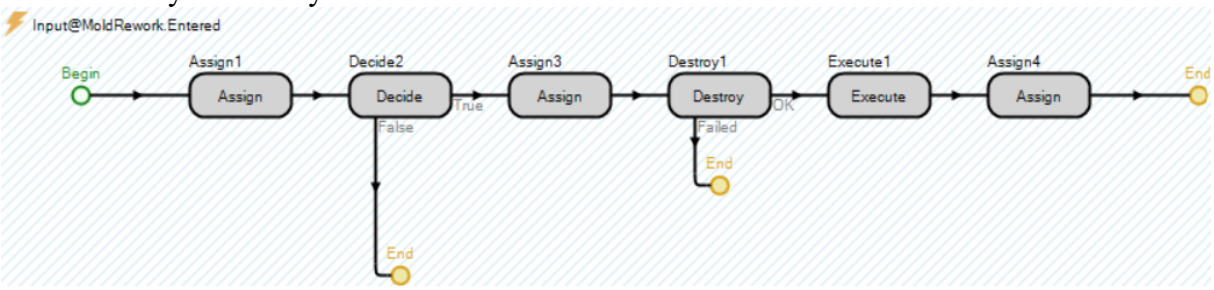

Fig. 5. Add-on process for lifespan check of the molds.

The concrete casting area has a fixed physical capacity in the facility. To check the availability of the concrete casting process in the model, a pseudo station was created in Simio model to hold molds when the casting server is full. The molds are directly transported to the concreting processes if *ConcreteCasting* server has available capacity. Otherwise, the mold entities are sent to the station, where they are stored until a mold is removed from the concreting process. An add-on process is triggered whenever a mold is removed from the casting server, which releases the next mold from the station into the concreting server.

Arrival rate is defined as the frequency at which new production orders enter the system. To be able to capture variability observed in the historical data, the arrival process was modeled using an exponential distribution based on the production data.

The warm-up period in the facility design refers to the initial phase of the simulation during which no data are collected. The aim is to make the model reach a stationary state before collecting the data to overcome unrealistic results and eliminate initialization bias. The performance indicator that is daily panel production was monitored for 1-year period to identify the point at which the system reached steady-state behavior.

After the quality control phase in the facility, concrete panels may need additional work such as surface treatment. Extra treatments are applied to these panels to meet the quality standards. In the model, this stage was represented with the server *Rework* at the end. Based on the data, about 25% of the panels needed extra surface treatment before the final approval. To implement this in the model, the selection weights of the paths were adjusted according to this proportion. The panels that do not require extra surface treatment directly proceed to *Sink* and destroyed from the system, which corresponds to the delivery to site phase in the concrete panel life cycle phases.

1.5 Integration of Adaptive Mold Systems

To integrate adaptive mold production systems, the model was modified as depicted in Fig.6. The initial model was retained and a parallel path representing adaptive mold system was added. In this setup, a specified percentage of the concrete panels, except for the panels produced with styrofoam molds, is manufactured using adaptive mold systems. The reason why styrofoam molds are excluded is that the panels produced with the styrofoam molds typically include complex and highly curved geometry, whose production with the adaptive molds is not quite

possible because of the technical limitations. However, as adaptive mold technology advances rapidly, this limitation is expected to disappear in the near future.

A server called *AdaptiveMoldShaping* was created to represent the process for shaping the surface of the adaptive mold with the help of the actuators. The statistical process time distribution is assigned triangular distribution with mean of 30 min. The servers for the casting, curing and demolding were assigned same processing time with the conventional process since the work being done does not change for these parts of the manufacturing.

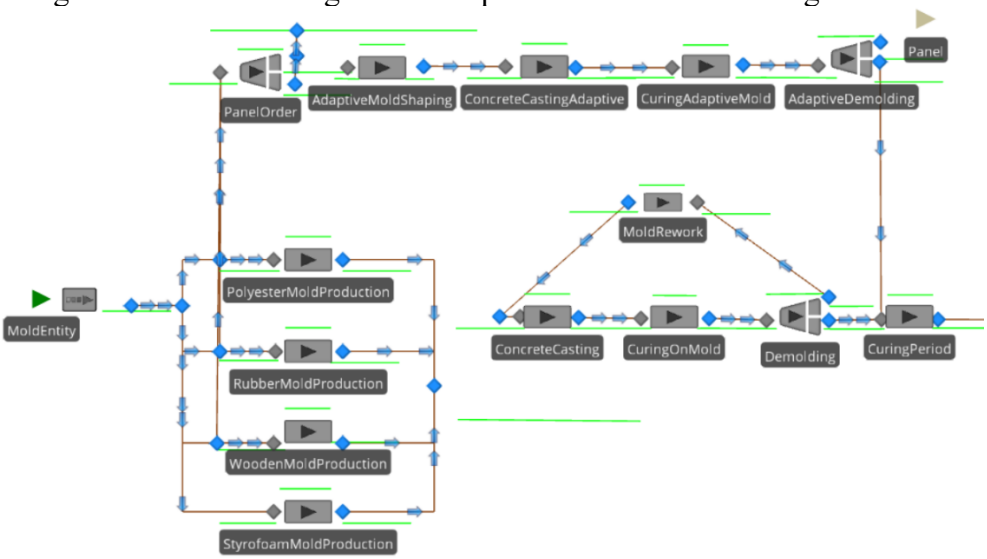

Fig. 6. Adaptive mold integrated model.

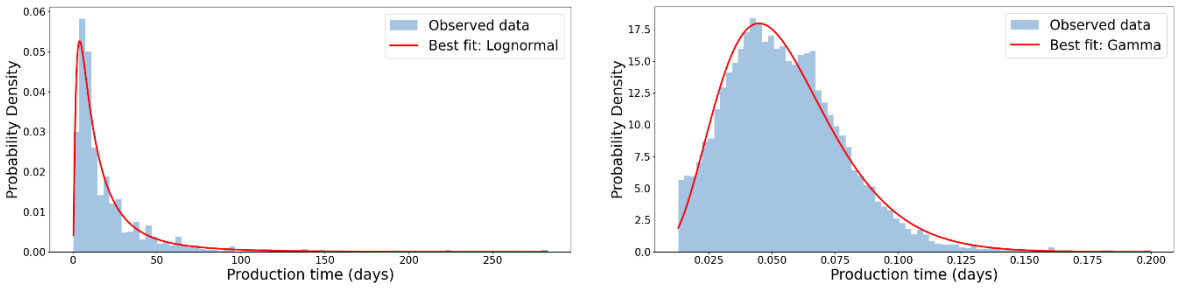
The aim of this adaptive-mold integrated model is to determine the optimum number of adaptive molds that fulfill a designated percentage of annual panel production. By simulating the scenarios where 5% and 10% of the total panel production are realized with the adaptive molds, this analysis identifies how many adaptive molds is required to meet the demand. Ultimately, these findings can provide critical insights into the feasibility of integrating this technology into the existing precast concrete facilities.

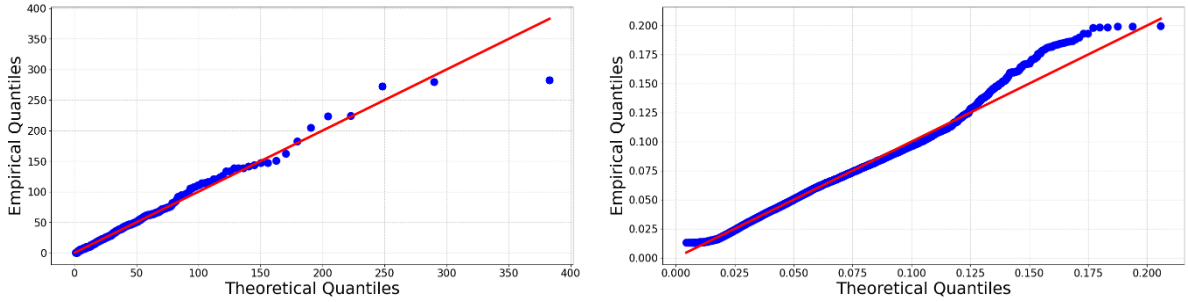


3. Results

2.1 Data Distribution Fitting

The outcomes of the distribution fitting analysis for each mold type and casting stage are presented in Table 1, which includes the fitted distribution and its parameters.

Table 1. Data distributions of the processes.



Process	Distribution Type	Parameters
Styrofoam Mold	Gamma Distribution	$\alpha = 2.057$, $\beta = 24.298$
Polyester Mold	Lognormal Distribution	$\alpha = 1.177$, $\beta = 2.737$
Rubber Mold	Gamma Distribution	$\alpha = 0.810$, $\beta = 36.456$
Wooden Mold	Lognormal Distribution	$\alpha = 1.067$, $\beta = 2.528$
Concrete Casting	Gamma Distribution	$\alpha = 5.254$, $\beta = 0.0106$

(a) **(b)**

Fig. 7. Distribution fitting for the production time data; (a) process of wooden mold, (b) process of concrete casting.

The production process histogram and fitted distribution are plotted for the wooden mold and concrete casting processes as representative in Fig 7. For these production process time data, Q-Q plots are provided in Fig. 8 to further validate the goodness-of-fit.

(a) **(b)**

Fig. 8. Q-Q plots for production time distribution fitting; (a) process of wooden mold, (b) process of concrete casting.

2.2 Model Verification

The warm-up period of the production system was determined based on the daily panel production. Accordingly, it was observed that the system starts to stabilize after approximately 105 days, corresponding to 15 weeks. As a result, the warm-up period of 15 weeks was selected for this facility model.

To ensure the reliability of the simulation model, a verification process was conducted by comparing key model outputs with real data. Two main outputs which are number of concrete panel and formwork production per year were calculated and the mean values are reported by running 10 simulation replications, as given in Table 2.

Table 2. Verification of simulation model.

	Model Output	**Real Data**	**Error (%)**
Concrete Panel Production (per year)	30492	30000	1.64%
Formwork Production (per year)	2616	2700	3.11%

Panel entities are the final output product of the system, created upon successful casting on a mold. The expected number of panels was 30,000. The simulation result reported a total of 30,492 panel entities, resulting in 1.64% deviation from the expected value. The simulation output produced total 2616 units of the formwork, resulting in an error of 3.11% compared to the expected value of 2700. This can be considered reasonable and within acceptable bounds for validation purposes.

2.3 Evaluation of Adaptive Mold Integration

The number of adaptive molds required was analyzed for the case in which 5% and 10% of the panels produced with the conventional molds are produced with the adaptive molds. The simulations were carried out using different numbers of adaptive molds with ten replications for each scenario. The results are illustrated in Fig. 9.

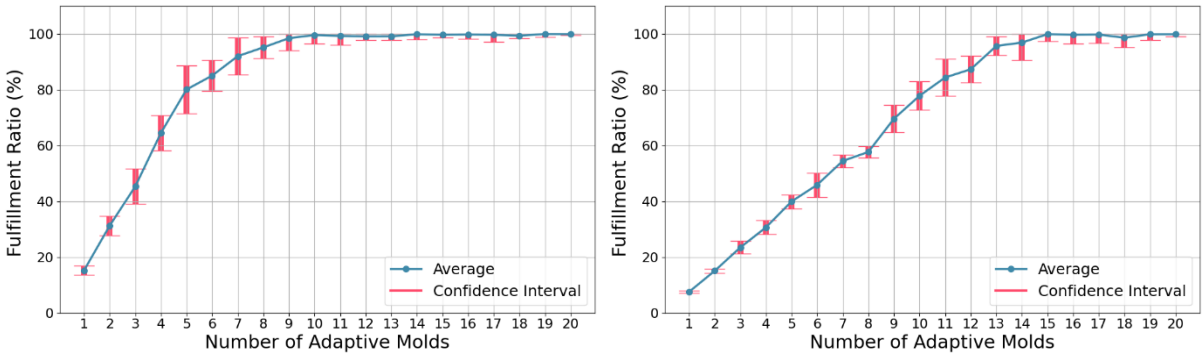


Fig. 9. The adaptive mold capacity analysis; (a) 5% replacement, (b) 10% replacement.

To evaluate the system performance, the fulfillment ratio is defined as the ratio of the number of panels produced to the number of panels ordered. The results in Fig. 9 indicate that achieving a full fulfillment ratio for the 5% and 10% panel production scenarios requires about 10 and 15 adaptive molds, respectively. Notably, this finding reveals that doubling the production with the adaptive molds leads to approximately 50% increase in the adaptive mold capacity, which suggest the non-linear scaling effects in the manufacturing process.

4. Discussion

This research presents the development and analysis of a discrete-event simulation model of a precast concrete panel production facility using the Simio software. The modeling process includes major stages of production line which are mold production and concrete casting. The objective of this study was not only to analyze an existing precast concrete panel production facility but also to evaluate the adaptability of the emerging technologies specifically, adaptive mold integration.

The integration of the adaptive molds into the facility in the simulation model can reveal significant insights for the efficient application of this prominent technology. In this analysis, number of adaptive molds in the system emerged as a critical factor to fulfill the assumed capacity for the panel production with this technology. This can be critically analyzed to decide on the number of the adaptive molds to incorporate into the facility. This simulation framework can be utilized as a decision-support tool to test the viability of the integration of the emerging novel technologies.

In future works, the mold production process can be modeled considering the sub-processes to enhance the accuracy, which leads to more detailed analysis of the manufacturing line. Furthermore, the adaptive mold integration can be further analyzed based on the complexity of the panel geometry, the type of formwork and costs. When deciding the optimum number of the adaptive molds, the cost of adopting of this technology into the existing facilities should be taken into account for a more comprehensive analysis. Accordingly, the optimum number can be explored for a more sustainable and cost-efficient solution for the thin-section concrete shell panel production.

5. Conclusion

In this study, an existing precast concrete panel production facility was modeled using Simio simulation software to investigate an emerging and novel adaptive mold technology. This technology has a great potential to transform the molding of the curved shell components into more cost-effective and time-efficient process. However, the integration of adaptive molds into the existing precast concrete panel facilities requires a detailed analysis to maximize the efficiency and decide on the optimum number of adaptive molds.

The simulation model was constructed based on the real process data provided by a precast concrete panel manufacturer. The major production processes were represented in the model and the parameters such as processing time or capacities were assigned according to the production process data. The model also was verified to validate its representativeness of the existing facility.

Various scenarios were explored for the integration of the adaptive molds, assuming a specific percentage of total panel production would be manufactured using this technology. This analysis allows to identify how many adaptive molds is required to meet the target panel production. Critically, doubling the panel production with the adaptive molds increases the required number of the adaptive molds by only 50%, which reveals a crucial nonlinear relationship. Ultimately, this simulation model can serve as a strategic tool to assess the integration of emerging technologies and guide the decision-making process for more feasible and sustainable production of curved shell structures.

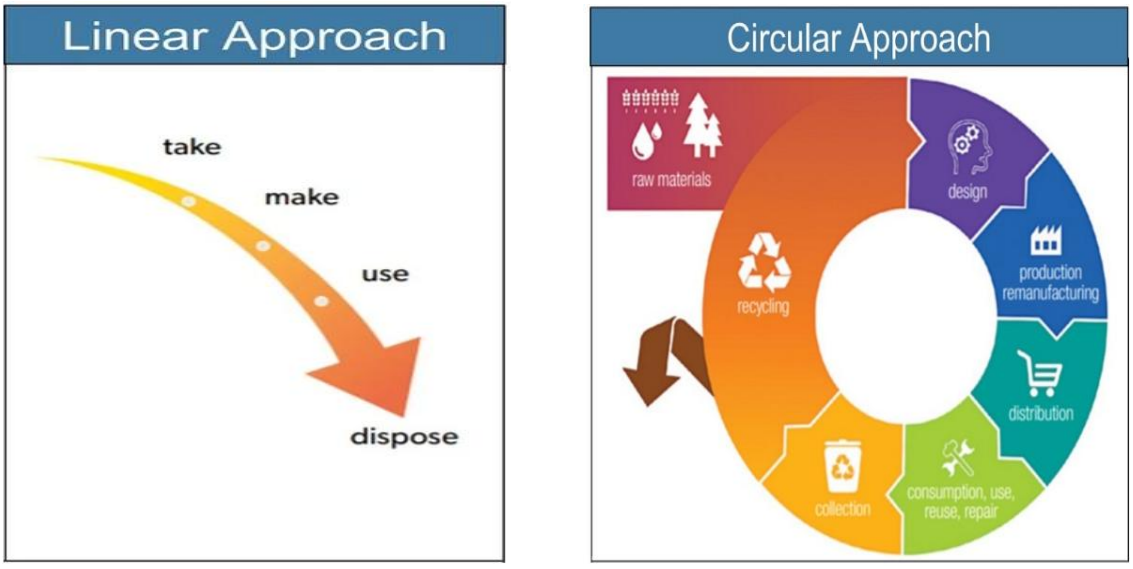
ABSTRACT

The rapid growth of the construction industry has significantly increased construction and demolition waste (C&DW) generation, creating a critical global environmental challenge. Traditionally, the construction sector has followed a linear "take-make-dispose" model, resulting in resource depletion, waste generation, and environmental pollution. Circular Economy (CE) offers an alternative approach by promoting resource efficiency, waste minimization, reuse, recycling, and recovery. This study presents a comprehensive literature review examining the major barriers to CE adoption in construction and demolition waste management (C&DWM) in developing countries. The review identifies key barriers related to policy and regulation, economic conditions, technical capacity, institutional governance, infrastructure, stakeholder knowledge, and social acceptance. Findings indicate that inadequate infrastructure for waste segregation, collection, recycling, and material recovery remains a major constraint. Limited access to appropriate recycling technologies and technical expertise further reduces the effective utilization of C&DW as secondary construction materials. Weak regulatory frameworks, unclear institutional responsibilities, high investment costs, limited financial incentives, and insufficient demand for recycled products also hinder CE implementation. In addition, limited stakeholder awareness, fragmented governance, inadequate C&DW databases, and the predominance of informal recycling systems create further challenges. Despite these barriers, opportunities exist through stronger policy incentives, improved regulatory frameworks, capacity building, public–private partnerships, and the application of digital and assessment tools such as Building Information Modeling (BIM) and Life Cycle Assessment (LCA). The study highlights the need for context-specific and integrated strategies that consider the socio-economic, institutional, and infrastructural conditions of developing countries to accelerate the transition towards sustainable and circular C&DWM systems.



