Publication Information

Title:	ACE2026 - Proceedings Book
Congress:	16th International Congress on Advances in Civil Engineering
Date:	12-14 October 2026
Venue:	Trabzon, Türkiye
Editors:	Şevket ATEŞ, Ph.D., Professor · Serhat DEMİR, Ph.D., Professor · Barbaros ATMACA, Ph.D., Associate Professor
Publisher:	Karadeniz Technical University · Department of Civil Engineering · Trabzon, Türkiye
Year:	2026

All papers in this volume have been peer-reviewed by at least two independent referees. The authors are solely responsible for the content of their contributions. No part of this publication may be reproduced, stored or transmitted in any form without the prior written permission of the publisher.

Preface

Dear Colleagues,

It is our great pleasure to present the Proceedings of ACE2026, the 16th International Congress on Advances in Civil Engineering.

The congress was hosted by the Department of Civil Engineering of Karadeniz Technical University and held on 12–14 October 2026.

The ACE congress series has long brought together researchers, academics, practitioners and graduate students to share recent advances across the whole field of civil engineering. ACE2026 continued this tradition in a hybrid format:

- The first two days were held on campus in Trabzon, in three parallel halls.
- The third day was held entirely online, in three virtual rooms.

This format allowed colleagues who could not travel to Trabzon to present their work and take part in the discussions.

Over the three days, 160 papers were presented in 27 sessions, together with three keynote lectures and five posters. The contributions covered the main branches of the discipline:

- Structures
- Construction Materials
- Transportation
- Construction Management
- Hydraulics
- Geotechnics

The authors came from more than 60 universities, research institutions and companies. Besides Türkiye, they were based in Algeria, Australia, Bangladesh, Canada, India, Iran, Japan, Northern Cyprus, Palestine and the United Arab Emirates. Machine learning and digital tools, low-carbon and sustainable materials, seismic performance and resilient infrastructure were among the themes that ran through the programme.

We are grateful to our keynote speakers for their inspiring lectures:

- Prof. Dr. Faiz Shaikh (Curtin University)
- Dr. Shahab Yasrebi (Geomaple Geotechnics Inc.)
- Prof. Dr. Ahmet Türer (Middle East Technical University)

We also sincerely thank:

- all authors and presenters for their valuable contributions;
- the members of the Scientific Committee and the reviewers for their careful evaluation of the papers;
- the session chairs, who guided the sessions and discussions.

The congress was organised in collaboration with Boğaziçi University, Middle East Technical University, Istanbul Technical University, Yıldız Technical University, Ege University, Eastern Mediterranean University, the Chamber of Civil Engineers of Türkiye (TMMOB İMO) and its Trabzon Branch. We acknowledge their support with gratitude.

We are equally indebted to our sponsors for their generous support:

- TAV Construction
- Pasifik Holding
- ES Denizcilik
- ideCAD
- Trabzon Metropolitan Municipality

Finally, we thank the members of the Organising Committee, our administrative staff and our students, who worked with great dedication behind the scenes.

This volume contains the full papers presented at the congress, published after the authors' final corrections. We hope it will be a useful reference for researchers and practitioners and will encourage new collaborations. We look forward to welcoming you at the next ACE congress.

On behalf of the Organising Committee

Prof. Dr. Şevket Ateş

Head, Department of Civil Engineering, Karadeniz Technical University

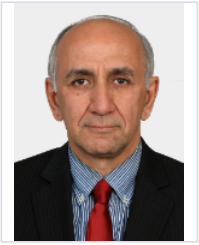
Assist. Prof. Dr. Amjad Al-Mudhafer - Iraq Al-Mustansiriyah University

Keynote Speakers

Prof. Dr. Faiz Shaikh

School of Civil and Mechanical Engineering, Curtin University, Perth, Australia

KEYNOTE LECTURE



Fresh state, rheological and harden properties of 3D printed concrete made by lithium refinery residue (lithium slag) as partial cement replacement

Faiz Shaikh, SM Arifur Rahman, Prabir Sarker

The lecture presents the use of lithium refinery residue (lithium slag) as a partial cement replacement in 3D printed concrete. Mix design, rheology and printability, buildability, and mechanical and microstructural properties are discussed, together with the reduction in embodied carbon and the prospects for sustainable applications.