Keywords: Construction and Demolition Waste; Circular Economy; Waste Management Barrier

1. Introduction

The construction industry is a major contributor to economic development through infrastructure expansion, urbanization, and employment generation. However, it is also one of

the most resource-intensive sectors, consuming substantial quantities of raw materials, energy, and water while generating significant C&DW. Rapid urbanization, population growth, and infrastructure development have further increased C&DW generation, particularly in developing countries. The conventional linear "take–make–dispose" model has contributed to resource depletion, landfill disposal, greenhouse gas emissions, and environmental degradation [1, 2].

The CE provides an alternative to this linear model by seeking to retain products, materials, and resources within the economic system for as long as possible through reduction, reuse, repair, refurbishment, remanufacturing, repurposing, recycling, and recovery [3, 4]. Unlike the conventional disposal-oriented approach, CE aims to minimize waste generation while improving resource efficiency and creating opportunities for secondary-material markets. The transition from the linear to circular approach is illustrated in Figure 1. The linear model follows a one-way pathway from resource extraction to disposal, whereas the circular model seeks to maintain material flows through recovery and reuse.

a) Linear "take–make–use–dispose" b) Circular approach for resource retention and recovery

Figure 1. Comparison of linear and circular economic approaches: (a) linear "take–make–use–dispose" model and (b) circular approach for resource retention and recovery. (Source: https://www.wsp.com/en-GL/insights/building-a-circular-economy)

Within the construction sector, CE extends beyond the recycling of C&DW and incorporates circular principles throughout the building life cycle. Strategies such as design for disassembly, adaptability, modular construction, adaptive reuse, selective demolition, material passports, BIM, and LCA can support material recovery and reduce waste generation[3, 5, 6]. Previous research indicates that applying circular strategies from the early design stage can improve the recovery potential of building materials and reduce environmental impacts at later stages of the building life cycle [7].

Despite these potential benefits, the practical adoption of CE in C&D waste management (C&DWM) remains limited, particularly in developing countries. Existing literature identifies weak regulatory enforcement, inadequate recycling infrastructure, high implementation costs, limited technical expertise, fragmented institutional responsibilities, and insufficient stakeholder awareness as important barriers to circular construction [4, 8]. Developing countries may also face limited waste segregation and recovery facilities, inadequate C&DW

databases, and difficulties in establishing reliable markets for recycled construction materials. The literature on India further highlights economic constraints, stakeholder awareness, institutional coordination, and the need for stronger enabling mechanisms for circular construction.

Although several studies have examined CE and C&DWM, the existing literature remains fragmented, with studies often focusing on individual countries, specific barriers, or particular circular strategies. There is a need for a broader synthesis of the interconnected barriers affecting CE adoption in developing-country contexts. Differences in economic conditions, institutional capacity, regulatory enforcement, technological readiness, and stakeholder awareness make it difficult to directly transfer circular practices developed in advanced economies to developing countries. Therefore, context-specific approaches are necessary to facilitate the transition from linear to circular construction systems [7, 9].
Accordingly, this review aims to synthesize the existing literature on the barriers affecting CE adoption in C&DWM in developing countries, examine the relationships among these barriers, and identify strategies and future research directions that can support circular construction. The review particularly focuses on policy and regulatory, economic, technical, institutional, infrastructural, and socio-cultural dimensions.

The objectives of this review are to:

a) Identify the major barriers affecting the adoption of CE practices in C&DWM in developing countries.
b) Classify these barriers into policy and regulatory, technical, economic, institutional, infrastructural, and socio-cultural dimensions.
c) Critically analyze the interrelationships among these barriers based on existing literature.
d) Propose recommendations and future research directions to facilitate the transition towards circular construction systems in developing countries.

2. Research Methodology

This study adopts a Systematic Literature Review (SLR) approach to identify, synthesize, and critically analyze the barriers affecting the adoption of CE practices in C&DWM in developing countries. A systematic approach was selected to ensure transparency and consistency in the identification and selection of relevant literature [10]. The review process was guided by the PRISMA 2020 framework, which provides a structured procedure for identification, screening, eligibility assessment, and inclusion of studies [11].

2.1 Literature Search and Selection

Relevant literature was searched using Scopus and Web of Science, focusing on peer-reviewed publications related to CE, C&DWM, barriers, challenges, and developing countries. The search employed combinations of keywords such as *"Circular Economy," "Construction and Demolition Waste," "Construction Waste Management," "Barriers," "Challenges,"* and *"Developing Countries"* using Boolean operators.
Studies published in English and directly addressing CE implementation, C&DWM, or barriers and enabling factors in developing countries were considered. Duplicate records, conference abstracts, editorials, and studies unrelated to construction or C&DW were excluded. The screening process involved title and abstract assessment followed by full-text evaluation of potentially relevant studies.

2.2 Data Extraction and Thematic Analysis

The selected studies were then analyzed thematically to identify recurring barriers and their relationships.
Based on the literature, the barriers were classified into six major categories:

1. Policy and regulatory barriers
2. Economic and financial barriers
3. Technical and technological barriers
4. Institutional and governance barriers
5. Infrastructure barriers
6. Social and behavioral barriers

The systematic review provides a structured basis for understanding the existing research on CE adoption in C&DWM. Before examining the barriers that constrain CE implementation, it is important to establish the role of CE within the construction sector and understand how circular strategies can be applied across the building life cycle. Therefore, the following section briefly discusses the concept of CE in C&DWM, its major circular strategies, the role of digital technologies, and the specific challenges associated with its implementation in developing countries.

3. Circular Economy in Construction and Demolition Waste Management

3.1 Concept of CE in the Construction Sector

The conventional construction sector largely follows a linear economic model based on the extraction of raw materials, production, construction, use, and eventual disposal. This “take–make–consume–dispose” model results in substantial resource consumption and waste generation. In contrast, the CE seeks to maintain the value of materials and products for as long as possible through strategies such as reducing, reusing, repairing, refurbishing, remanufacturing, repurposing, recycling, and recovering resources [3, 12].
The construction sector is particularly important for CE because buildings contain large quantities of materials that can potentially be reused or recovered. CE in construction, therefore, involves more than recycling demolition waste at the end of a building's life. It requires circular thinking throughout the building life cycle, beginning with planning and design and continuing through construction, operation, maintenance, renovation, demolition, and material recovery [1, 9].
Circular construction strategies include DfD, design for adaptability, adaptive reuse, modular construction, material reuse, selective demolition, recycling, and recovery. Such strategies can reduce the consumption of virgin materials and increase the possibility of recovering components and materials at the end of a building's service life [13–15].
The CE concept can therefore be understood as a shift from “waste management” to “resource management.” Instead of treating C&DW as an unwanted output requiring disposal, circular construction considers buildings and infrastructure as material stocks from which resources can be recovered and returned to productive use.

3.2 Circular Strategies Across the Building Life Cycle

Circularity can be incorporated at different stages of the building life cycle. Early-stage decisions are particularly important because design and material-selection decisions influence

future waste generation and the potential for reuse and recovery. Table 1 and Figure 2 below show CE strategies across the building life cycle

Table 1 Circular Economy strategies across the building life cycle (Source: The Authors)

S.no	Building life-cycle stage	Major circular strategies	Potential contribution
1.	Planning and design	Design for disassembly, adaptability, and durability	Facilitates future reuse and recovery
2.	Material selection	Recycled and reusable materials	Reduces demand for virgin resources
3.	Construction	Prefabrication, modular construction, and waste minimization	Reduces material waste
4.	Operation and maintenance	Repair, maintenance, and adaptive reuse	Extends building service life
5.	Demolition	Selective demolition and deconstruction	Improves component recovery
6.	End-of-life	Reuse, recycling, and material recovery	Reduces landfill disposal

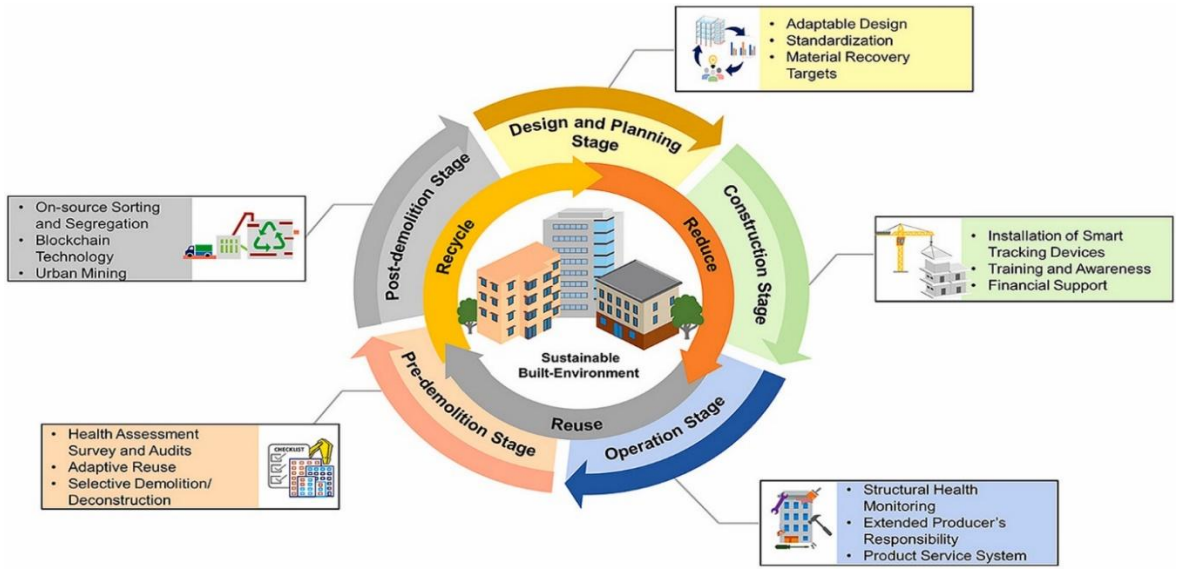


Figure 2 Circular Economy strategies across the building life cycle [16]

The literature indicates that circular strategies should not be considered independently because decisions at one stage affect opportunities at subsequent stages. For example, designing connections that can be dismantled rather than permanently bonded can make components easier to recover during demolition. Similarly, documenting materials and components during design and construction can support their identification and reuse in the future [5, 17].

Adaptive reuse is another important CE strategy because retaining an existing building can avoid the material consumption and waste generation associated with complete demolition and new construction. Life-cycle studies have consequently emphasized the importance of

considering whether an existing building can be repurposed before selecting demolition and replacement as the preferred option [18, 19].

3.3 Role of Digital Technologies in Circular Construction

These technological means can enable CE processes through better management of information and traceability of materials in the construction process. BIM can be used to identify and document building components, estimate the amount of material and waste production, plan for demolition, and design for disassembly [6].

In addition, the material passport can give information about materials used in building constructions. The information can help identify reusable materials during the renovation or demolition of buildings [5]. However, the implementation of these technologies requires appropriate digital infrastructure, standardized data, trained professionals, and institutional support.

The use of LCA will enhance such digital techniques in assessing the environmental impacts of different materials, as well as waste management options. The use of LCA together with CE will enable the identification of whether the use of reuse, recycling, or recovery options is environmentally beneficial in a certain situation. According to the literature, however, it is difficult to integrate such techniques in practice, especially in developing countries [6, 20, 21]. Thus, digital technologies should be regarded as enabling tools rather than standalone solutions. Their effectiveness depends on the availability of reliable material data, institutional capacity, technical expertise, and supportive regulatory frameworks.

4. Circular Economy in Developing Countries

The transition towards CE becomes particularly important for developing nations since the process of urbanization and infrastructural development is resulting in increased use of construction materials on one hand, while simultaneously producing huge amounts of C&DW [4, 9]. However, the conditions for implementation of the transition in developing nations are quite different from those in developed nations due to differences in institutional capacity, infrastructure, regulatory framework, and market development [7].

Developing nations generally suffer from a lack of waste management infrastructure, ineffective regulation enforcement, a lack of funding, technical know-how, institutional fragmentation, and a lack of awareness amongst stakeholders. Such conditions tend to hinder the process of segregation, recycling, material recovery, and circular design [4, 22]. The current review also finds the lack of segregation, collection, recycling, and material recovery infrastructure, economic constraints, weak regulation, technical knowledge, and institutional fragmentation as significant barriers to the transition [7, 23].

The literature also indicates that CE practices cannot simply be transferred from developed countries without considering local socio-economic and institutional conditions [3, 9]. For example, circular systems based on sophisticated digital platforms, advanced recycling technologies, or highly developed secondary-material markets may be difficult to implement where basic collection, segregation, and recycling systems are still developing [4]. Therefore, context-specific CE strategies are required for developing economies.

This is particularly relevant for countries such as India, where rapid construction activity is accompanied by increasing C&D waste generation, while challenges remain in terms of regulatory implementation, recycling infrastructure, stakeholder coordination, and market development for recovered materials [7, 20, 24]. Strengthening the alignment between CE objectives, construction policies, and C&DWM practices is therefore essential for establishing a more circular construction sector in India [7].

Consequently, the successful adoption of CE in developing countries requires simultaneous

attention to policy, economic viability, infrastructure, technical capacity, institutional coordination, and stakeholder behavior [4, 22]. These interconnected factors form the basis for the barrier analysis presented in the following section.

The above discussion clearly shows that CE presents a chance for changing the paradigm of C&DWM from the traditional disposal process into a process of conserving, reusing, recycling, and recovering resources. Yet, the application of circular approaches is inconsistent between countries, and developing nations have unique obstacles to overcome in terms of regulation capability, financial ability, infrastructure, technology, and collaboration among stakeholders. The literature also shows that such obstacles are interrelated instead of being independent, and the weakness in one factor tends to exacerbate the problems in other areas. Hence, in order to understand why CE has not been adopted by developing nations, this section will examine the barriers to the implementation of circular C&DWM through critical analysis.

5. Barriers to the Adoption of CE in Construction and Demolition Waste Management

The adoption of CE in C&DWM in developing countries is constrained by interconnected policy, economic, technical, institutional, infrastructural, and social factors. These barriers often reinforce one another, making it difficult to establish effective circular material flows [4, 22].

5.1 Policy and Regulatory Barriers

Lack of a proper regulatory framework and enforcement is still one of the challenges to the implementation of CE. The regulations of C&DW in the developing nations tend to concentrate on only collection and disposal, and not on waste prevention and recycling [4, 7, 22, 23, 25]. Lack of clear-cut roles of the various parties involved, lack of monitoring, and lack of recycled building material standards hinder the CE process [7].

5.2 Economic and Financial Barriers

The transition to circular construction often involves higher initial costs for waste segregation, transportation, processing, recycling facilities, and workforce training. At the same time, low demand for recycled materials and competition from relatively inexpensive virgin materials can reduce the economic attractiveness of recycling [7, 20, 25]. Limited access to finance further restricts investment, particularly among small and medium-sized construction enterprises. Subsidies, tax incentives, landfill charges, and development of stable markets for recovered materials can improve the economic feasibility of CE.

5.3 Technical and Technological Barriers

Poor source segregation, heterogeneous waste streams, limited recycling technologies, and inadequate technical expertise reduce the quality and quantity of recovered materials. Developing countries may also lack appropriate testing facilities and standards for assessing recycled construction products [4]. Digital tools such as BIM and material passports can improve material identification, tracking, and recovery, but their implementation requires reliable data, technical skills, and supporting infrastructure [5, 6]. Thus, technology adoption needs to be aligned with local technical capacity.

5.4 Institutional and Governance Barriers

Implementation gaps may arise because of fragmented roles in the different agencies of government and inadequate coordination between the public entities and construction actors. The lack of accurate C&DW databases poses further challenges with regard to the estimation

of waste generation, planning for recycling facilities, and monitoring the recovery efficiency [4, 7]. It is thus necessary to enhance institutional capability at the local level and coordination efforts among the various stakeholders.

5.5 Infrastructure Barriers

Inadequate infrastructure for collection, segregation, transportation, sorting, and recycling is a major constraint in developing countries. Limited availability of recycling facilities can increase transportation and processing costs and encourage disposal rather than recovery [4]. Infrastructure development should therefore be supported by reliable information on waste quantities, composition, and geographical distribution to ensure that recycling facilities are appropriately located and sized.

5.6 Knowledge and Capacity Barriers

Low levels of awareness and technical expertise on the part of architects, engineers, contractors, laborers, and local government bodies can serve as impediments to the implementation of circular practices. CE principles, such as deconstruction, recycling, selective demolition, and the use of recycled materials, involve a set of skills that might not have been taught during traditional construction [3, 7]. Professional training, academic programs, and demonstration projects can help build the required capacity.

5.7 Informal Sector and Social Barriers

The presence of an informal recycling system is a problem as well as an advantage for C&DWM. First of all, informal recycling could take place outside the waste management system and be accompanied by a fragmentation of flows of materials; nevertheless, such informal recyclers can provide a significant contribution to material recycling [4]. Secondly, the quality of recycled material may cause reluctance from construction contractors and customers [7]. Appropriate integration of informal recovery networks, quality certification, and stakeholder awareness can help address these challenges.

5.8 Interrelationship Among Barriers

These barriers are not mutually exclusive but are interconnected, creating a system where each one reinforces the other. For instance, poor regulation can hinder infrastructure development; poor infrastructure can cause higher recycling costs; high costs may result in lower demand for recyclables; and reduced demand can hinder private sector investments. In the same way, poor technical capacity may hinder the effectiveness of both regulatory and technological interventions [13, 19, 20, 22]. Therefore, there is a need for a holistic strategy for overcoming such barriers to ensure the success of CE. Seven main categories of barriers have been identified in the literature review. They include: policy and regulatory barriers; economic and financial barriers; technical and technological barriers; institutional and governance barriers; infrastructure barriers; knowledge and capacity barriers; and informal-sector and social barriers. These barriers are discussed in detail in Table 2 below.

Table 2 Major barriers to CE adoption in C&DWM (Source: The Authors)

S.no	Barrier category	Key issues
1.	Policy & regulatory	Weak enforcement, fragmented regulations, lack of standards
2.	Economic & financial	High costs, limited finance, and weak recycled-material markets
3.	Technical & technological	Poor segregation, limited technology, and technical expertise
4.	Institutional & governance	Poor coordination, weak local capacity, and limited data
5.	Infrastructure	Inadequate collection, sorting, and recycling facilities
6.	Knowledge & capacity	Limited CE awareness and professional skills
7.	Informal & social	Informal recovery, low acceptance of recycled materials

The analysis of the preceding section demonstrates that the adoption of CE in C&DWM is constrained by a combination of policy, economic, technical, institutional, infrastructural, and social barriers. These challenges are interconnected, and addressing them individually is unlikely to achieve effective circularity. Therefore, a coordinated set of strategies and enabling measures is required to create a supportive environment for CE adoption. The following section discusses the key strategies and enablers that can help overcome these barriers and facilitate the transition towards sustainable and circular C&DWM in developing countries.

6. Suggestive Measures & Recommendations

The barriers discussed in Section 5 indicate that CE adoption requires coordinated interventions across policy, economic, technical, institutional, and social dimensions. The following strategies can help create an enabling environment for circular C&DWM in developing countries.

6.1.Policy and Economic Measures

C&DW management regulations need to be strengthened through the formulation of proper waste prevention measures, waste source segregation, waste reuse, and recycling practices, accompanied by proper monitoring and enforcement [4, 8]. Standards for recycled construction products may promote market trust, whereas circular procurement can create demand for recovered waste [7].

Financial tools like subsidies, taxes, low interest rates, and landfill fees may make recovery and recycling more economically feasible [26]. Equally important is the development of a consistent market for recycled construction waste, since a lack of demand would deter private sector recycling investments.

6.2 Infrastructure, Technology, and Capacity Building

Adequate facilities for collection, segregation, sorting, and recycling are essential for establishing circular material flows. Infrastructure should be planned according to local waste quantities and composition [4, 13]. Appropriate technologies such as BIM, GIS, material passports, and LCA can further support material identification, tracking, waste estimation, and environmental assessment [5, 6]. However, technology adoption should be aligned with local

financial and technical.
Training and capacity building for architects, engineers, contractors, local authorities, and waste workers are also necessary to improve the implementation of circular practices. Greater awareness can increase acceptance of recycled materials and encourage the adoption of circular design and waste-management practices [3, 27].

6.3 Institutional and Stakeholder Collaboration

Effective CE implementation requires coordination among government agencies, construction professionals, developers, contractors, recyclers, and material suppliers. Public–private partnerships can support investment in recycling infrastructure and facilitate knowledge and technology transfer [17]. In developing countries, the informal recovery sector should also be considered within CE strategies, where appropriate, because its existing material-recovery networks can contribute to resource recovery.

6.4 Integrated Approach

The literature indicates that no single intervention can overcome the barriers to CE adoption. Policy support creates the enabling environment, economic incentives improve feasibility, infrastructure enables material recovery, technology supports efficient management, and capacity building facilitates implementation. Therefore, these measures should be implemented in an integrated and context-specific manner to support the transition from conventional waste disposal towards circular C&DWM.
The strategies discussed in Section 5 demonstrate that overcoming barriers to CE adoption requires coordinated interventions across policy, economics, infrastructure, technology, and stakeholder participation. However, the effectiveness of these measures depends on their integration and adaptation to the specific conditions of developing countries. The following section discusses the key findings of the review, the interrelationships among the identified barriers and enablers, and their implications for achieving circular C&D waste management.

7. Conclusion

The reviewed literature demonstrates that the transition towards CE in C&DWM in developing countries is influenced by a combination of policy, economic, technical, institutional, infrastructural, and social factors. These barriers are interconnected, indicating that CE adoption cannot be achieved through isolated interventions.
A key finding is that policy and institutional support provide the foundation for circular transformation. Regulations can establish requirements for segregation, recycling, and recovery; however, their effectiveness depends on enforcement, institutional capacity, and stakeholder coordination. Economic conditions are equally important because high recycling costs and limited demand for secondary materials can discourage investment, even when appropriate regulations exist.
The review also indicates that infrastructure and technical capacity act as critical enabling conditions. Without adequate collection, segregation, and recycling facilities, the practical implementation of CE remains limited. Similarly, technologies such as BIM, material passports, and LCA can support circular construction, but their effectiveness depends on data availability, technical skills, and institutional readiness.
An important implication is that CE strategies developed in developed economies cannot be directly transferred to developing countries. Differences in infrastructure, governance, financing, construction practices, and informal recovery systems require context-specific approaches. Therefore, developing countries should initially strengthen basic waste-

management systems, regulatory enforcement, and local capacity while progressively introducing advanced circular technologies and market mechanisms.
Overall, the findings suggest that successful CE adoption requires a system-level approach in which policy, finance, infrastructure, technology, and stakeholder participation reinforce one another. This integrated perspective provides a basis for developing practical and context-specific C&DWM frameworks for developing countries.

8. Future Research Direction

Based on the identified barriers and gaps, future research should focus on:

a) Standardized C&DW Quantification**:** Develop consistent and locally adaptable methods for estimating C&DW generation at city and project levels.
b) City-Level Waste Databases**:** Establish reliable databases on waste quantity, composition, material flows, and recycling rates to support evidence-based planning.
c) Integration of CE and LCA**:** Combine CE strategies with LCA to evaluate the environmental benefits of reuse, recycling, and material recovery.
d) Economic Feasibility of Circular Practices**:** Assess recycling costs, transportation, market demand, and financial incentives to develop economically viable circular business models.
e) Informal-Sector Integration**:** Investigate appropriate approaches for integrating informal material-recovery networks into formal C&DWM systems.
f) Context-Specific CE Frameworks**:** Develop and validate CE frameworks that reflect the institutional, economic, infrastructural, and socio-cultural conditions of developing countries.
g) Digital Technology Adoption: Explore affordable and scalable applications of BIM, GIS, and material passports for waste estimation, material tracking, and recovery planning.
h) Stakeholder Collaboration**:** Examine effective mechanisms for improving coordination among governments, designers, contractors, recyclers, and other stakeholders.

Abstract. Formwork systems represent a significant proportion of the cost, material consumption, and environmental footprint in reinforced concrete construction. As the industry accelerates its transition toward net-zero emissions, evaluating the environmental profiles of commonly utilized formwork materials such as timber, steel, aluminum, and plastic becomes essential. Each material exhibits a distinct ecological impact driven by factors like embodied carbon, reusability, and end-of-life recyclability. This study presents a comprehensive literature review investigating these systems through the perspectives of sustainability, carbon footprint reduction, and circular economy principles. The primary objective is to synthesize empirical data from recent peer-reviewed research to assess the environmental implications of various materials and identify key decision criteria for sustainable formwork selection. Ultimately, the findings indicate that formwork materials should be selected based on their full life-cycle performance and circularity rather than solely on their initial environmental impacts.

Keywords: Carbon footprint, Circular economy, Formwork systems, Sustainability.

1 Introduction

The building industry is responsible for a considerable share of resource consumption worldwide, as well as the associated waste generation and emissions [12]. Notably, CO_2 emissions from the construction sector account for almost 40% of the industry's annual emissions. Operating at the core of this highly resource-intensive environment, reinforced concrete (RC) structures constitute the backbone of global infrastructure. Within this supply chain, formwork systems are fundamental to the structural formation process. Despite being temporary elements, formwork constitutes the predominant financial and environmental burden in RC projects, accounting for up to 60% of the concrete structure's unit cost, 15% of the overall construction expenses, and a massive portion of the embodied carbon load ([9, 10]). Advances in construction technology have introduced a wide range of formwork materials, including conventional timber and alternative systems made of steel, aluminum, and plastic.

As the construction industry moves toward net-zero emission targets, formwork selection needs to consider more than initial investment cost. Existing Life Cycle Assessment (LCA) studies of conventional and modern formwork materials generally focus on cradle-to-gate environmental impacts. However, this approach may not fully account for factors such as on-site reusability, occupational health and safety (OHS) conditions during erection, and end-of-life recyclability.

This study systematically reviews the existing literature to identify the main findings and research gaps related to the environmental performance and circularity of formwork systems. It also outlines future research directions for integrating extended service life, wear-out coefficients, end-of-life recyclability, and practical site-related factors, including labor

efficiency and OHS risks, into formwork selection. The study aims to support future construction management research in developing more comprehensive, life-cycle-based decision-making approaches.

2 Methodology

To examine the environmental implications and circular economy potentials of formwork systems, this study adopted a comprehensive review methodology guided by Systematic Literature Review (SLR) principles. The data collection process was conducted through Scopus and Web of Science (WoS), the most prominent and prestigious databases in academic literature.

To effectively filter the vast literature towards the specific research objective, the search string was formulated based on three main concepts: System Focus, Environmental/Economic Impact and Circularity, and Analyzed Material Types. Accordingly, the following Boolean search string was executed in the databases: ("formwork") AND ("circular economy" OR "life cycle assessment" OR "LCA" OR "embodied carbon" OR "carbon footprint" OR "sustainability" OR "sustainable") AND ("timber" OR "wood" OR "steel" OR "aluminum" OR "plastic").

To capture the most recent technological advancements and sustainability paradigms, the search was limited to peer-reviewed journal articles and conference proceedings published in English from 2010 to the present. The initial search yielded 218 potential records from Scopus and 211 from Web of Science, resulting in a total pool of 429 publications.

The initial pool of 429 articles was subjected to a rigorous screening process to maintain the strict focus of the study. First, duplicate records across the two databases were removed. Subsequently, a title and abstract screening was conducted. Studies that evaluated formwork systems solely based on structural strength, concrete mechanics (e.g., load-bearing capacity), or those that focused on whole-building Life Cycle Assessments without isolating formwork as a specific analytical unit were excluded from the scope.

Due to the rigid nature of search engine algorithms, it was identified that several fundamental studies analyzing the site dynamics (e.g., occupational health and safety, operational speed) and eco-efficiency of formwork systems using alternative terminologies (e.g., "wear-out coefficient", "jump formwork") were filtered out during the initial search. To eliminate this literature blind spot and enhance analytical depth, the Backward Snowballing technique was integrated into the methodology.

The reference lists of the core articles filtered through the standard Boolean search were manually screened. Crucial studies that fell outside the primary keyword syntax but were vital for a comprehensive circular economy perspective were included. As a result of this meticulous PRISMA-based screening and synthesis process, a final set of 10 highly relevant core studies—comparing formwork systems across environmental, economic, and operational (workforce/safety) dimensions—was selected for the critical review. Ultimately, these selected studies established the empirical foundation to identify critical research gaps and outline strategic future research directions for the industry.

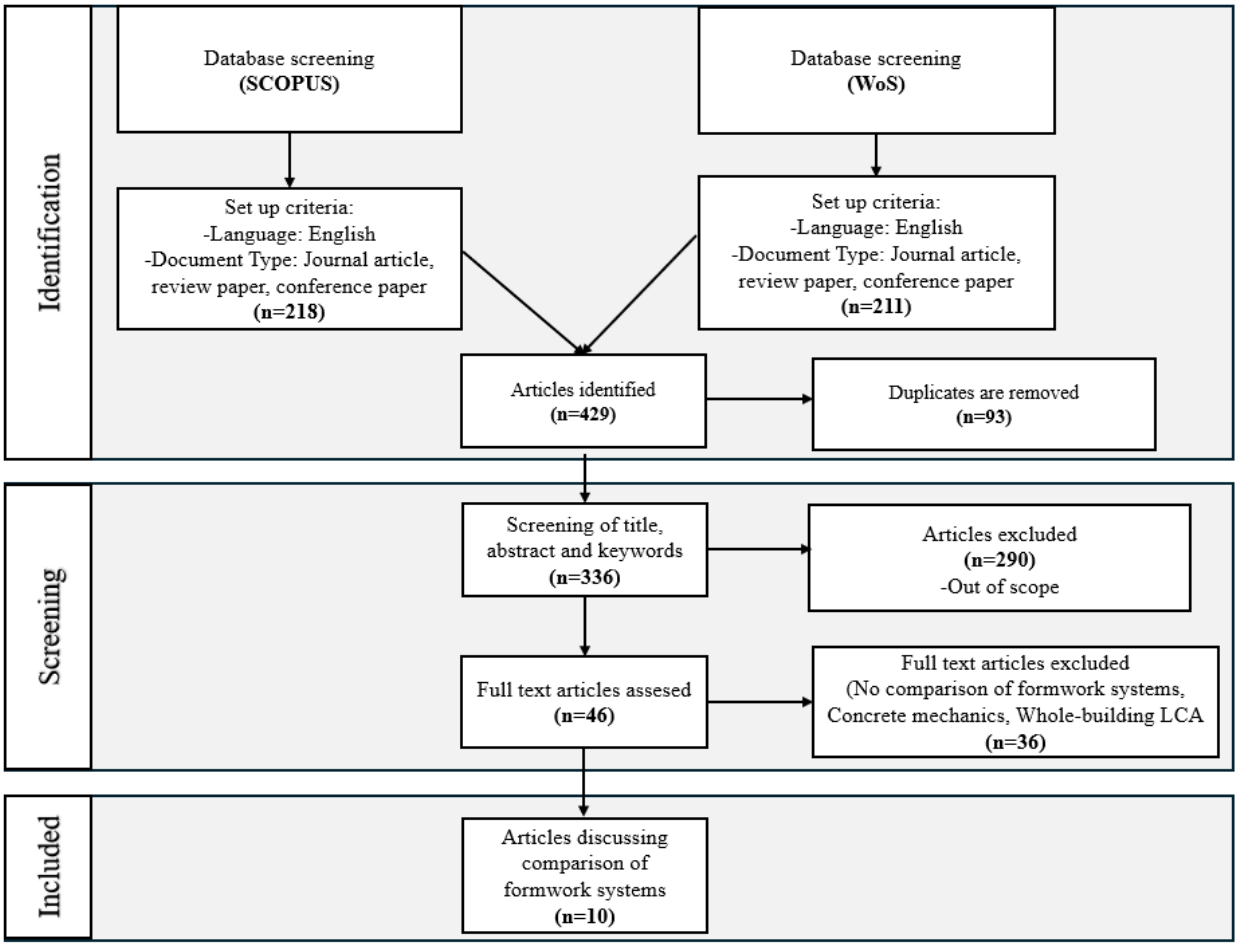

Fig. 1. The PRISMA flow diagram of the literature selection process

3 Review of Existing Literature

The reviewed literature indicates a gradual shift in the evaluation of formwork systems. While earlier studies mainly examined initial costs and material properties, recent research considers a wider range of environmental, economic, and operational factors. Table 1 summarizes the methods, findings, and limitations of the selected studies and provides a basis for identifying the main research gaps.

Table 1. Critical synthesis of the selected literature

Author and Year	Examined Systems	Core Focus & Methodology	Key Findings
Rahim & Haron, 2013	Timber vs. IBS (Lightweight Steel) Formwork	Case Study (Cost, Labor, and Wastage in High-Rise Buildings)	Timber causes massive wastage and demands high skilled labor. Conversely, steel IBS reduces overall costs and construction time via high reusability.
Parekh, 2015	Timber, Aluminum, Steel Formwork	Feasibility and Performance Analysis in Mass Construction	Aluminum formwork delivers rapid, high-quality, and low-maintenance construction, but its cost-effectiveness strictly depends on mass construction and highly repetitive projects.

Author and Year	Examined Systems	Core Focus & Methodology	Key Findings
Kazi & Parkar, 2015	Timber, Plastic (PLASTECH) and Steel (DOKA, PERI, RMD, MIVAN) Formwork	Cost, Quality, and Speed Comparison in Fast-Track Construction	Plastic minimizes idle costs in highly uncertain projects, whereas MIVAN is economically viable exclusively in mass housing.
Asadi et al., 2017	Timber and Steel (DOKA, MIVAN) Formwork	Comparative Analysis based on Site Constraints and Repetition	MIVAN reduces cost/time in repetitive projects, but wood remains preferred in non-repetitive projects facing severe space and storage restrictions.
Gaddam & Achuthan, 2020	Timber, Aluminum, Jump Formwork	Multi-Project Case Analysis (Cost and Duration Comparison)	Advanced systems like jump formwork generate significant indirect cost savings by reducing project duration, overcoming initial cost barriers.
Donkor et al., 2022	Timber and Steel Formwork	Field Survey (Quantitative Questionnaire Study)	While timber has initial cost benefits, steel shows better performance in durability, surface finish, and labor productivity.
Bakırhan & Kayılı, 2023	Timber, Steel and Aluminum Formwork	Scenario-Based Environmental and Economic LCA	While timber is economical for single-use scenarios, factoring in actual multi-use service lives reveals that steel systems show better performance for mass housing, achieving a 70% cost reduction and a 60.6% lower global warming potential.
Balasbaneh et al., 2024	Plastic, Steel, Plywood, Timber Formwork	LCA, LCC, and MCDM (1-use vs. 50-use scenarios)	While timber is optimal for a single use, MCDM analysis ultimately identifies plastic as the best overall formwork material after 50 cycles regarding embodied energy and economic cost.
Apdeni et al., 2024	Aluminum and Timber Formwork	Site Case Study (Eco-Efficiency and Cost Analysis)	Despite being initially 2.25 times more expensive, aluminum's 200-cycle reusability and zero waste achieved significantly higher eco-efficiency than timber.
Baskaran et al., 2025	Steel, Timber, Aluminum, Plastic Hybrid Formwork	LCA integrated with Material Wear-Out Coefficients	Hybrid systems provide the most sustainable solutions by offsetting the high environmental burdens of short-lived timber with the extreme durability of aluminum (250 cycles), thereby minimizing overall material depletion.

The reviewed studies show a gradual shift from basic cost comparisons to life-cycle-based sustainability assessments.