ABOUT THE SPEAKER

Prof. Shaikh is a Professor at the School of Civil and Mechanical Engineering, Curtin University. He has more than 220 peer-reviewed publications, including over 170 journal papers, two books and seven book chapters. His research covers engineered geopolymer and cementitious composites, nanomaterials in concrete, supplementary cementitious materials, recycled aggregates and industrial by-products, durability, repair and strengthening of reinforced concrete, and numerical modelling.

Dr. Shahab Yasrebi, PhD, P.Eng

President, Geomaple Geotechnics Inc., Toronto, Canada

KEYNOTE LECTURE

Urban Tunneling Challenges in Rapidly Developing Cities: Risk, Ground Uncertainty, and Digital Transformation in Underground Construction

The lecture examines the growing demand for underground space in megacities and the challenges of tunnelling in dense urban settings: geotechnical uncertainty and risk management, the interaction of new tunnels with existing infrastructure, and construction constraints in metropolitan areas. Lessons from international tunnelling and deep excavation projects are discussed, together with the role of artificial intelligence, monitoring systems and digital twins in underground construction.

ABOUT THE SPEAKER

Dr. Yasrebi is a geotechnical consultant with more than 37 years of international experience in underground infrastructure, deep excavations, ground improvement and site investigation across North America, the Middle East and Asia. He has led complex urban tunnelling projects, is a specialist in the New Austrian Tunnelling Method (NATM), and has authored more than 250 technical publications.

Prof. Dr. Ahmet Türer

Department of Civil Engineering, Middle East Technical University (METU), Ankara, Türkiye

KEYNOTE LECTURE

Snow Damage Patterns at Solar Power Plants: Structural Failures, Snow Drifting and Design Challenges in Ground-Mounted PV Systems

Drawing on forensic evidence from solar power plants damaged under heavy snow in Türkiye, the lecture discusses snow accumulation and drifting around PV arrays, the limitations of TS 498 for ground-mounted systems, aerodynamic gap and balanced snow depth concepts, wind–snow interaction and snow trapped beneath panels, buckling of cold-formed C-section supports, and failures caused by poor connections and workmanship. Lessons from insurance and forensic investigations and the application of ASCE 7-22 and EN 1991-1-3:2025 to solar infrastructure are presented.

ABOUT THE SPEAKER

Prof. Türer is a structural engineer and a full-time faculty member of the Department of Civil Engineering at METU. His work focuses on structural engineering, forensic investigations and structural health monitoring.

Fresh State, Rheology, Buildability and Mechanical Properties of 3D Printed Concrete Containing Lithium Slag

Faiz Shaikh*[1], SM Arifur Rahman[1] and Prabir Sarker[1]
[1] ORCID IDs: 0000-0002-5234-0619; 0000-0003-3725-3186; 0000-0002-5014-7444;

Abstract. 3D printed concrete (3DPC) reduces construction waste, labour and time and enables complex geometries without formwork, but its cement-intensive mixtures remain a sustainability challenge. This keynote paper summarises an investigation into lithium slag (LS), the de-lithiated beta spodumene residue of lithium refining, as a supplementary cementitious material in 3DPC. Four printable mixes were studied: a control mix of cement, fly ash and silica fume, a mix in which 40% of the cement was replaced by LS (40LS), and the same two mixes with 1 vol.% polyvinyl alcohol (PVA) fibre. Flowability, rheology, buildability, heat of hydration, compressive, flexural and interlayer bond strength, crack patterns, microstructure and embodied carbon and energy were evaluated. All mixes remained within the printable flow range. The 40LS mix showed the highest viscosity recovery (82.7%) and creep recovery (37%) and the best buildability, with 28 layers and a 410 mm stack height compared with 21 layers and 305 mm for the control. LS reduced the 7- and 28-day compressive strengths by about 11% and 6%, its 7-day flexural strength loss was recovered at 28 days, and it lowered the interlayer bond strength. PVA fibre increased the flexural strength of the LS mix by about 25% but made the layer interface the weakest plane. Replacing 40% of the cement with LS reduced the embodied carbon by 33% and the embodied energy by 20% relative to the control.

Keywords: 3D concrete printing, Lithium slag, Supplementary cementitious materials, Rheology, Buildability, Embodied carbon.