Initial studies in the literature heavily prioritized operational speed, direct costs, and physical on-site wastage. Rahim and Haron [14] compared conventional timber formwork with lightweight steel Industrialized Building Systems (IBS). They reported that the limited reusability of timber increases skilled-labor requirements and material waste, whereas steel systems can reduce overall costs and labor demand. Parekh [13] found that aluminum formwork supports faster erection and higher construction quality, although its economic performance depends largely on mass construction and repetitive project designs. Kazi and Parkar [8] examined fast-track formwork technologies, including Plastech, Doka, and MIVAN. Their study showed that industrialized systems may lead to substantial idle costs when construction is interrupted, indicating that operational flexibility should also be considered in formwork selection.

As the literature progressed, researchers began to increasingly factor in site restrictions and indirect economic benefits. Asadi et al. [1] reported that MIVAN can reduce construction time and cost in highly repetitive projects, while conventional timber may remain more suitable for non-repetitive projects with limited site and storage space. Gaddam and Achutam [7] indicated that jump formwork and aluminum systems can shorten project duration and generate indirect cost savings that help offset their higher initial costs. Donkor et al. [6] found through a quantitative field survey that, although timber is often selected because of its lower acquisition cost, steel performs better in terms of durability, surface finish, and labor productivity.

In recent years, the analytical focus has fundamentally shifted toward Life Cycle Assessment (LCA), reusability dynamics, and the "initial carbon fallacy." Bakırhan and Kayılı [3] mathematically demonstrated that evaluating formwork without accounting for its service life leads to flawed decisions. Under a hypothetical single-use scenario, steel exhibited carbon emissions 19 times higher than timber; however, when actual multi-use lifespans were factored in, timber's global warming potential was 60.6% higher. This paradigm shift is extensively supported by Balazbaneh et al. [4], who utilized a Multi-Criteria Decision-Making (MCDM) model. Their findings revealed that at a 1-use scenario, timber is the optimal choice, but at a 50-use scenario, the hierarchy completely reverses, crowning plastic and steel as the most sustainable options. Similarly, a site case study by Apdeni et al. [2] reported that despite aluminum being 2.25 times more expensive initially, its extraordinary 200-cycle reusability and zero material waste yield far higher eco-efficiency than conventional systems.

Recent research has also examined the potential benefits of combining different formwork materials. Baskaran et al. [5] evaluated hybrid formwork systems and identified the wear-out coefficient as an important assessment criterion. Their findings suggest that combining durable materials such as aluminum or steel with lower-impact materials such as timber or plastic may provide a more balanced solution by reducing overall material consumption and distributing environmental impacts over a longer service life.

4 Discussion and Conclusion

Despite the progress from operational comparisons to life-cycle-based assessments, an important research gap remains. Current sustainability models account for physical wear-out coefficients and theoretical carbon impacts, but they often overlook practical construction-site conditions. Future construction management studies should therefore combine material-level environmental assessments with economic and operational criteria through multi-criteria decision-making approaches.

Future research should also move beyond traditional cradle-to-gate assessments and single-use carbon metrics. Initial embodied carbon values may be misleading when the service life and repeated use of formwork materials are not considered. Life Cycle Assessment (LCA) studies should therefore incorporate the wear-out coefficient and report environmental impacts on a per-use basis over the service life, rather than only on a per-kilogram basis. The maximum number of reuse cycles and end-of-life recovery options, including recyclability and scrap value, should also be considered to provide a more accurate assessment of eco-efficiency and circularity.

Environmental performance should be evaluated together with social and operational factors. Relevant site-related criteria include occupational health and safety (OHS) risks, storage requirements, workforce demand, labor productivity, erection speed, crane dependency, and waste generation during construction. Project repetition and site constraints should also be considered because they may significantly influence the economic and operational performance of a formwork system. Including these criteria would allow future assessment models to better reflect actual construction conditions.

A formwork system may show favorable environmental performance in theory but still create practical difficulties if it requires substantial skilled labor, increases material-handling risks, or causes operational bottlenecks. The reviewed literature indicates that the suitability of a formwork system depends on both its material characteristics and the conditions under which it is used. Therefore, environmental, economic, social, and operational indicators should be considered together when evaluating the sustainability and circularity of formwork systems.

Abstract. Bidding decisions in international construction represent a strategically significant and resource-intensive process, requiring contractors to evaluate multiple competing criteria under time pressure and organisational constraints. Firms operating in large-scale infrastructure markets must rapidly screen hundreds of opportunities against limited organizational capacity, weighing financial scale, geographic risk, technical fit, and strategic alignment simultaneously. The continued reliance on expert scoring systems leaves rich information sources, particularly unstructured project description texts, largely outside the decision-making process.

This paper presents a pilot study developing and evaluating a machine learning based Decision Support System (DSS) for bidding decisions in international transportation (road and railway) infrastructure projects. A proprietary dataset of 2259 infrastructure project records was used, combining structured project attributes with Natural Language Processing (NLP) derived features extracted from text descriptions. The study's primary focus is the applicability of GraphSAGE to the bid/no-bid decision problem, chosen for its capacity to model inter-project relationships through graph-based aggregation and to generalise to new project nodes through inductive learning. Logistic Regression, Random Forest, and XGBoost serve as baseline models. A dual strategy graph was constructed connecting projects through shared Region values and text embedding cosine similarity, and SHAP analysis was applied to interpret model decisions.

Logistic Regression achieved the highest overall accuracy at 98.33% with an AUC-ROC of 0.9976, while GraphSAGE recorded the highest precision of 96.24%, demonstrating its value as a conservative and reliable bid recommender. SHAP analysis applied to the best-performing model revealed that text embedding features account for 72.5% of total feature importance, substantially exceeding the 24.6% contribution of structured features. This demonstrates that project description texts carry decision-relevant signals far beyond what structured project attributes alone can capture.

Keywords: Bidding decisions; Machine learning; GraphSAGE; NLP.

1 Introduction

International construction contractors are routinely confronted with extensive project screening processes that require the simultaneous evaluation of competing criteria, including financial scale, geographic risk profile, technical fit, and strategic priority [12]. Poor management of the bid/no-bid decision carries significant consequences on both ends. Misallocated resources and weakened market position when unsuitable projects are pursued, and the loss of strategically viable opportunities when promising ones are overlooked, each outcome with direct implications for a firm's long term-competitive standing.

A fundamental limitation of current practice is the heavy reliance on expert scoring systems and the resulting inability to systematically exploit the rich informational content embedded in project databases, particularly written project descriptions. This gap represents not merely a methodological shortcoming but a tangible efficiency loss arising from the failure to translate available institutional knowledge into the decision-making process.

Recent advances in machine learning and NLP offer promising pathways to address this limitation. Graph neural networks allow structural and semantic relationships between projects to be incorporated into the model, enabling access to contextual information that conventional flat classifiers cannot capture. GraphSAGE, introduced by Hamilton et al. [1], extends this capability through inductive learning, generating representation vectors for project nodes not encountered during training. This feature offers a significant practical advantage when modeling new datasets to which new project records are continuously added.

This study takes the applicability of GraphSAGE to bid/no-bid decision making as its primary research objective and makes four original contributions in this direction. First, a multimodal feature engineering data-pipeline is developed that integrates structured project attributes with Sentence-BERT based text embeddings. Second, a dual strategy graph construction method is proposed, connecting projects based on shared Region data and text embedding cosine similarity. Third, a comparative experimental design against three baseline models is established to enable a meaningful evaluation of GraphSAGE's independent contribution. Fourth, SHAP analysis is employed to reveal the dominant influence of text embedding features on model decisions. This finding underpins a two-stage DSS architecture capable of generating meaningful preliminary recommendations even in the absence of expert scoring criteria. The empirical basis for the study is a proprietary dataset drawn from a contractor operating across multiple sectors, filtered to transportation infrastructure projects. Full details of the dataset composition, feature engineering pipeline, and model configurations are described in the sections that follow.

2 Literature Review

The growing adoption of artificial intelligence in construction has attracted substantial scholarly attention, resulting in several broad-scope reviews that provide the conceptual backdrop for this study. Pan and Zhang [2] conducted a systematic review combining scientometric and qualitative analysis of 4,473 journal articles published between 1997 and 2020, documenting the progression of AI applications in construction engineering and management and identifying six key future research directions, among them NLP and intelligence optimization, and process mining. García et al. [3] extended this synthesis with a hybrid bibliometric analysis covering studies from 2015 to 2022, using a BERT-based topic modelling methodology to identify principal application clusters, which include construction management, tunnelling, concrete technology, and pavement engineering. Xu et al. [4] complemented these surveys by tracing the theoretical transition from shallow to deep learning in construction contexts, evaluating the relative strengths and limitations of each generation of models and proposing directions for domain-specific deep network development.

Within the construction project management domain, machine learning has been applied most extensively to cost estimation, schedule prediction, and risk classification. Gondia et al. [5] developed ML-based predictive models for construction project delay risk using a multivariate dataset drawn from 51 historical projects, finding that decision tree and Naive Bayes classifiers effectively captured the interdependencies among delay-inducing factors. Mahmoodzadeh et al. [6] applied four optimized ML models, namely Gaussian Process Regression, Support Vector Regression, Linear Regression, and Decision Tree, to a dataset of 350 historical tunnel projects from 34 sites worldwide, using the Grey Wolf Optimisation algorithm for hyperparameter tuning and finding that Linear Regression delivered the strongest prediction performance for both construction cost and duration. At the building level, Alshboul et al. [7] demonstrated the superiority of XGBoost over deep neural networks and Random Forest for green building cost prediction, with XGBoost achieving an R^2 of 0.96, outperforming the neural network baseline by 5% and Random Forest by 9.4%.

A separate body of work applies machine learning to legal and contractual dimensions of construction project management, where structured project data intersects with complex dispute histories and procurement records. Ayhan et al. [8] developed a data-driven dispute occurrence prediction model using empirical survey data from construction experts, finding that the C5.0 decision tree algorithm achieved a validation accuracy of 83.92%, and identifying the most influential variables contributing to dispute risk. Un et al. [9] extended this line of enquiry to dispute outcome prediction, training five ML classifiers on a dataset of arbitration cases from Turkey and finding that Support Vector Machine achieved the highest accuracy at 71.65%, with twelve significant project and contractual variables identified as the most predictive features. Jacques de Sousa et al. [10] applied ML classification algorithms to a dataset of over 5000 public construction procurement contracts from the Portuguese national repository, evaluating the effect of data balancing strategies including oversampling, undersampling, and SMOTE on the prediction of budget compliance, and demonstrating the practical viability of ML-driven compliance forecasting in public procurement contexts.

Natural language processing has emerged as a complementary analytical tool in construction, enabling the extraction of structured information from the large volumes of unstructured text generated across project lifecycles. Moon et al. [11] developed a Named Entity Recognition model for automated construction specification review, training a Word2Vec-embedded BiLSTM-CRF architecture on road project specifications and achieving a mean F1 score of 0.917, with precision and recall of 0.919 and 0.914 respectively, demonstrating that NLP can support contractors in systematically understanding specification requirements during the bidding phase.

Graph neural networks represent a more recent development in construction informatics. Wu et al. [12] applied a domain-adapted graph-based deep learning model to the knowledge base completion problem in package-based constraint management, arguing that general-purpose knowledge base completion methods fail to capture the semantic specificity of construction constraint networks and demonstrating that construction-domain knowledge embedding substantially improves link prediction performance over general-purpose baselines. While this application differs from the classification task examined in the present study. Mostofi et al. [13] developed a Graph Convolutional Network model for construction safety risk assessment by restructuring a historical accident dataset into a network in which accidents were connected based on shared project type, enabling the model to learn from relational dependency information rather than treating each incident in isolation. The GCN severity predictor achieved a prediction accuracy of 94.47%, outperforming conventional feedforward neural network baselines and demonstrating that graph-structured representations of construction records carry predictive signal beyond what independent feature vectors alone can capture.

Against this background, quantitative bidding decision modelling has remained an underexplored area, and the published work that does exist tends to rely on structured project attributes alone. Araújo et al. [14] proposed a classification model that uses a fuzzy preferential procedure adapted from ELECTRE TRI-C to assign construction opportunities to ordinal attractiveness categories,

demonstrating that multi-criteria classification can provide contractors with a systematic and consistent basis for bid/no-bid decisions. However, no prior study has combined graph neural networks with transformer-based NLP embeddings for this problem, and none has empirically examined the relative contribution of unstructured project description text to model decisions. The present study addresses both gaps.

3 Data and Methodology

3.1 Dataset

The dataset used in this study is drawn from the proprietary project tracking database of an international construction contractor, filtered to include only transportation infrastructure projects, yielding a working dataset of 2259 project records. All data was recorded as of July 2023, and project names and web addresses were excluded from the analysis to protect commercial confidentiality. Each project record contains two types of features. The first comprises structured attributes covering numerical and categorical data such as project value, geographic region, and construction stage. The second consists of text features in the form of written project descriptions, organized across four columns (Project Overview, Project Scope, Project Background, and Latest Update).

The dataset includes scoring columns assigned by tender evaluation experts. Each of these columns has a specific weight percentage, and numerical evaluations for each project are provided under the headings Project Status Score, Project Value Score, Country Grade, Risk Level, and Business Development Rating (BD Rating). A weighted formula combines these five numerical values into a single total score called TOTAL POINT. A binary target variable named Bid_Label has been created from the TOTAL POINT score. To produce the most balanced class distribution, a threshold value of 4.7 is applied to the TOTAL POINT score, resulting in 50.1% of the projects being labeled as BID and 49.9% as NO BID. This near-perfect balance does not require a special correction technique for class imbalance. The dataset is summarized in Table 1.

Table 1. Dataset Summary

Attribute	**Value**
Total projects	2259
Training set (80%)	1807 projects
Test set (20%)	452 projects
Structured features	309 columns
Free-text description columns	4 (Project Overview, Project Scope, Project Background, Latest Update)
Target variable	Bid_Label (1=BID, 0=NO BID, threshold=4.7/7.4)
Class balance	50.1% BID / 49.9% NO BID

3.2 Data Preparation and Feature Engineering

Seven columns were removed from the dataset, including database identifiers, privacy-sensitive fields, and a sector column with a constant value following the initial filtering step. The Latest Momentum Score column contained non-numeric entries such as "X" and "x", which were treated as zero-momentum signals and recoded as 0. A binary indicator, Is_Eliminated, was created to record whether a project had been flagged for elimination under the original scoring system. Categorical columns were converted to numerical format through one-hot encoding, which generates a separate binary column for each possible category value. The Country and

Secondary Sector columns, which could contain multiple values per cell, were processed using multi-label binary encoding.

Date and quarter columns were decomposed into numerical components. An estimated project duration feature was also derived, along with a months-since-last-update variable capturing the recency of project information. The five expert scoring criteria and the Is_Eliminated indicator were excluded from the feature set prior to model training, as these variables directly compose the TOTAL POINT score from which Bid_Label is derived. Following all processing steps, the structured feature matrix comprised 309 columns. The dataset was then split into a training set of 1807 projects (80%) and a test set of 452 projects (20%) using stratified sampling to preserve the class distribution in both subsets.

3.3 NLP Processing Data Pipeline

A three-stage processing data pipeline was applied to the four free-text description columns to extract numerical features from the written content. In the first stage, sentence embeddings were generated using the all-MiniLM-L6-v2 model based on Sentence-BERT. Each text column was transformed into a 384-dimensional vector, and the four vectors were concatenated to produce a 1536-dimensional text feature matrix per project.

In the second stage, topic modelling was performed using Latent Dirichlet Allocation (LDA). Eight thematic clusters were extracted from the corpus, covering topics such as highway expansion, railway development, and bridge rehabilitation, contributing eight additional numerical features per project. In the third stage, a pre-trained DistilBERT model was applied to the Latest Update column to produce a signed sentiment score capturing the overall tone of recent project updates. The final feature matrix combines 309 structured features, 8 topic scores, 1 sentiment score, and 1536 text embedding dimensions, yielding a total of 1,845 features per project.

3.4 Graph Construction

GraphSAGE requires a graph in which each project is represented as a node and relationships between projects are encoded as edges. A dual-strategy approach was adopted. The first strategy connects projects sharing the same geographic region, capturing shared market conditions and regulatory environments. The second connects projects whose sentence embedding vectors exhibit a cosine similarity above 0.80, linking projects with comparable technical descriptions regardless of geographic location.

The resulting training graph comprises 2132 nodes and 1536042 edges, with an average degree of approximately 1440 connections per node. Graph construction parameters are detailed in Table 2. Figure 1 provides a visual representation of a 50-node sample, where blue nodes denote BID-labelled projects and red nodes denote NO BID-labelled projects.

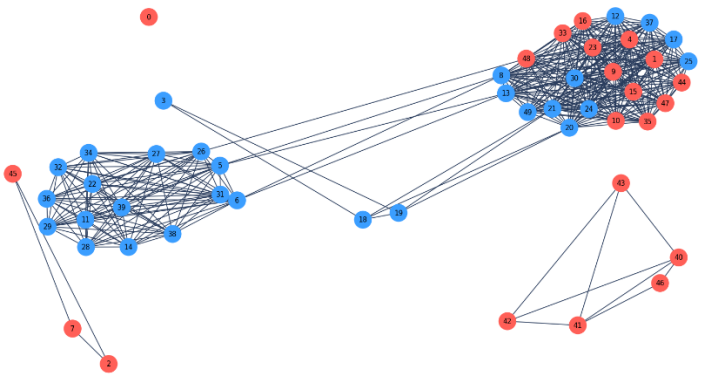

Figure 1: 50-node project similarity graph (Blue = BID, Red = NO BID.)

Table 2. Graph Construction Parameters

Parameter	Value	Description
Total nodes	2,132	Training projects
Total edges	1,536,042	Combined from both strategies
Average node degree	~1,440	Average connections per project
Strategy A	Shared Region	Geographic similarity
Strategy B	Cosine similarity > 0.80	Semantic text similarity
Node features	1,845 dimensions	Structured features + NLP embeddings

4 Model Development

Four machine learning models were developed and evaluated, one serving as the primary model under investigation and three as performance baselines. The adoption of a multi-model experimental design is not solely motivated by performance comparison but reflects a methodological necessity. The independent contribution of graph structure and NLP-derived features to the decision process can only be isolated and quantified through systematic comparison against models of varying complexity.

Logistic Regression, at the baseline hierarchy, models the linear decision boundary between two classes within the 1845-dimensional feature space. L2 regularization was applied to prevent overfitting, with the added benefit of stable convergence under high-dimensional input. The second baseline, Random Forest, targets non-linear relationships in the feature space through an ensemble architecture of decision trees. With 200 trees and a minimum of 5 observations per split, the configuration provides both variance reduction and natural resistance to overfitting. The third baseline, XGBoost, represents the gradient boosting paradigm in which each successive tree is built to minimize the residual error of the previous model. Configured with 300 trees, a learning rate of 0.05, and a maximum depth of 6, the model is widely regarded as the current best-practice standard for structured tabular data.

GraphSAGE generates each node's representation by sampling and transforming features from its local neighborhoods, enabling the production of generalizable embeddings for nodes not encountered during training. The architecture employed consists of two SAGEConv layers with 128 hidden dimensions and a dropout rate of 30%, trained over 200 epochs using the Adam optimizer, with a total of 505,602 learnable parameters.

Standard SHAP approximation methods for GNNs require perturbing individual features independently of the graph structure, which introduces numerical instability in dense graph settings. SHAP analysis was therefore applied to the best-performing Logistic Regression model using a Linear SHAP explainer, which derives exact Shapley values directly from the model’s coefficient matrix without approximation, providing stable explanations across the 1,845-dimensional feature space. Explanations were computed for all test projects. This analysis constitutes the methodological backbone of the study, not only producing a feature importance ranking but numerically establishing which feature group dominates model decisions.

5 Results

5.1 Model Performance on the Test Set

Table 3 reports the performance of all four models on the 452-project test set. Logistic Regression achieved the strongest overall results with 98.33% accuracy, an F1 Score of 0.9828, and an AUC-ROC of 0.9976. F1 Score provides a balanced measure of precision and recall across both classes. Precision quantifies the proportion of predicted BID projects that are

correctly classified, while recall measures what fraction of actual BID projects were successfully identified. GraphSAGE reached 87.89% accuracy and an AUC-ROC of 0.9332, but achieved the highest precision of 0.9624 across all four models, indicating that its BID recommendations are highly reliable.

Table 3. Model Performance on Test Set (n = 452)

Model	Accuracy	Precision	Recall	F1 Score	AUC-ROC
Logistic Regression	0.9833	0.9703	0.9957	0.9828	0.9976
Random Forest	0.8455	0.7932	0.9174	0.8508	0.9410
XGBoost	0.9165	0.8831	0.9522	0.9163	0.9861
GraphSAGE	0.8789	0.9624	0.7783	0.8606	0.9332

The ROC curves for all four models are presented in Figure 2. Each curve illustrates the trade-off between the true positive rate and the false positive rate. As shown in Figure 2, Logistic Regression produces the curve nearest to that corner.

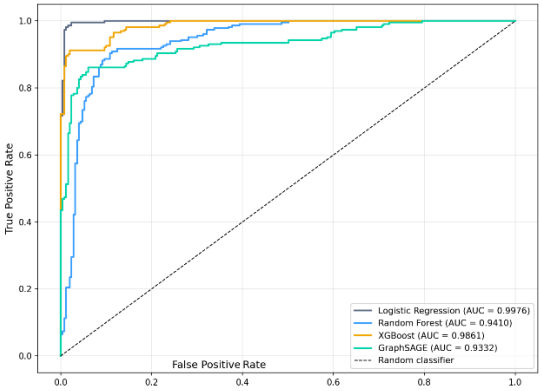

Figure 2: ROC curves for all four models.

The confusion matrices, presented in Figure 3, report the number of correct and incorrect predictions for each class. Logistic Regression produced approximately 8 total errors across the 452 test projects, with only 1 false negative and 7 false positives, confirming near-perfect recall. GraphSAGE produced approximately 55 total errors, with a high false negative count consistent with its lower recall of 0.7783, but only 7 false positives, consistent with its leading precision of 0.9624.

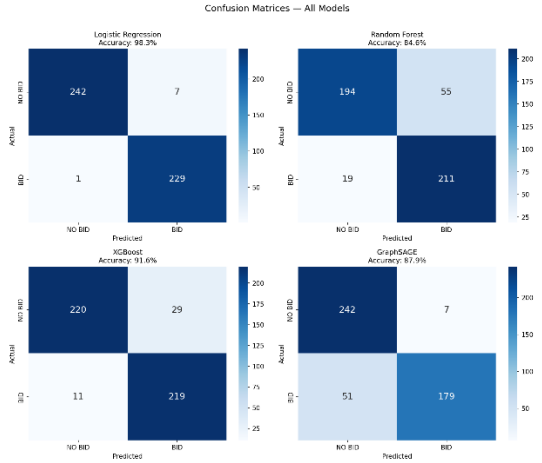

Figure 3: Confusion matrices for all four models.

Five-fold cross-validation was additionally conducted to confirm result stability. Logistic Regression achieved a mean F1 Score of 0.9858 with a standard deviation of 0.0026, confirming highly consistent performance across different data partitions. XGBoost returned a mean F1 of 0.9626 (SD = 0.0066) and Random Forest 0.9151 (SD = 0.0141).

5.2 SHAP Feature Importance Analysis

SHAP analysis applied to the best-performing Logistic Regression model showed that text embedding features derived from written project descriptions account for 72.5% of total feature importance, with topic model scores and sentiment contributing a further 2.9%. Structured features contribute 24.6%, with NLP-derived features thus dominating model decisions by a substantial margin, as illustrated in Figure 4. This result suggests that project description texts carry decision-relevant signals beyond what structured attributes alone reflect.

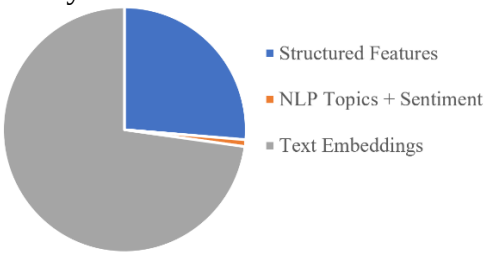

Figure 4: NLP vs. structured feature contribution (72.5% vs. 24.6%).

Among structured features, country-level and regional indicators are the strongest predictors, with Country_India and Region_Europe leading the ranking, followed by Country_China, Region_North America, and Region_Asia, suggesting that geographic exposure plays a notable role in historical bid decisions.

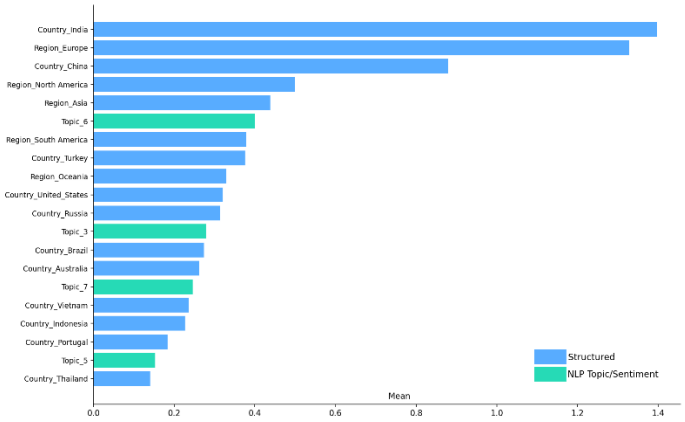

Figure 5: Top 20 features by mean (SHAP value).

Figure 5 presents the top 20 features ranked by mean absolute SHAP value. Most high-ranking features are text embedding dimensions, displayed in orange, while structured features, shown in blue, appear lower in the ranking. Although individual embedding dimensions carry small SHAP values, their collective contribution across 1536 dimensions exerts a dominant influence on model output.

6 Discussion

The variation in model performance across the four models warrants careful interpretation. Logistic Regression's leading accuracy of 98.33% suggests that the feature space, combining geographic signals with high-dimensional text embeddings, is largely linearly separable, which is broadly consistent with the structured nature of historical contractor bid decisions.

A notable result from the SHAP analysis is that text embedding features account for 72.5% of total feature importance, with structured features contributing 24.6%, suggesting that written project descriptions carry more decision-relevant signal than structured attributes alone. GraphSAGE achieves lower overall accuracy than Logistic Regression (87.89% vs. 98.33%), but records the highest precision of 0.9624 across all four models, meaning its BID recommendations are rarely incorrect. The lower recall is consistent with known characteristics of GNNs under dense graph conditions and self-loop inference at test time.

The proposed two-stage DSS translates these findings into a practical framework, generating text-based preliminary recommendations without expert scoring in Stage 1 and incorporating full evaluation in Stage 2. Figure 6 presents the DSS output for three representative projects, illustrating how each project receives an ensemble probability score and a final recommendation derived from all four models.

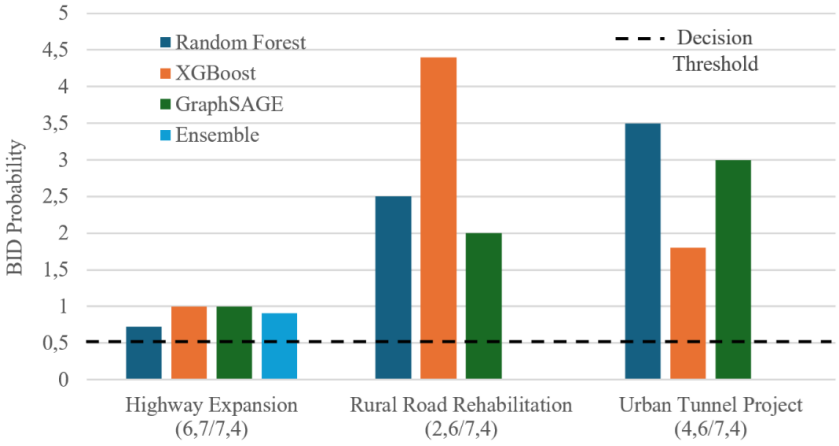

Figure 6: DSS bid recommendation dashboard for three example projects

This study is subject to several limitations. The dataset originates from a single company in one sector, which limits generalizability. The exclusion of the five expert scoring criteria, while necessary to avoid target leakage, removes signals whose independent predictive value remains untested. The self-loop inference configuration at test time additionally prevents a fully inductive evaluation of GraphSAGE's graph-learning capability

7 Conclusion

This study demonstrates that machine learning and graph-based representation learning can be effectively combined to support bid/no-bid decision-making in international infrastructure construction.

All four models produced competitive results on the test set. Logistic Regression achieved the highest overall accuracy at 98.33%, while GraphSAGE recorded the highest precision of 96.24%. SHAP analysis revealed that text embedding features account for 72.5% of total feature importance, substantially exceeding the 24.6% contribution of structured features, suggesting that project descriptions carry decision-relevant signals beyond what structured attributes alone capture. The two-stage DSS proposed in this study operationalises these findings, enabling preliminary text-based recommendations before full expert scoring is applied.

Abstract. In a world of advancing technology and digitalization, data centers have become digital economic assets for organizations and governments. Unlike traditional buildings they feature high electrical system density, multi layered mechanical redundancy, and the need for uninterrupted operation. Furthermore, these buildings require tight interdisciplinary coordination, with virtually zero margin of error. Therefore, risk management must be an integral part of these processes. A literature review indicates limited research on the role of BIM in risk management for data center projects.
This study examines eight previously defined BIM value domains under a single BIM maturity parameter linked to four probabilistic risk modules. PERT is used for planning risk, the log normal for cost overrun, the normal PUE uncertainty, and the Poisson for design conflicts. The aim is to compare "BIM off/on" scenarios at the commonly used P80 confidence level for project risk targeting, and a browser based decision support platform has been developed that combines deterministic EVM monitoring with a 10,000 iteration Monte Carlo simulation. The results show that raising BIM maturity from a low to a high level resulted in improvements of 15.0% in schedule duration (P80), 1.3% in cost, 18.9% in PUE, and 86.8% in expected clash count. Consequently, since all results share a common maturity factor, it is argued that the benefits of BIM should be evaluated as a composite and multidimensional impact rather than a single metric. This perspective is particularly relevant to data centers due to their high coordination requirements, low error tolerance, long operational lifespans, and increasing industry demand.

Keywords: Building Information Modeling; Data Center; Monte Carlo Simulation; Project Risk Management; Earned Value Management; Digital Twin

1 Introduction

Digital infrastructure now underpins nearly every critical sector of the global economy. Data centers have consequently become nationally strategic assets, supporting AI workloads, cloud platforms, financial transaction systems, healthcare data infrastructure, telecommunications, and e commerce, while also constituting a security critical element for defense and public systems. Global data center electricity consumption is projected to reach approximately 415 TWh in 2024 and approach 945 TWh by 2030 [16]. Türkiye's position bridging Europe and Asia, together with its young, technology oriented population, points to its potential as an emerging regional hub for this growth.

Data center construction projects are fundamentally more complex than conventional buildings, with unusually demanding design and construction phases driven by their critical role. Unlike an approach that traditional project management tools struggle to support, high density electrical infrastructure, sensitive cooling systems, uninterruptible power supplies, and

layered N+1/2N redundancy require a multidisciplinary and tightly coordinated approach in both the design and implementation phases. Over the past two decades, BIM has reshaped construction practice more broadly through its documented benefits in coordination, planning, and cost control [1,2]; its role is arguably even more decisive in data center projects, where coordination failures, planning drift, and energy inefficiencies carry more severe consequences than in typical construction.

This study examines where and how BIM generates value in data center construction, arguing that this value is best assessed through the lens of risk management, a strategic necessity rather than an optional enhancement. Section 2 reviews the relevant literature; Section 3 outlines the strategic and technical profile of data center projects; Section 4 addresses the BIM value domains associated with this profile; Section 5 presents the simulation methodology; Section 6 discusses limitations; and Section 7 reports the results.

2 Literature Review

BIM is useful not only for geometric modeling but also for managing project information. Previous studies show that it can improve coordination, cost management, and clash reduction across different building types [1,2]. Industry organizations have also reported the operational costs of design failures under the Uptime Institute's Tier framework. However, research focused specifically on data centers is still limited [17].

A parallel literature links BIM to digital twin development, treating BIM models as the structural basis from which real time facility twins can be derived, and extending this to BIM IoT integration for asset tracking [8,9] and the conceptual transition from static models to construction phase digital twins. A third approach applies Monte Carlo simulation to construction risk, including integrated BIM Monte Carlo planning frameworks [5], Monte Carlo based planning risk simulation in a BIM environment [6], structured reviews of BIM related project risk [3], and prioritization of AHP based BIM risk factors [4]. However, none of these studies combine planning, cost, energy, and collision frequency risk into a single BIM maturity as a focused probabilistic framework calibrated to the technical profile of data center projects. This study addresses this gap.

A recurring limitation in the literature in this area is the lack of BIM skills, particularly due to the limited availability of device specific BIM object libraries and the slow adaptation of manufacturers. This leads to unfavorable outcomes for data centers, considering the dependencies on specialized mechanical and electrical devices. This study aims to create an integrated framework specific to data centers by leveraging the literature in BIM, digital twin, and Monte Carlo risk modeling.

3 Data Center Projects: Strategic and Technical Profile

The growing importance of digital infrastructure has made data centers critical assets with major economic and national security implications, rather than simply technology investments. The rapid growth of AI and machine learning has increased demand for GPU clusters, high-density racks, and advanced cooling systems. At the same time, cloud computing, digital healthcare, and financial technologies have increased the need for reliable, low-latency data processing and storage.Türkiye's geographical position between Europe, the Middle East, and Asia, combined with its expanding digital economy, gives it strong potential to develop as a regional data center hub making operational continuity, data sovereignty, and cybersecurity increasingly significant at the national level.

Data centers are more technically complex than typical construction projects. Their electrical systems include medium voltage distribution, transformers, UPS units, power distribution units, and extensive cable management. Mechanical systems also require close coordination. CRAC/CRAH units, chillers, cooling towers, and airflow systems must meet PUE requirements to support energy efficiency and long term sustainability [12,20]. These systems need careful

coordination, especially in high-density areas. N+1 and 2N redundancy configurations also affect design decisions and project costs from the early stages.

Data centers differ from traditional buildings in terms of the need for continuous operation, high system availability, minimal error tolerance, and strict timelines. Commissioning, in particular, is one of the most critical project phases. The goal is to ensure that the facility operates safely, reliably, and in accordance with specified performance requirements. The process involves systematically testing and validating critical systems and their integrated performance prior to handover. Given the complexity and operational importance of these systems, commissioning represents a particularly challenging and unique phase of data center construction.

4 BIM Concept and Value Areas in Data Center Projects

Building Information Modeling (BIM) is a structured digital modeling approach in which a construction project's geometric data are integrated with associated information on materials, costs, scheduling, and operational processes. The conventional dimensional classification of this approach extends from 3D geometric representation, through 4D scheduling and 5D cost analysis, to 6D sustainability assessment and 7D facility/operations management [12] BIM supports the project throughout its lifecycle by allowing architectural, structural, and mechanical, electrical, and plumbing (MEP) teams to work within the same digital environment instead of relying on separate discipline specific documents.

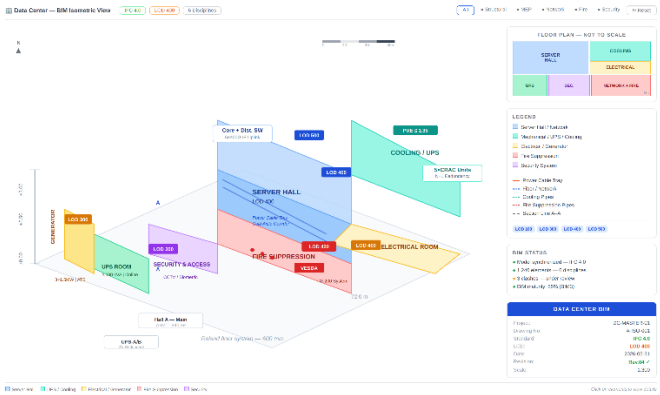

Fig. 1. The integration of architectural, MEP etc. disciplines into a single federated model (LOD 400, IFC 4.0) in an isometric BIM coordinating perspective of a data center facility.