1 Introduction

3D printed concrete (3DPC) has proven to be a promising technology that reduces construction waste, manpower and time while offering innovative architectural solutions [1]. It enables the fabrication of complex structures without conventional formwork and without the noise associated with on-site compaction. However, printable mixtures are cement-intensive, because they must be pumpable and extrudable yet stiffen quickly enough to carry the weight of the layers above [2, 3]. This high cement content is a major sustainability challenge and motivates the use of high volumes of supplementary cementitious materials (SCMs) such as fly ash, slag, silica fume and metakaolin.

Lithium slag (LS) is a by-product of the lithium extraction process whose use as an SCM is currently being researched for conventional cast concrete. Western Australia has three main lithium refinery operations — the Tianqi Lithium Kwinana refinery, the Albemarle Kemerton plant and the Covalent Lithium Kwinana refinery — with a combined production capacity of approximately 150,000 tonnes per year. Approximately 8–9 tonnes of residue are generated to refine one tonne of battery-grade lithium, so that some 1.2–1.5 million tonnes of lithium refinery residue are produced every year and require sustainable management to prevent environmental pollution. This study investigates, for the first time, the potential of LS as an SCM for the production of decarbonised 3DPC, and evaluates its effect on the fresh state,

rheology, buildability, hydration, mechanical properties, microstructure and environmental impact of printable mixes with and without fibre reinforcement.

2 Materials and Methods

2.1 Lithium Slag and Other Materials

The LS used in this study, also known as de-lithiated beta spodumene (DBS), has flaky and angular particles (Fig. 1) and an as-received water content of 28.3%. The average particle sizes of the cement and the LS were 17 μm and 38 μm, respectively. Table 1 compares the chemical composition and physical properties of the cement (OPC), LS, fly ash (FA) and silica fume (SF). LS is rich in SiO_2 (54.6%) and Al_2O_3 (21.1%) with a low CaO content (7.5%), and its specific gravity of 2.46 is markedly lower than that of cement (3.1).

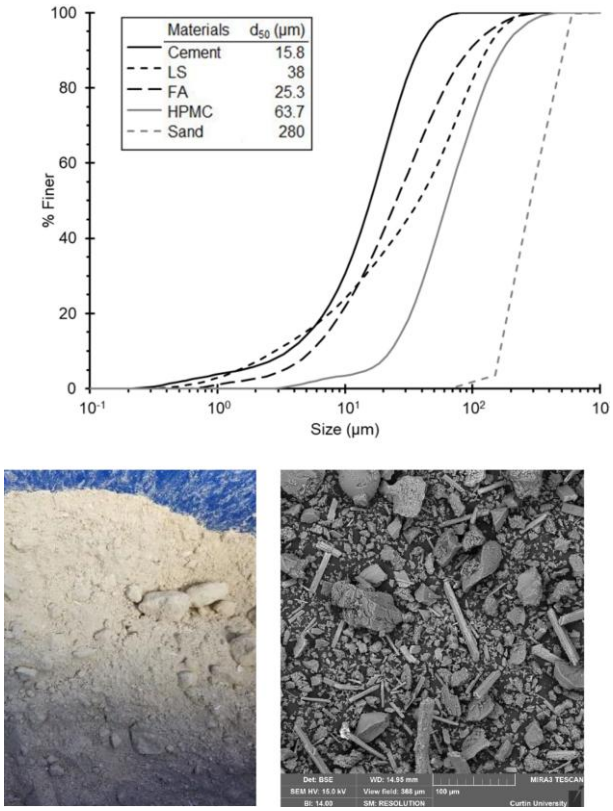

Fig. 1. Lithium slag: particle size distributions of the binder materials and sand (top) (Adopted from [6]), appearance of the as-received LS and SEM image showing its flaky, angular particles (bottom) (Adopted from [7]).

Table 1. Chemical composition and physical properties of the binder materials.

Parameter	OPC	LS	FA	SF
SiO_2 (%)	20.7	54.6	51.1	94.2
Al_2O_3 (%)	5.7	21.1	25.6	–
Fe_2O_3 (%)	2.9	1.5	12.5	–
CaO (%)	63.1	7.5	4.3	–
MgO (%)	1.3	0.6	1.5	–
SO_3 (%)	3.3	5.6	0.2	0.8
K_2O (%)	0.4	0.9	0.7	<0.01
Na_2O (%)	0.3	0.7	0.8	<0.01
LOI at 750 °C (%)	1.9	7.8	0.6	3.2
Specific gravity	3.1	2.46	2.20	2.22
Specific surface area (m^2/kg)	360	342	416	19934

Source: Data from [6]

2.2 Mix Proportions and Printing

Four mixes were designed (Table 2). In the control mix the binder consisted of cement, 20% FA and 10% SF; in the 40LS mix, 40% of the cement was replaced by LS. The binder and sand were combined in a 60:40 mass ratio at a water-to-binder ratio of 0.30. A superplasticiser (SP), a viscosity-modifying admixture (VMA) and hydroxypropyl methylcellulose (HPMC) were used, and the SP dosage was adjusted to maintain the design flow. The fibre-reinforced mixes (Control-F and 40LS-F) contained 1 vol.% PVA fibre.