This capability translates into eight interlocking value areas in data center projects especially, which are outlined below.

4.1 Interdisciplinary Coordination and Clash Detection

Data centers have inherently limited space, and cable trays, cooling pipes, sprinkler systems, and structural elements often overlap. Physical conflicts, unnoticed until construction begins, can bring work to a complete standstill. BIM's conflict detection feature solves this problem by revealing these conflicts long before installation, during the design phase. This reduces conflicts by up to 40% [2] and greatly limits rework, material waste, and on site design revisions.

4.2 4D Scheduling and Program Control

Linking the project schedule to the BIM model produces a 4D simulation that renders the timeline visible and manageable, enabling more precise planning of critical equipment deliveries, specialized infrastructure works, and phased commissioning. Overlapping activities can be identified in advance, and resources can be planned more effectively. In addition, stakeholders are ensured to work from the same plan. As a result, the timeline becomes more than just a record; it transforms into an active management tool.

4.3 5D Cost Control and Take off Accuracy

Using the BIM model for quantity take offs and cost estimates can speed up procurement and improve accuracy. When the model is updated, quantities such as cable lengths, piping runs, and the number of equipment units are also updated, reducing the risk of incorrect orders and keeping the project budget under control.

4.4 Equipment Layout Optimization

Heavy equipment such as UPS systems, generators, CRAC/CRAH units, transformers, and server racks should be positioned to allow efficient operation and easy maintenance access. The BIM model tests multiple 3D layout scenarios to identify the optimal configuration, while integrated airflow simulation reveals how hot aisle/cold aisle arrangements affect energy consumption before construction begins.

4.5 Commissioning Readiness

Commissioning is arguably the most demanding phase of data center delivery. Because the BIM model consolidates every system component, connection, and operating parameter into a single dataset, it provides a direct foundation for comprehensive, accurate commissioning plans, test procedures, and checklists allowing missing or faulty installations to be caught early.

4.6 Facility Management Handover and Digital Twin Enablement

Traditionally filing the documents on paper like equipment specifications, material data, maintenance schedules, and warranty records can easily lost. This is a risk of missing data. BIM allows this information to be transferred directly to CMMS/CAFM systems. When the model is linked to live sensor data, the model can also be developed into a digital twin for real time energy monitoring, predictive maintenance, and capacity planning [8,9,19].

4.7 Energy Efficiency and Sustainability

Energy analysis with a BIM model during the design phase enables evaluation of cooling strategies. It also supports PUE improvements by assessing natural ventilation and heat gains through the building facade. In addition, BIM assists in material selection and documentation for LEED and BREEAM certifications, which are becoming increasingly important for owners and investors [13, 14, 15].

4.8 Project Risk Management

Project information with a large scale BIM model allows teams to identify and assess the risks in the design review. Visual simulations allow teams to discuss potential problems before construction begins. This is particularly important given the long lead times and complex supply chains of critical data center equipment. Adoption of BIM has been shown to reduce Information Requests (RFI) by 30–50% [2,18]. This is a significant efficiency gain at the data center scale.

5 Methodology

5.1 Simulation Platform

An HTML/JavaScript based decision support platform was developed to translate the eight BIM value domains identified in Section 4 into a quantitative risk assessment framework. The platform integrates deterministic tracking based on physical progress, Earned Value Management indices (Equations 1–3), PUE, and 5D cost analysis with four independent Monte Carlo modules covering duration (PERT), cost (lognormal), energy (normal), and clash count (Poisson). Each module was run for 10,000 iterations to derive the P10, P50, P80, and P95 percentiles. A single BIM maturity variable (μ_BIM) drives all four modules through the impact ratios defined in Equations (6)– (7), enabling comparison between "BIM off" and "BIM on" scenarios.

$$CPI = BCWP / ACWP,\ SPI = BCWP / BCWS\ (1),\ (2)$$
$$EAC = BAC / CPI\ (3)$$

5.2 Risk Modules

Duration risk was modeled using a PERT distribution to represent the characteristic right skewness of construction activity durations (Equation 4). Three point duration estimates for five construction phases are presented in Table 1. MEP installation, which carries the widest uncertainty range, was found to contribute most to schedule risk in the sensitivity analysis. The BIM effect is applied multiplicatively to each simulation sample (Equation 5):

$$\mu = (a + 4m + b) / 6\ (4) \qquad T_{on} = T_{off} \times (1 - \rho_duration \times r)\ (5)$$

Cost risk was modeled using a lognormal distribution, consistent with its strictly positive and right skewed structure. The BIM effect is applied to the distribution parameters prior to sampling, reducing both the expected cost overrun and the spread of the distribution. PUE risk was modeled using a normal distribution, consistent with the Central Limit Theorem under the assumption of independent contributing factors [20]. BIM lowers the mean PUE value while narrowing the standard deviation by a factor of 0.7. Clash risk was modeled using a Poisson distribution, appropriate for representing independent and comparatively rare coordination conflicts within a fixed project scope.

The effect of BIM maturity on duration and cost is defined by Equations (6)–(7); the same ρ_duration and ρ_cost ratios are applied proportionally, as a function of μ_BIM, to the target PUE mean and to the Poisson λ_on parameter: the BIM on PUE mean is shifted from the BIM off baseline toward the target value by this ratio, while λ_on is obtained as λ_on = λ_off × (1 − ρ_clash), where ρ_clash follows the same functional form as ρ_duration but is scaled with coefficients specific to clash reduction. This approach ensures that all four risk modules are governed consistently by a single maturity score.

$$\rho_duration = 0.05 + 0.0015 \times \mu_BIM\ (6) \qquad \rho_cost = 0.04 + 0.0012 \times \mu_BIM\ (7)$$

At 85% BIM maturity, these equations yield an approximate 18% duration impact and a 14% cost impact.

Table 1. Three point PERT duration estimates by construction phase (weeks)

Phase	Optimistic	Most Likely	Pessimistic
Foundation works	6	8	12
Structural steel	7	9	14
MEP installation	10	14	22
Equipment installation	6	8	13
Testing & commissioning	5	8	14

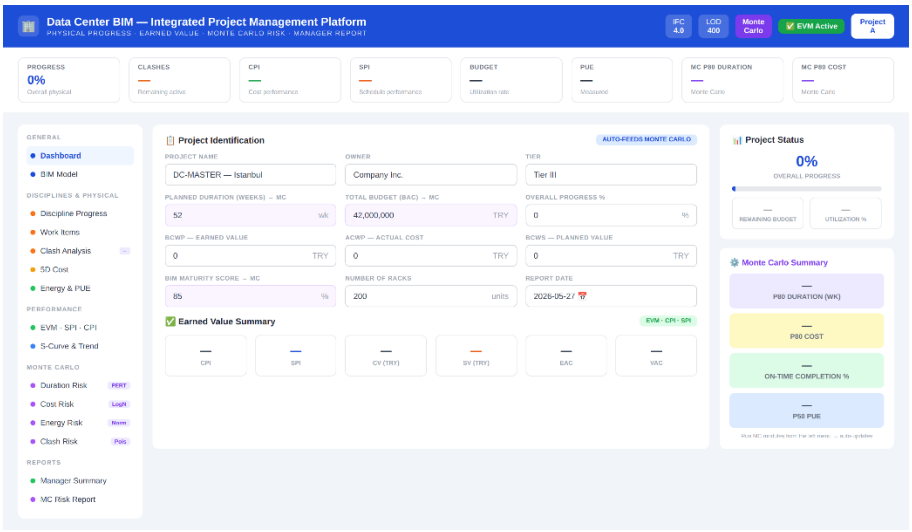

Fig. 2. Main dashboard of the integrated simulation platform, showing project definition fields, the BIM maturity input ("BIM Maturity Score"), Earned Value summary cards, and the Monte Carlo summary panel.

Table 2. Monte Carlo module specifications and BIM maturity linkage

Module	Distribution	Parameters	BIM Effect
Duration	PERT	5 phases (Table 1)	Equations 5–6
Cost	Lognormal	Mean overrun 10%; σ = 8% of BAC	μ, σ reduction via Equation 7
PUE	Normal	Off: μ=1.65, σ=0.12; On: μ=1.35	0.7σ reduction + mean shift
Clash count	Poisson	λ_off=47; λ_on=5; unit rework cost 75,000 TRY	λ reduction with maturity

5.3 Percentile Based Risk Assessment

For each module, P10, P50, P80, and P95 percentiles were obtained after 10,000 iterations. P80 was selected as the primary comparison metric, offering a balanced approach between the limited operational confidence provided by P50 and the excessive contingency cost implied by P95. A supplementary tornado sensitivity analysis, based on 2,000 independent samples per phase, identified MEP coordination as the most effective intervention area for reducing schedule risk.

6 Results and Discussion

Table 3 reports the P80 outcomes for all four modules under the BIM off and BIM on scenarios at 85% BIM maturity.

Table 3. Monte Carlo simulation results: P80 values and the effect of BIM integration.

Risk Factor	Distribution	BIM off (P80)	BIM on (P80)	Improvement	Improvement (%)	Unit
Duration	PERT	52.47	44.59	7.88	15.03	weeks
Cost	Lognormal	48.96	48.32	0.64	1.30	million TRY
Energy (PUE)	Normal	1.75	1.42	0.33	18.90	PUE
Clashes	Poisson	53	7	46	86.79	clash count

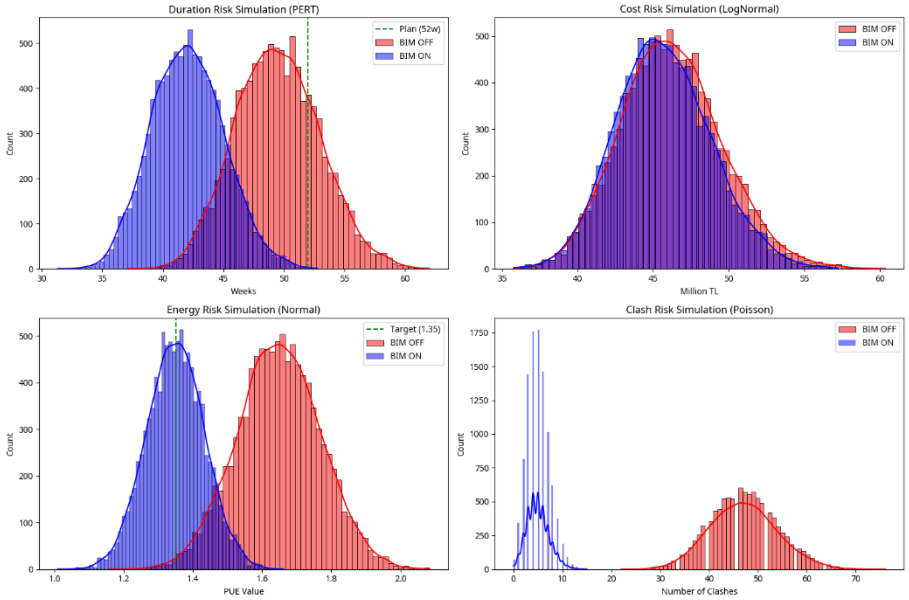

Fig. 3. Monte Carlo simulation results (10,000 iterations) for the BIM off and BIM on scenarios: (a) project duration (PERT), (b) total project cost (lognormal), (c) Power Usage Effectiveness (normal), and (d) number of design clashes (Poisson).

6.1 Duration Risk

The simulation results indicate that improving the schedule is one of the biggest advantages of using BIM. Without BIM, the P80 project duration is 52.47 weeks. With BIM, this decreases to 44.59 weeks. This means the project is completed 15.0% faster. This result is consistent with previous studies showing that BIM can reduce uncertainty on the critical path by improving MEP coordination and delivery planning [5,6]. A sensitivity analysis shows that MEP installation, with an estimated duration of 10–22 weeks, is the most significant source of planning uncertainty (Table 1). Therefore, BIM-based MEP coordination provides a significant advantage in reducing planning risk.

6.2 Cost Risk

BIM reduces the P80 cost by 1.3%, from TRY 48.96 million to TRY 48.32 million. Considering the right skewed lognormal cost distribution, this result shows that BIM primarily reduces the risk of excessive cost overruns rather than significantly reducing the average cost [2]. This finding is also consistent with the advantages of 5D quantity surveying discussed in Chapter 4.3, where BIM enables the prevention of quantity errors and rework.

6.3 Energy Risk (PUE)

Under BIM integration, the P80 PUE value improves from 1.75 to 1.42 an 18.9% gain accompanied by a tighter distribution overall. This narrowing points to reduced operational variability, suggesting that BIM supported equipment layout, airflow modeling, and cooling optimization (Sections 4.4, 4.7) improve not just average energy performance but its consistency across seasonal and load conditions [20]. Because PUE compounds across a multi decade operational life, even this improvement translates into substantial cumulative savings.

6.4 Clash Risk

Coordination conflicts reveal the greatest impact of BIM by far. The P80 number drops from 53 to 7; this is an 86.8% reduction and exceeds the single stage figures of up to 40% often cited in the literature [2]. This difference stems from the scope difference. The simulation reflects the cumulative effect of BIM across MEP, structural and architectural disciplines rather than a

single coordination phase. Since each conflict leads to rework, delay and safety risk, the near complete elimination of high conflict results in P80 directly increases site efficiency [7]. Given that unresolved conflicts are the main cause of delays in the MEP phase, this explains a large part of the time improvement reported in 6.1.

6.5 Synthesis: The Cumulative Value of BIM Integration

The four P80 results in Table 3 vary considerably, from 1.3% for cost to 86.8% for clashes. However, these improvements are not independent. All four modules are driven by the same BIM maturity parameter (Section 5.2). As BIM maturity increases, cost uncertainty decreases, project duration becomes shorter, PUE uncertainty is reduced, and fewer clashes are expected. Therefore, BIM benefits should be considered together across schedule, cost, energy, and coordination rather than through a single metric [3,4].

The construction profile of data centers as described in Section 3 is coordination intensive, has low error tolerance and long operating lifespans. These results illustrate the value of BIM driven risk mitigation. Any building project would be interested in a 15% reduction of P80 duration or 87% reduction of expected clashes. But in data centers, delays can impact hyperscale tenant revenue, while conflicts identified during commissioning can threaten Tier certification. So the effect of these improvements may be greater than the percentages imply.

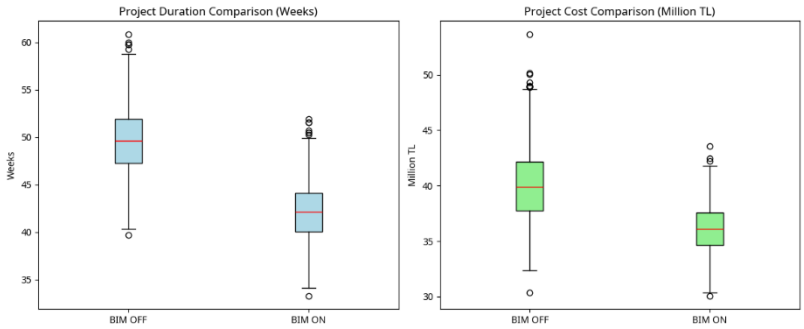

Fig. 4. Box plot comparison of (a) project duration and (b) total project cost between BIM off and BIM on scenarios.

There are two industry constraints that affect the interpretation of these findings. First, BIM object libraries are limited for specific equipment and manufacturers' slow adaptation process continue to limit modeling accuracy [10,11]. This limitation is more important for data centers because they rely on specialized MEP equipment, and it is also evident in the simulation itself. At low BIM maturity, all four percentile ranges become wider and the BIM on and BIM off scenarios move closer together. This shows that maturity affects the overall risk profile rather than simply indicating model quality [3,4]. Further improvements are also possible. AI based clash detection can reduce the λ_on value better than manual coordination [7]. Broader IoT adoption could increase digital twin applications [8,9]. As BIM standards keep evolving, this approach presented here may be more generally applied.

7 Limitations and Conclusion

Several limitations should be considered when interpreting the results. The input values used in the platform were derived from conceptual estimates informed by the literature rather than from a single audited case study. Therefore, the reported percentages (e.g., 15.0% improvement in duration) should be interpreted as indicators of the direction and relative magnitude of BIM's impact rather than definitive benchmarks.

The connections between BIM maturity and its effects in Equations (6) and (7) were determined using intuitive calibration instead of statistical analysis. Although the four Monte Carlo

modules are considered independent, interactions may occur in real situations. For example an open issue may lead to schedule delay as well as additional costs. This implies that the model may not be capturing risks that influence both sectors at once. The study has not been compared to a completed project or validated by professionals. The results therefore mainly illustrate the promise of the suggested method as a decision support tool, while still requiring further refinement and validation.

This study investigated the multidimensional value of BIM in data center construction through a conceptual, simulation based framework covering eight value areas. The developed platform integrates deterministic EVM tracking with four BIM maturity driven Monte Carlo risk modules. Increasing BIM maturity from low to high results in P80 improvements of 15.0% in duration, 1.3% in cost, 18.9% in PUE, and 86.8% in expected clash count. Since these four indicators are driven by a common maturity variable, their benefits should be evaluated cumulatively rather than independently. Considering the intensive coordination requirements, low error tolerance, and long operational lifespan that distinguish data centers from conventional buildings, the practical value of BIM investment extends beyond the reported percentages. This supports positioning BIM not as an optional enhancement but as a strategic necessity for reliable and competitive data center delivery.

Future research should focus on empirically calibrating the framework using real projects with varying scales, geographical contexts, and BIM maturity levels; modeling correlations among the four risk modules to capture joint tail risk; further integrating BIM models with commissioning processes; and extending this integration toward digital twin validation. In addition, industry specific investigation of equipment manufacturers' adoption of BIM compatible object libraries could directly address a structural constraint identified in the literature [10,11].

Abstract. An automation-based smart curing cover was developed in this study to reduce water use and automate the concrete curing process through controlled water release based on relative humidity data. The system integrated an automatic control infrastructure consisting of a DHT11 temperature and humidity sensor, an Arduino Uno microcontroller, a relay module, and a solenoid valve with a physical cover comprising hydrophobic upper and hydrophilic lower layers. Water was automatically released when the relative humidity beneath the cover fell below 95%. The performance of the developed system was evaluated against water-spraying curing and wet-burlap curing in terms of water consumption and 7- and 28-day compressive strength. The smart curing cover reduced water consumption by approximately 53.6-57.1% compared with the conventional methods. The mean equivalent standard cylinder compressive strengths obtained with the smart curing cover were 31.73 MPa at 7 days and 40.45 MPa at 28 days, demonstrating compressive strength performance comparable to that of the conventional curing methods. The findings indicate that the developed system can reduce water consumption while maintaining concrete strength development and eliminating the need for periodic human intervention in the watering process, thereby providing an automated and water-efficient alternative for concrete curing.

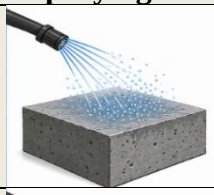
Keywords: Concrete curing; Smart Curing Cover; Automated curing; Moisture control.

1 Introduction

Concrete curing is intended to maintain the moisture required for hydration by limiting water loss from the concrete or providing an external water supply [1]. Appropriate moisture and temperature conditions, particularly at early ages, are required for cement hydration to continue and for concrete to develop the desired mechanical and durability-related properties. Excessive moisture loss from the concrete surface may hinder cement hydration and contribute to shrinkage, cracking, and inadequate strength development. Maintaining adequate moisture conditions during the early stages of concrete hardening is therefore a fundamental requirement for effective curing [1].

Water spraying and wet coverings are among the conventional curing methods widely used to maintain moisture at the concrete surface [1, 2]. However, the effectiveness of these methods depends on the continuity and frequency of water application, as well as on the amount of water supplied and the timing of application [2, 3]. In conventional manual curing practices, water application may not be directly controlled according to the actual moisture condition of the concrete, which can result in either excessive or insufficient watering [3]. Excessive application may lead to unnecessary water consumption, whereas insufficient or discontinuous application may compromise the continuity of surface moisture; moreover, reliance on repeated human intervention increases labor requirements [2, 3].

To overcome these limitations, automated concrete curing systems employing sensors, microcontrollers, and Internet of Things (IoT) technologies have been developed. Taffese and Nigussie [3] proposed a conceptual IoT-based automated curing system in which temperature and relative humidity within the concrete are monitored in real time and a smart valve and sprinkler system are controlled according to a predefined moisture threshold. Yang et al. [4] developed an automated curing system in which spraying intervals are determined through a programmable logic controller (PLC) by considering hydration-related behavior together with real-time temperature and relative humidity data, while curing water is applied through fog spraying. Lo et al. [5] developed an IoT-based system that monitors variables including air temperature, relative humidity, wind speed, concrete temperature, and concrete moisture content to evaluate environmentally induced water loss and applies water to the concrete surface through a microcontroller-controlled pump when required. Reddy and Hamsalekha [6] developed a microcontroller-based curing system in which the moisture detected within the concrete is compared with a predefined threshold to automatically switch a water pump on and off. More recently, Feng et al. [7] developed a robotic system in which plastic-film placement and water spraying are performed by separate modules, while computer vision is used to classify the curing condition of the concrete surface and automatically determine whether spraying is required. Ascona García et al. [8] integrated temperature and humidity sensors embedded in concrete elements with an Arduino-based control system to perform automated irrigation cycles, reporting a 20% reduction in water consumption compared with conventional curing. Nevertheless, the active water-application components of these studies predominantly rely on spraying, fogging or sprinkler mechanisms. Consequently, limited attention has been given to curing approaches that integrate sensor-controlled water release, retention of the released water at the concrete surface, and its distribution across the surface within a physical cover.



In this study, an automation-based smart curing cover was developed to provide controlled water release in response to the relative humidity adjacent to the concrete surface. The developed system integrates a hydrophobic upper layer designed to limit moisture loss and a hydrophilic lower layer that distributes the supplied water across the concrete surface through capillary action with a sensor-controlled automatic water-release mechanism. Its curing performance was comparatively evaluated against conventional water-spraying and wet-burlap curing methods in terms of water consumption and 7- and 28-day compressive strength.

2 Methodology

To evaluate the developed smart curing cover system experimentally, the study comprised three curing methods (water-spraying curing, wet-burlap curing, and curing with the smart curing cover) and two test ages (7 and 28 days), using a total of six concrete specimens. Accordingly, the overall experimental arrangement is presented in Table 1. The experimental study began with the development of the technical infrastructure of the smart curing cover, which was subsequently integrated with a physical cover system designed to retain water on the concrete surface and promote its uniform distribution. In addition, a main reservoir was connected to the

smart curing cover via a hose to store and deliver the water required by the system in a controlled manner. Concrete specimens were then produced and subjected to the three mentioned curing methods. Throughout the curing period, the amount of water consumed was recorded. To evaluate the 7-day early-age and 28-day compressive strength development of the concrete, core specimens were extracted from the relevant specimens and subjected to uniaxial compression tests. The methodological details of the study, including the technical infrastructure and physical design of the smart curing cover, specimen production, curing processes and compressive strength testing, are presented in the following subsections.

Table 1. Experimental groups and curing methods considered in the study.

		Conventional wet-curing methods		**Developed curing method**
		Water-spraying curing	**Wet-burlap curing**	**Smart curing cover**
Compressive strength groups	**7-day**			
	28-day			

2.1 Technical Infrastructure of the Smart Curing Cover

The technical infrastructure of the smart curing cover was developed based on sensing the relative humidity in the environment adjacent to the concrete surface, evaluating the acquired data using a microcontroller, and automatically controlling water flow in response to the predefined humidity condition. For this purpose, the system was configured as an integrated control circuit comprising a sensing unit (DHT11 temperature and humidity sensor), a data-processing control unit (Arduino Uno microcontroller), a switching element for regulating water flow (relay module), a solenoid valve controlling water passage, a 12 V power supply, a breadboard, and jumper wires providing the electrical connections between the components. The main technical components of the system and the circuit connections between them are illustrated in Fig. 1.

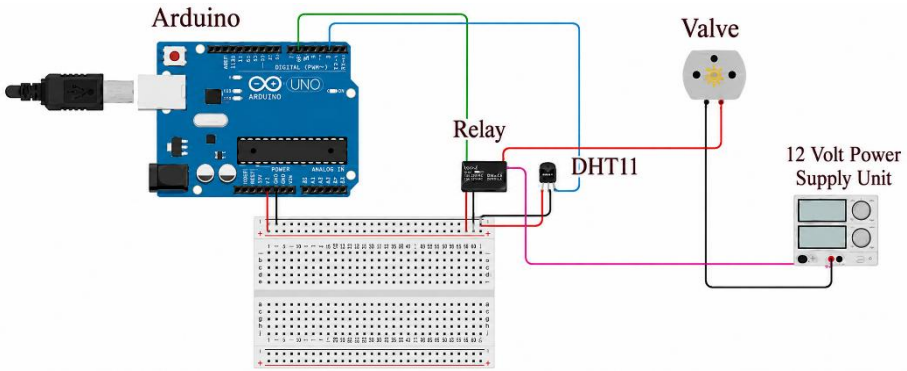


Fig. 1. Wiring diagram of the technical infrastructure of the smart curing cover

As shown in Fig. 1, the Arduino Uno microcontroller serves as the central control unit of the system. Temperature and relative humidity in the region adjacent to the concrete surface were measured using the DHT11 sensor and transmitted digitally to the Arduino. Although the sensor

simultaneously measured both temperature and relative humidity, relative humidity was selected as the primary control variable governing automatic water release. The relative humidity threshold used in the decision mechanism was set at 95%, taking into account the minimum relative humidity condition specified in TS EN 12390-2 [9] for curing concrete specimens. Accordingly, the control algorithm continuously evaluated the relative humidity measured by the sensor and compared it with this threshold. When the measured relative humidity fell below 95%, the Arduino activated the relay module, thereby opening the solenoid valve powered by the 12 V power supply and allowing water to flow from the reservoir to the smart curing cover. When the relative humidity reached or exceeded 95%, the relay was deactivated, causing the solenoid valve to close and the water flow to cease. Through this configuration, the system functioned as a closed-loop automatic control mechanism operating through a measurement–evaluation–decision–actuation cycle. Accordingly, the developed technical infrastructure enabled water application, which in conventional curing methods depends on periodic manual intervention, to be automatically controlled on the basis of sensor data. In addition, a Python-based data-logging system was developed to enable the temperature, relative humidity and relay-status data obtained through the Arduino to be monitored and stored on a computer. The data were recorded together with date and time information, allowing the operating behavior of the system to be monitored throughout the curing period.

2.2 Physical Design of the Smart Curing Cover

Following the development of the technical infrastructure of the smart curing cover, the system components were integrated with a physical cover system designed to retain moisture at the concrete surface and distribute the released water over the surface. Accordingly, the smart curing cover was designed to consist of two main layers with hydrophobic and hydrophilic properties from the outer to the inner surface. The side view and layered structure of the smart curing cover are shown in Fig. 2. As shown in the figure, a vinyl/PVC-based hydrophobic covering material was used as the upper layer to limit the uncontrolled transfer of water to the external environment and contribute to moisture retention beneath the cover. The lower layer, which was in contact with the concrete surface, consisted of a hydrophilic capillary irrigation mat with a high water-absorption capacity and the ability to distribute water across the entire surface through capillary action. Owing to these properties, the water supplied from the center of the cover was absorbed by the hydrophilic layer rather than remaining confined to the inlet region and was distributed toward the edges and corners of the cover.

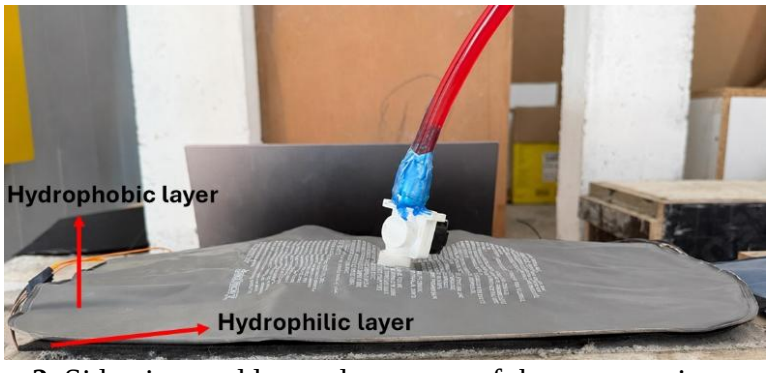

Fig. 2. Side view and layered structure of the smart curing cover

The solenoid valve responsible for water release was positioned at the center of the hydrophobic upper layer, allowing the water supplied from the main reservoir to be transferred directly to the hydrophilic lower layer. The central position of the valve was selected to enable water supplied from a single point to be distributed across the cover by utilizing the absorption and capillary-spreading properties of the hydrophilic layer. The central placement of the solenoid

valve on the cover is shown in Fig. 3a. Meanwhile, the DHT11 temperature and humidity sensor was placed within the hydrophilic layer using a specially designed protective housing to enable measurements beneath the cover while protecting the sensor from direct contact with water. The sensor was positioned in the lateral region opposite to the water-discharge direction of the solenoid valve. This arrangement was intended to prevent the water released when the valve was opened from directly contacting and wetting the sensor, thereby avoiding any misleading effect of direct wetting on the measurements. The physical placement of the sensor within the hydrophilic layer is shown in Fig. 3b.

(a) Top view (b) Bottom view

Fig. 3. Physical arrangement of the water-release and sensing components of the curing cover

A main reservoir positioned outside the cover was incorporated into the system to supply the water required by the smart curing cover. The main reservoir was connected to the solenoid valve through a hose, enabling water to be conveyed from the reservoir to the cover system. In addition, the reservoir was graduated to determine the total amount of water consumed by the smart curing cover during the curing process. The connection between the smart curing cover and the main reservoir and the graduated configuration of the reservoir are shown in Fig. 4a and Fig. 4b, respectively. Through these arrangements, the hydrophobic upper layer, hydrophilic lower layer, solenoid valve, DHT11 sensor and its protective housing, main reservoir, and hose connection were integrated into a single curing system.

Fig. 4. Details of the main reservoir supplying the smart curing cover

2.3 Specimen Production

A total of six concrete specimens were produced in accordance with the experimental arrangement presented in Table 1. All specimens were prepared with dimensions of 26×42×12 cm, and the same dimensions were used for all experimental groups to limit the influence of specimen geometry on the experimental results. C30/37 ready-mixed concrete was used for specimen production; thus, variability arising from the concrete mixture was reduced to enable a more reliable comparison of the effects of the different curing methods on strength development. Following completion of the production process and the initial setting of the specimens, the curing procedures specified in the experimental plan were initiated.

2.4 Curing Processes

Following the initial setting of the specimens, three curing methods -water-spraying curing, wet-burlap curing, and curing with the smart curing cover- were applied simultaneously in accordance with the experimental groups defined in Table 1. The amount of water used for each method was specifically recorded throughout the curing processes. An overall view of the concrete specimens, divided into two different groups and subjected to the three curing methods, is presented in Fig. 5.

Fig. 5. Curing of the concrete specimens using three different methods

Water-spraying curing and wet-burlap curing, which were considered conventional curing methods, were applied at 12 hours intervals during the first 7 days. In each application, 200 mL of water was used to maintain the amount of water applied in a controlled and constant manner. In the water-spraying curing method, the measured water was applied directly to the concrete surface, whereas in the wet-burlap curing method, the concrete surface was covered with burlap and the burlap was rewetted with the same amount of water at each application interval. In the smart curing cover method, the developed covers were placed on the concrete surfaces following the initial setting of the specimens, and no periodic manual watering was applied during the curing process; instead, the process was governed entirely by the automatic control system. Water release was automatically performed according to the relative-humidity-based control mechanism described in Section 2.1 and the required water was supplied from the graduated main reservoirs connected to the smart curing cover system. The total amount of water used during curing with the smart curing cover was determined from the changes in the water levels in the reservoirs. This enabled comparison between the amount of water used in

the conventional methods and the amount of water used by the smart curing cover under sensor-based control. Following the curing applications, the specimens were maintained until the 7- and 28-day test ages specified for compressive strength evaluation.

2.5 Compressive Strength Testing

Following the curing processes, core specimens were extracted from the corresponding concrete specimens to determine the 7- and 28-day compressive strengths of the concrete. Core extraction was performed on the 7th and 28th days after concrete casting in accordance with the experimental groups defined in Table 1. At each test age, three core specimens were extracted from the corresponding concrete specimen for each of the three curing methods. The core extraction locations were selected from similar regions to maintain consistent sampling conditions among the specimens; the cores were positioned along the longitudinal direction of the concrete specimen and on the centerline of its short axis. The core specimens used in the compression tests were prepared with a diameter of 95 mm and a height of 90 mm, corresponding to a length-to-diameter ratio of 0.95. Fig. 6 shows the specimens considered for the 7-day compressive strength evaluation and the core specimens extracted from them.

Fig. 6. Core specimens extracted from the concrete specimens

The extracted core specimens were subjected to uniaxial compression tests using a 300-ton-capacity compression testing machine at a loading rate of 0.6 MPa/s. In accordance with TS EN 13791 [10], the length-to-diameter ratio of the core specimens was 0.95, which falls within the range of 0.90–1.10 specified for 1:1 core specimens. Therefore, the maximum compressive strength values obtained from the tests were considered equivalent standard cube strengths. The corresponding equivalent standard cylinder strengths were calculated by multiplying these values by a factor of 0.82, in accordance with the cube-to-cylinder strength conversion specified in TS EN 13791 [10]. Thus, the equivalent standard cylinder strengths obtained for both test ages and all three curing methods were used for comparative evaluation.

3 Results and Discussion

The performance of the developed smart curing cover was comparatively evaluated against conventional water-spraying and wet-burlap curing methods based on the amount of water used during the curing process and the 7- and 28-day compressive strengths of the concrete.

3.1 Water Consumption Performance

In the conventional curing methods, the concrete specimens received 200 mL of water at 12 hours intervals during the first 7 days, resulting in a total water consumption of approximately 2800 mL per specimen. For the two concrete specimens cured with the smart curing cover, the total amounts of water consumed from the main reservoirs over the same period were measured as approximately 1300 mL and 1200 mL, respectively. Based on these values, the smart curing cover reduced water consumption by approximately 53.6% and 57.1%, respectively, compared

with the 2800 mL used in the conventional methods. This reduction in water consumption can be attributed to the fact that, whereas water was continuously applied at predetermined intervals in the conventional methods regardless of the existing moisture condition, the smart curing cover released water only when the relative humidity fell below the 95% threshold. Once the threshold was reached again, the water flow was stopped, further limiting unnecessary water application. In addition, the automatic operation of the watering process eliminated the need for periodic user intervention. Thus, the smart curing cover provided advantages in terms of both reducing water consumption and automating the curing process independently of manual labor.

3.2 Compressive Strength Performance

The compression test results obtained from the core specimens extracted from the 7- and 28-day concrete specimens subjected to the three curing methods are presented in Tables 2 and 3, respectively. For each curing method and test age, the mean equivalent standard cylinder compressive strength was calculated from the three core specimens, and these mean values were additionally visualized in Fig. 7 to facilitate a clearer comparison among the methods. In the figure, the dashed lines represent the mean strength values obtained with the smart curing cover, whereas the bars represent the mean values obtained with the conventional curing methods. The percentage values shown above the bars indicate the relative differences between the mean strengths obtained with the conventional curing methods and the corresponding mean strength obtained with the smart curing cover, which was taken as the reference at each test age. Positive values indicate a higher mean strength than the smart curing cover, whereas negative values indicate a lower mean strength. The mean 7-day equivalent standard cylinder compressive strengths were determined as 31.73, 29.90, and 32.20 MPa for the smart curing cover, water-spraying curing, and wet-burlap curing, respectively. Taking the smart curing cover as the reference, the mean value obtained with water-spraying curing was approximately 5.7% lower, whereas that obtained with wet-burlap curing was approximately 1.5% higher. Accordingly, the 7-day mean strength obtained with the smart curing cover fell between those of the two conventional methods and exhibited comparable early-age strength performance. At 28 days, the mean equivalent standard cylinder compressive strengths were calculated as 40.45, 38.76, and 39.87 MPa for the smart curing cover, water-spraying curing, and wet-burlap curing, respectively. Relative to the mean value obtained with the smart curing cover, the mean strengths achieved with water-spraying curing and wet-burlap curing were approximately 4.2% and 1.5% lower, respectively. In terms of 28-day strength development, the smart curing cover achieved a higher mean compressive strength than both conventional curing methods and effectively sustained the development of the 28-day strength. Considering the 7- and 28-day results together, the findings demonstrate that the developed smart curing cover system was able to provide effective curing performance without causing any reduction in concrete compressive strength development, despite its substantially lower water consumption.