Table 2. Mix proportions.

Mix ID	OPC	LS	FA	SF	Sand	w/b	SP	VMA	HPMC	PVA
Control	531	–	152	76	506	0.30	0.64	0.60	0.1	–
Control-F	531	–	152	76	506	0.30	1.19	0.60	0.1	1
40LS	319	212	152	76	506	0.30	2.51	0.60	0.1	–
40LS-F	319	212	152	76	506	0.30	3.07	0.60	0.1	1

OPC, LS, FA, SF and sand in kg/m^3; SP, VMA and HPMC in wt.% of binder; PVA in vol.%.

Source: Data from [6]

The mixing and printing protocol is shown in Fig. 2. The dry materials were mixed at 60 rpm; the PVA fibre and HPMC were added after 3 min, and the SP, VMA and water were added in two portions after 4 and 6 min (at 60 and 120 rpm), with scraping of the bowl at 5 min and final mixing at 240 rpm after 10 min. The mixes were then printed with a gantry-type 3D concrete printer for the buildability tests and the preparation of specimens.

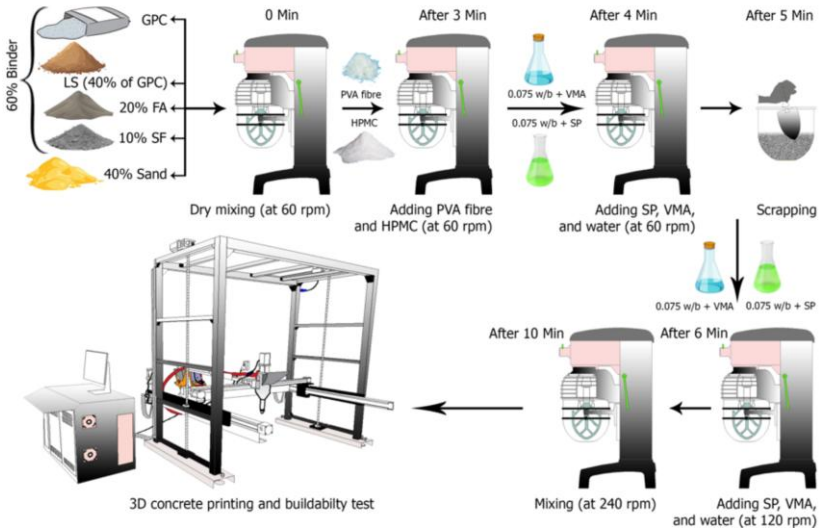

Fig. 2. Mixing protocol and 3D concrete printing (Adopted from [6]).

2.3 Test Methods

The workability of the fresh mixes was measured by the flow test immediately after mixing and after 30 and 60 min. The rheology was measured with a Malvern Kinexus Pro+ rheometer using shear-rate protocols to obtain the plastic viscosity, the viscosity recovery rate (VRR) and the creep recovery. The heat of hydration was measured by isothermal calorimetry. Buildability was assessed by printing cylindrical stacks layer by layer, recording the number of layers and the stack height, and by measuring the deformation ratios of the layers. Compressive, flexural and interlayer bond (tensile) strengths were determined on specimens cut from printed elements at 7 and 28 days, and the microstructure was examined by scanning electron microscopy (SEM) with backscattered electron (BSE) imaging and energy-dispersive X-ray spectroscopy (EDS). Finally, the embodied carbon (EC) and embodied energy (EE) of the mixes were calculated.

3 Results and Discussion

3.1 Flowability and Rheology

The initial flow values of all mixes were within 200 ± 10 mm (Table 3). The flow decreased slightly after 30 min owing to the evaporation of water and markedly after 60 min owing to the onset of hydration, but all mixes remained within the printable flow region of about 140–160 mm reported in the literature.