Table 2. 7-day compressive strength values

Curing Method	**Core No**	**Maximum Load (kN)**	**Maximum Compressive Strength (MPa)**	**Equivalent Standard Cylinder Compressive Strength (MPa)**
Curing with the Smart Curing Cover	1	273.97	38.65	31.69
	2	259.89	36.67	30.07
	3	288.86	40.75	33.42
Water-Spraying Curing	4	265.63	37.48	30.73
	5	245.72	34.67	28.43
	6	264.01	37.25	30.55
	7	270.42	38.15	31.28

Wet-Burlap Curing	8	280.95	39.64	32.50
	9	283.73	40.03	32.82

Table 3. 28-day compressive strength values

Curing Method	**Core No**	**Maximum Load (kN)**	**Maximum Compressive Strength (MPa)**	**Equivalent Standard Cylinder Compressive Strength (MPa)**
Curing with the Smart Curing Cover	1	334.27	48.17	39.50
	2	346.80	49.97	40.98
	3	345.97	49.85	40.88
Water-Spraying Curing	4	326.73	47.08	38.61
	5	329.78	47.52	38.97
	6	327.60	47.21	38.71
Wet-Burlap Curing	7	335.95	48.41	39.70
	8	345.36	49.77	40.81
	9	330.38	47.67	39.09

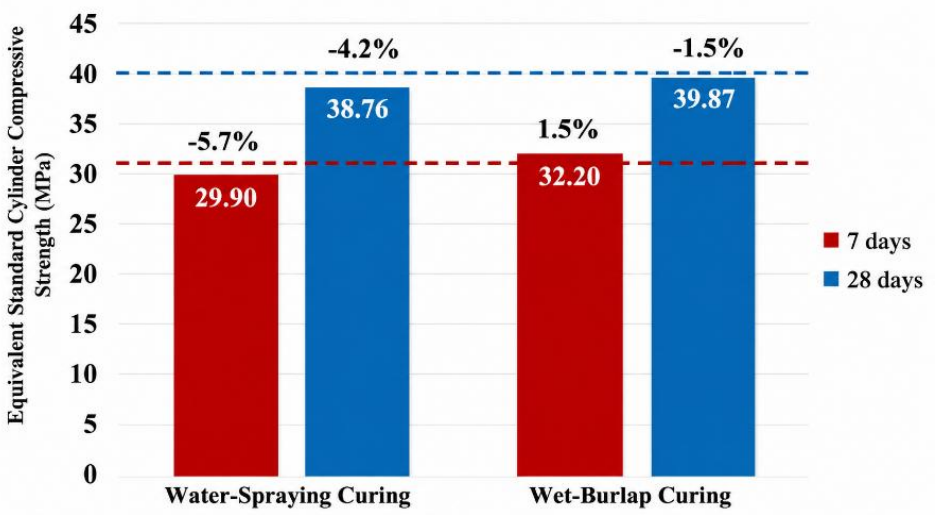

Fig. 7. Comparison of mean equivalent standard cylinder compressive strengths obtained with the three curing methods.

4 Conclusions

The smart curing cover developed within the scope of this study reduced water consumption by 53.6–57.1% while maintaining 7- and 28-day compressive strength performance comparable to conventional water-spraying and wet-burlap curing methods. The results indicate that controlling water release in response to relative humidity can limit unnecessary water application and reduce the need for periodic human intervention without adversely affecting strength development. By combining automatic water release, moisture retention, and a more uniform distribution of the supplied water across the concrete surface, the developed smart curing cover provides a water-efficient and automation-based alternative to conventional wet-curing practices. Further validation using a larger number of independent specimens and under field conditions is recommended for a more comprehensive assessment of the system.

Abstract. Construction contracts constitute one of the most common contractual relationships in the construction industry and frequently lead to legal disputes due to the complex nature of construction projects. In Türkiye, these contracts are evaluated within the scope of work contracts under the Turkish Code of Obligations and are mainly regulated by Article 470 of the Code of Obligations No. 6098, with Article 355 of the former Code No. 818 serving as a comparative legal reference. This study aims to establish a comprehensive database for the evaluation of construction contract disputes in Türkiye between 2000 and 2021 through Supreme Court decisions. The Supreme Court of Appeals, functioning as the highest judicial review authority under Turkish law, provides final legal interpretations regarding construction-related disputes and therefore represents a reliable source for identifying recurring contractual problems in practice. Within the scope of the research, all Supreme Court decisions associated with work contracts under Articles 355 and 470 were examined and categorized according to their dispute subjects. The analyzed case files were classified under specific headings, enabling the development of dispute classification tables reflecting real judicial cases in the construction sector. The findings reveal the most frequent sources of disputes encountered in construction contracts and provide valuable insights for risk identification and management processes in construction project management. The study is expected to contribute to the development of more realistic risk assessment approaches by utilizing judicial case analyses as a practical reference for construction managers, legal professionals, and researchers.

Keywords: Construction Contract; Construction Disputes; Supreme Court Decisions; Risk Management.

1 Introduction

The construction sector operates in an environment characterized by high financial exposure, long project durations, and considerable technical complexity [1]. These characteristics make construction projects particularly vulnerable to disagreements among project stakeholders. In Türkiye, construction agreements are generally classified as work contracts. Their legal framework is primarily governed by Article 470 of the Turkish Code of Obligations (TCO) No. 6098 and, historically, by Article 355 of the former Code No. 818 [2]. Under these provisions, the contractor undertakes to create and deliver a work, while the employer undertakes to pay the agreed compensation.

Despite contractual provisions established at the outset of a project, actual project conditions frequently differ from those originally anticipated. Unforeseen site conditions, design modifications, delays in material delivery, payment defaults, and other changes during project execution may create conflicts between the parties [3, 4]. When contractual or alternative

dispute resolution mechanisms fail to resolve these conflicts, disputes may proceed to litigation. In the Turkish judicial system, the Supreme Court of Appeals (Yargıtay) serves as the highest judicial review authority for the relevant decisions. Its case law therefore provides an important empirical source for examining recurring contractual problems in the construction industry [5].

Previous research has largely focused on dispute causes, claim management, proactive risk management, and contractual analysis. Although these studies provide valuable insights, empirical analyses based on actual judicial decisions remain relatively limited [6, 7]. Historical litigation data can provide additional evidence regarding the contractual and administrative problems that repeatedly develop into formal disputes.

Accordingly, this study analyzes Supreme Court decisions concerning construction-related work contracts rendered between 2000 and 2021. The decisions were systematically categorized according to their principal dispute subjects in order to identify recurring sources of construction litigation in Türkiye. The findings are subsequently interpreted from a construction risk management perspective.

The main objective of the study is to demonstrate how judicial case analysis can contribute to the identification of contractual risks and support the development of more proactive dispute prevention strategies. By linking recurring dispute categories with construction risk management practices, the study seeks to provide practical insights for construction managers, contract administrators, legal professionals, and researchers.

2 Legal and Methodological Framework

2.1 Statutory Context of Work Contracts

Under Article 470 of TCO No. 6098, a work contract is a bilateral agreement under which the contractor undertakes to produce a work or achieve a specific result, while the employer undertakes to pay the agreed price [8]. This result-oriented nature distinguishes work contracts from contractual relationships based primarily on the provision of services or effort.

The contractor is generally expected to perform the work with due care, use appropriate materials, and deliver the work in accordance with contractual and legal requirements. The employer, on the other hand, is primarily responsible for accepting the completed work when it conforms to the contract and paying the agreed compensation [9].

When disputes arise, courts evaluate the parties' performance and obligations under the relevant statutory provisions governing issues such as defective performance, delay, acceptance, payment, and price adjustments. Article 480 of the TCO, for example, may become relevant in disputes involving price adjustments arising from circumstances that could not reasonably have been foreseen by the parties [10]. The interpretation of these provisions in Supreme Court decisions therefore provides an important basis for examining litigation exposure in construction projects.

2.2 Data Collection and Qualitative Categorization Methodology

The study collected judicial decisions from public and legal databases covering the period from January 2000 to December 2021. The search primarily focused on decisions rendered by the 15th Civil Chamber of the Supreme Court (Yargıtay 15. Hukuk Dairesi), which dealt extensively with disputes arising from work contracts during the study period.

The evaluation followed a structured qualitative process:

Filtering: Decisions were screened using search terms and legal references associated with Articles 355 and 470, construction contracts, defective work, additional works, and contractual termination.

Relevance screening: Decisions concerning non-construction work contracts, procedural dismissals, and repetitive precedents that did not provide additional information regarding the nature of the dispute were excluded.

Qualitative categorization: The selected decisions were examined to identify their underlying dispute subjects. The cases were subsequently classified into functional categories based on their principal contractual themes.

Pattern mapping: The categorized cases were evaluated to identify the relative frequency of the principal dispute categories and their relationship with recurring project and contractual risks.

3 Findings and Dispute Analysis

The qualitative analysis established a descriptive profile of construction litigation in Türkiye. The examined disputes were grouped into five core categories: scope changes and additional works, defective execution, contractual delay and time extensions, payment and price adjustments, and contract termination and damages.

3.1 Distribution of Dispute Categories

Table 1 presents the classification of the analyzed construction contract disputes and summarizes the principal legal issues associated with each category.

Table 1. *Classification of construction contract disputes.*

Primary Dispute Subject	Applicable TCO Article	Relative Frequency (%)	Key Contested Issue
Additional Work & Scope Changes	Arts. 470, 481	28.5	Lack of written variation orders
Defective Work & Workmanship	Arts. 474, 475	24.2	Latent defects and inspection timing
Contractual Delay & Time Extension	Arts. 473, 478	21.0	Force majeure and concurrency of delays
Payment & Price Adjustments	Arts. 480, 482	16.8	Unexpected cost increases and unit price disputes
Contract Termination & Damages	Arts. 484, 486	9.5	Unilateral termination and its consequences

The results indicate that additional work and scope changes constituted the largest single dispute category, accounting for 28.5% of the analyzed cases. Defective work and workmanship followed at 24.2%, while contractual delays and time extensions represented 21.0%. Together, these three categories accounted for more than 70% of the disputes examined.

Payment and price adjustment disputes represented 16.8% of the cases, while contract termination and damages constituted the smallest category at 9.5%. Although less frequent, termination disputes often involve significant legal and financial consequences because they may affect the continuation of the project and the parties' subsequent rights and obligations.

3.2 Key Findings and Judicial Interpretations

Scope Changes and Additional Work: Disputes concerning scope variations represented the largest category in the dataset. A recurring issue in these disputes involved instructions for additional work that were not adequately documented through formal written change orders. The Supreme Court decisions examined in this category demonstrate the importance of contractual procedures and evidentiary requirements when parties claim additional compensation for work that is alleged to fall outside the original scope [11, 12].

From a construction management perspective, these findings highlight the importance of systematic change management. Verbal instructions, informal requests, and undocumented changes may create uncertainty regarding both entitlement and valuation. Therefore, changes should be recorded in writing and formally evaluated with respect to their cost and time consequences.

Defective Work and Inspection: Defective performance constituted the second-largest dispute category. These disputes frequently involved questions regarding the identification of defects, the timing of inspections, and notification to the contractor. Under Article 474 of the TCO, the employer is required to inspect the completed work and notify the contractor of defects within the legally required framework [13].

The findings demonstrate that technical inspection and contractual administration are closely related. Delayed inspection or inadequate documentation may complicate the determination of whether a defect existed at the time of delivery and whether the relevant rights were preserved. Effective inspection procedures and written defect notifications can therefore play an important role in preventing disputes.

Delays and Time Extensions: Delay disputes represented 21.0% of the analyzed cases. These disputes may arise from various causes, including contractor-related delays, late site handover, delayed design approvals, external events, and concurrent delays involving more than one party. Determining responsibility is particularly important because the outcome may affect extensions of time, compensation, or the application of delay-related contractual consequences [14].

The findings emphasize that delay management should not be limited to schedule monitoring. Detailed site records, project correspondence, progress documentation, and timely notices are also essential for establishing the factual and contractual basis of delay claims.

Payment and Price Adjustments. Payment and price adjustment disputes accounted for 16.8% of the analyzed cases. These disputes generally involve disagreements concerning the valuation of work, unit prices, additional costs, or the financial consequences of changed project conditions. The findings illustrate the importance of maintaining transparent procedures for measuring completed work and determining the applicable contractual price.

Contract Termination and Damages: Contract termination and related damage claims represented 9.5% of the cases. These disputes involve questions concerning the termination of the contractual relationship and the legal and financial consequences of incomplete or disputed

performance. Clear contractual provisions concerning termination procedures and the documentation of performance are therefore essential for reducing uncertainty when serious disagreements arise.

3.3 Qualitative Risk Exposure Evaluation

Rather than applying a strict mathematical risk model, the findings were interpreted through a qualitative risk perspective. The relative frequency of dispute categories provides an indication of recurring areas of contractual exposure, while the nature of the disputes provides information regarding their potential legal and operational consequences.

Scope variations and defective performance represent particularly significant risk areas because they combine relatively high frequency with substantial evidentiary requirements. Delay disputes may similarly create considerable exposure when project records are insufficient to establish responsibility for the delay.

The analysis suggests that construction disputes should not be considered only as isolated legal events. They can also be interpreted as indicators of recurring weaknesses in project planning, contract administration, communication, documentation, and risk allocation.

4 Discussion and Strategic Risk Management Implications

The findings reveal an important connection between construction management practices at the project level and the issues that later emerge in litigation. Many disputes do not necessarily result from a single technical failure or deliberate misconduct. Instead, they may develop through inadequate documentation, unclear communication, inconsistent contractual procedures, or the failure to manage changes and delays systematically.

4.1 Implications for Project Management

The analysis provides several practical implications for construction project managers:

Formalize communication: The recurrence of disputes concerning additional works demonstrates the importance of eliminating ambiguity in site instructions. Change orders, requests for extensions of time, project correspondence, and meeting decisions should be documented in writing and communicated through the contractual procedures established for the project [15].

Establish structured inspection procedures: Formal inspection and handover procedures can help clarify whether the work conforms to contractual requirements. Written inspection records and timely notification of defects are particularly important for preserving the parties' rights and reducing uncertainty concerning defective performance.

Maintain comprehensive delay records: Contractors and project teams should maintain detailed site records to document the occurrence, duration, and causes of delay events. Daily site records, correspondence, progress reports, and schedule updates may become essential when determining responsibility for delays and their consequences [16, 17].

4.2 Contract Drafting and Systemic Controls

The findings also have implications for contract drafting and administration. Construction contracts should establish clear procedures for variations, site instructions, payment, inspection, delay notices, extensions of time, and termination.

A contract alone cannot prevent all disputes. However, well-defined procedures can reduce uncertainty and provide a framework for addressing disagreements before they develop into

formal litigation. Effective contract administration is equally important because even detailed contractual provisions may lose their practical value when project participants do not follow them during project execution.

An integrated dispute prevention framework should therefore combine clear contractual provisions with systematic documentation and project-level monitoring [18]. Such an approach can support earlier identification of potential conflicts and reduce the need to rely on judicial interpretation after a dispute has escalated.

5 Conclusion

This study evaluated construction contract disputes in Türkiye through the analysis of Supreme Court decisions rendered between 2000 and 2021. The decisions were examined and categorized according to their principal dispute subjects, revealing five recurring areas of litigation: additional work and scope changes, defective work and workmanship, contractual delays and time extensions, payment and price adjustments, and contract termination and damages.

The findings show that disputes concerning scope variations, defective workmanship, and performance delays account for more than 70% of the analyzed cases. These results indicate that construction litigation is strongly associated with recurring contractual and administrative problems related to scope, quality, time, payment, and performance.

Although construction disputes and claim management have been extensively discussed in previous research, the systematic analysis of Supreme Court decisions provides an additional empirical perspective. Judicial cases reflect disputes that have developed beyond ordinary project-level disagreements and have required formal legal evaluation. For this reason, they provide valuable evidence regarding the types of contractual problems that repeatedly emerge in practice.

The results further suggest that a considerable proportion of disputes may be associated with weaknesses in project administration, particularly inadequate documentation of changes, delays in identifying and notifying defects, and insufficient records concerning delay events. Aligning day-to-day project administration with contractual requirements can therefore support earlier resolution of disagreements and reduce litigation exposure.

Overall, the findings indicate that construction disputes are repetitive rather than entirely random, while Supreme Court decisions provide valuable empirical evidence regarding the recurring causes and characteristics of such disputes. The systematic analysis of judicial cases can therefore contribute to the identification of contractual and project-related risks at an earlier stage. In this respect, judicial case analysis may support the development of more realistic risk identification and management approaches in construction projects.

Future research may extend the existing dispute database and use larger judicial datasets to investigate the relationships between dispute categories, project characteristics, and contractual variables. Moreover, the database developed in this study may provide a foundation for future machine learning and artificial intelligence-supported dispute prediction systems in construction contract management. Such systems could support a transition from the retrospective analysis of disputes toward more proactive and predictive approaches to risk identification and dispute prevention.

Acknowledgments

The authors express their gratitude to legal scholars and industry experts who offered guidance on legal database navigation and Supreme Court case indexing during the preliminary data collection phase.

Conflict of Interest

The authors declare no conflict of interest.

Funding

The authors received no specific financial support for the research, authorship, or publication of this study.

Data Availability Statement

The data supporting the findings of this study consist of judicial decisions examined within the scope of the research. The classified dataset may be made available by the corresponding author upon reasonable request.