All printable mixes behaved as pseudo-plastic, shear-thinning non-Newtonian fluids (Fig. 3a). The LS, SP and HPMC enhanced the flocculation and water retention of the mixes, which significantly increased their plastic viscosity and yield stress. The VRR of the control and 40LS mixes was about 73.3% and 82.7%, respectively. The creep recovery was 21.7% for the control and 37% for 40LS, and 28.8% and 15.5% for the corresponding fibre-reinforced mixes (Fig. 3b). A higher creep recovery indicates a greater ability to return to the original shape and thus less deformation under self-weight; the 40LS mix combined the highest VRR and creep recovery of all mixes.

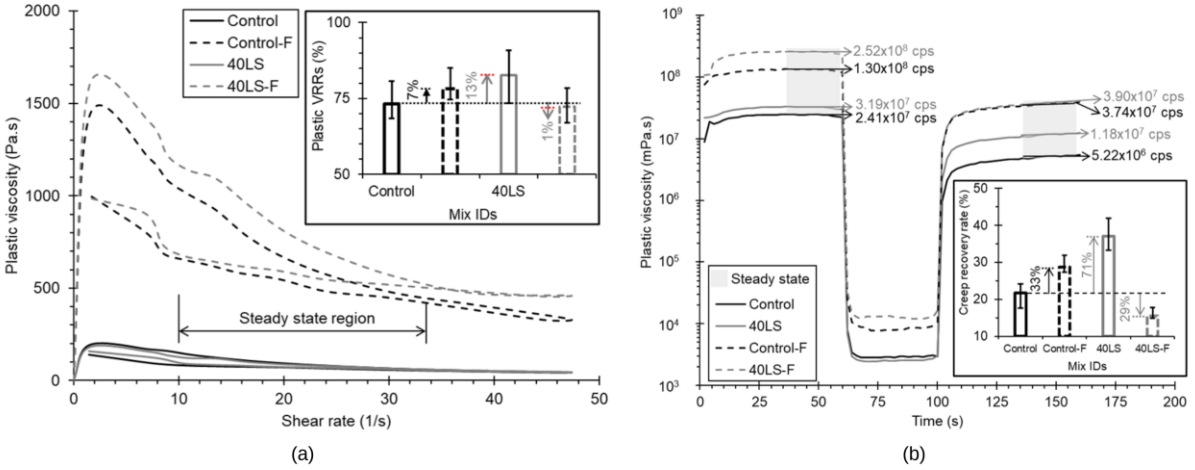

Fig. 3. Rheological behaviour: (a) plastic viscosity versus shear rate with the viscosity recovery rates (inset); (b) viscosity during the creep-recovery protocol with the creep recovery rates (inset). (Adopted from [6])

3.2 Buildability

The control mix could be printed to 21 layers with a stack height of 305 mm, whereas the 40LS mix reached 28 layers and 410 mm (Table 3, Fig. 4). The fibre-reinforced mixes reached 24 layers (360 mm, Control-F) and 21 layers (350 mm, 40LS-F). The better buildability of 40LS can be attributed to its higher VRR and creep recovery and to the lower specific gravity of LS

(2.46), which reduces the gravitational load on the middle and upper layers, limits excessive layer deformation and preserves the structural integrity of the stack.

Table 3. Fresh-state properties and buildability of the mixes.

Property	Control	Control-F	40LS	40LS-F
Flow, initial (mm)	195	200	200	190
Flow after 30 min (mm)	175	165	170	160
Flow after 60 min (mm)	148	138	150	144
Viscosity recovery rate (%)	73.3	n.r.	82.7	n.r.
Creep recovery (%)	21.7	28.8	37.0	15.5
Number of printed layers	21	24	28	21
Stack height (mm)	305	360	410	350

Flow values read from the flow-test chart; n.r. = not reported in the text.
Source: Data from [6]

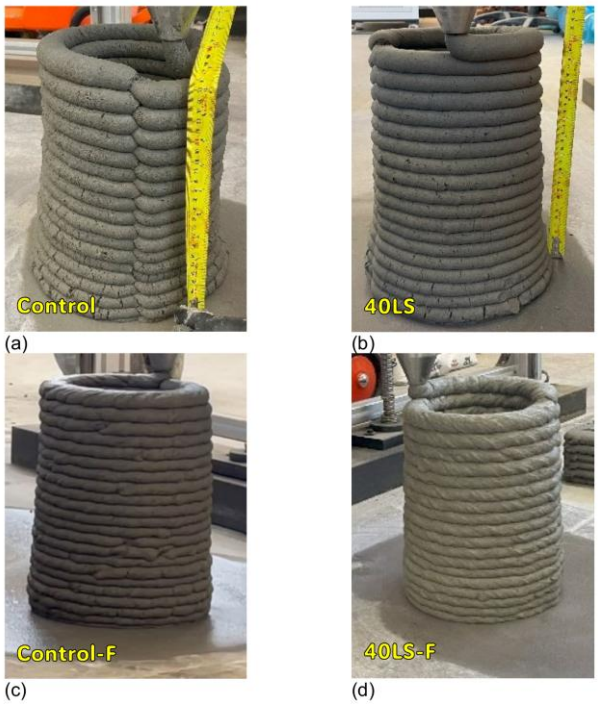

Fig. 4. Buildability tests: (a) Control, (b) 40LS, (c) Control-F and (d) 40LS-F. (Adopted from [6])

3.3 Heat of Hydration

All mixes exhibited a rapid release of heat within the first 60 min owing to wetting and dissolution, followed by a typical dormant phase, during which ettringite (AFt) forms through the interaction between the binder and the pore water (Fig. 5). In the control mix, the C_3S and C_2S of the cement ended the dormant phase and produced the main hydration peak after about 6–7 h. In the 40LS mix, the high LS content and SP dosage diluted the cement clinker and extended the dormant phase: the main peak was delayed by about 21.2 h and its height was reduced by 53%. The cumulative heat at 72 h was about 600 J/g for the control and 370 J/g for 40LS, i.e. 38% lower.

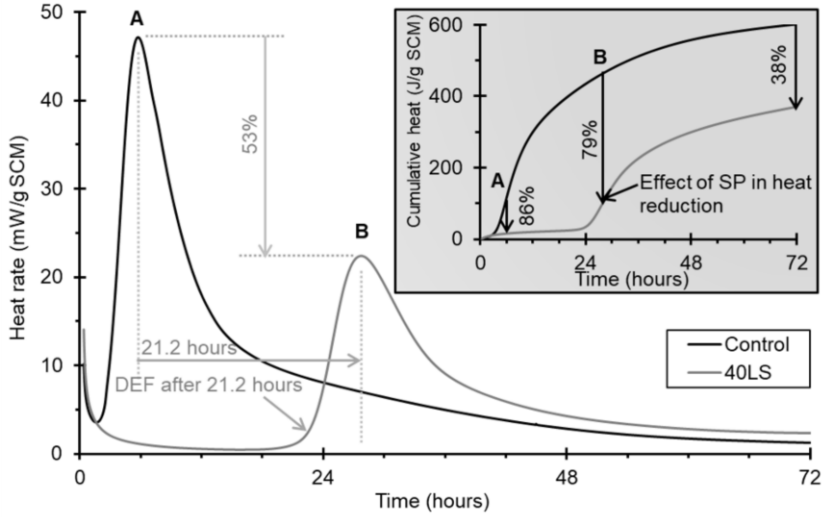

Fig. 5. Heat flow and cumulative heat (inset) of the Control and 40LS mixes, showing the delayed and reduced main hydration peak of 40LS. (Adopted from [6])

3.4 Mechanical Properties

The incorporation of LS reduced the 7- and 28-day compressive strengths by about 11% and 6%, respectively, and the addition of PVA fibre did not improve the compressive strength of either the control or the LS mix (Fig. 6a). The strength activity indices showed that the mixes satisfied the pozzolanicity requirements of ASTM C618 [4], BS 8615-1, AS 3582 and the RILEM TC 267-TRM approach [5]. The flexural strength of the LS mix was about 23% lower than that of the control at 7 days, but this loss was recovered at 28 days (Fig. 6b). PVA fibre increased the flexural strength of the LS mix by about 25% through crack bridging.

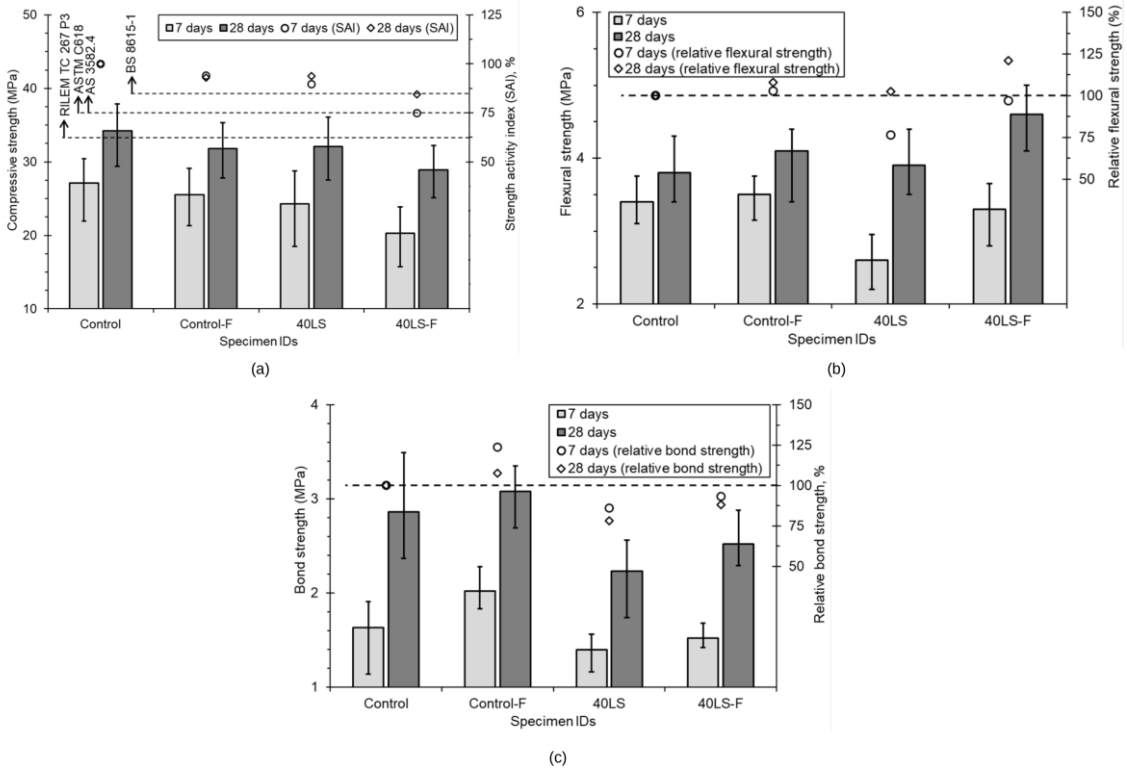

Fig. 6. Strength of the printed specimens at 7 and 28 days: (a) compressive strength with the strength activity index, (b) flexural strength and (c) interlayer bond strength, with values relative to the control. (Adopted from [6])

LS reduced the interlayer bond strength at both ages (Fig. 6c). PVA fibre improved the bond strength of both mixes, by 7% and 10% at 7 and 28 days in the LS mix and by 24% and 8% in the control mix. Because the printer nozzle moves horizontally along the printing direction, the PVA fibres are oriented parallel to the layers. This anisotropy helps to resist crack propagation through fibre bridging and increases the flexural capacity, but in combination with clinker dilution it weakens the interlayer adhesion, so that the bond strength of 40LS-F remained below that of the control.

The crack patterns confirmed this mechanism. In the control and 40LS specimens, the debonding cracks propagated through the middle of the printed layers rather than along the interface, indicating that the layer bond was relatively strong compared with the concrete matrix. In the PVA fibre reinforced specimens, the cracks propagated along the interface between two printed layers, which therefore became the weakest part of the element.

3.5 Microstructure

The BSE images and EDS maps (Fig. 7) show C-S-H and C-A-S-H together with unreacted FA particles in the control mix, AFt needles in the control-F mix, and HPMC, microcracks, pores and partially reacted LS particles in the LS mixes. The 40LS and 40LS-F mixes showed the early-age development of C-A-S-H and amorphous intermediate hydration products.

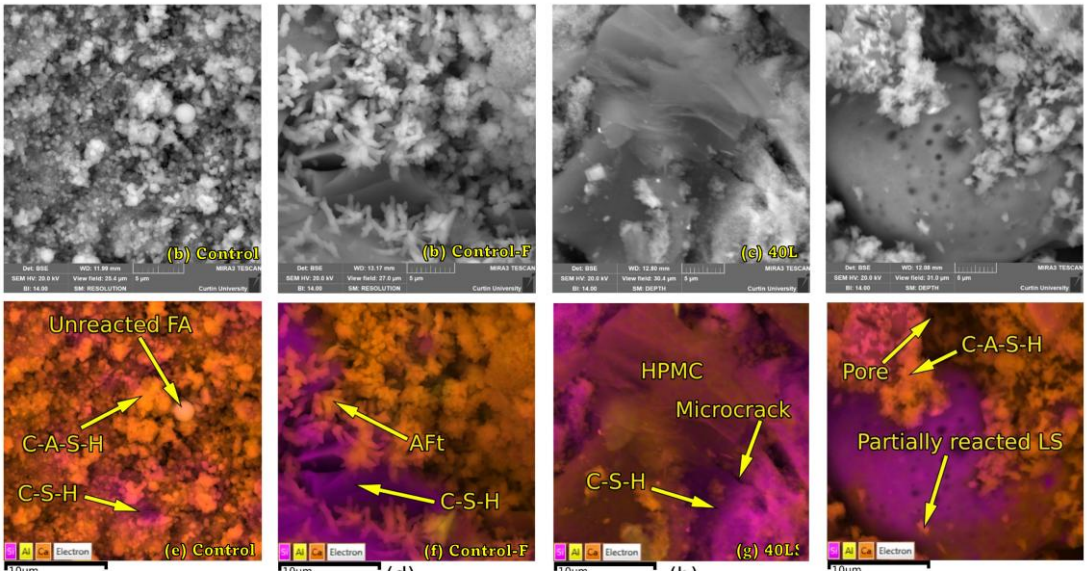

Fig. 7. BSE images (top) and EDS maps (bottom) of the printed mixes, showing C-S-H, C-A-S-H, AFt, unreacted FA, HPMC, microcracks, pores and partially reacted LS. (Adopted from [6])

3.6 Embodied Carbon and Energy

The use of LS as an SCM significantly reduced the environmental impact of the printed concrete (Table 4). The cement was the dominant contributor in all mixes, and the SP and PVA fibre added smaller amounts. The EC of the 40LS mix was 305 kg CO_2-eq/m³, 33% lower than that of the control, and its EE was 2652 MJ/m³, 20% lower. For reference, a conventional 35 MPa concrete has an EC of 375 kg CO_2-eq/m³ and an EE of 2800 MJ/m³, i.e. lower than the cement-rich control mix but higher than the 40LS mix. Besides reducing the environmental footprint, the use of LS encourages the recycling and utilisation of an industrial waste.

Table 4. Embodied carbon (EC) and embodied energy (EE) of the mixes.

Quantity	Control	Control-F	40LS	40LS-F
EC (kg CO_2-eq/m³)	456	468	305	317
Reduction in EC vs. Control	–	–	33%	31%
EE (MJ/m³)	3296	3608	2652	2966
Reduction in EE vs. Control	–	–	20%	10%

Totals of the constituent contributions; reductions relative to the Control mix. Reference 35 MPa concrete: EC = 375 kg CO_2-eq/m³, EE = 2800 MJ/m³.

Source: Data from [6]

4 Conclusions

The following conclusions can be drawn from this study:

- The 40% LS mix exhibited better buildability than the cement-based control (28 versus 21 layers), supported by its higher viscosity recovery and creep recovery and the lower specific gravity of LS. The addition of 1 vol.% PVA fibre reduced the buildability of the LS mix.
- The LS-based 3DPC showed a comparable flexural strength and a slightly lower compressive strength at 28 days, but a lower interlayer bond strength than the cement-based 3DPC.
- 1 vol.% PVA fibre significantly improved the flexural strength and slightly improved the bond strength at both ages, without improving the compressive strength; fibre alignment made the layer interface the weakest plane.
- The control and 40LS mixes released about 600 J/g and 370 J/g of cumulative heat at 72 h. The 40LS mix showed a delayed main hydration peak due to clinker dilution and the high SP content needed to maintain the design flow.
- BSE-EDS analysis of 40LS and 40LS-F showed the early-age development of C-A-S-H and amorphous intermediate hydration products.
- Replacing 40% of the cement with LS in printable mixes reduced the embodied carbon by 33% and the embodied energy by 20% compared with the control mix.

Urban Tunneling Challenges in Rapidly Developing Cities: Managing Ground Uncertainty, Risk, and Digital Transformation

Shahab Yasrebi[1]
[1] Geomaple Geotechnics Inc. (GGI), 60 Green Ln, Unit 12A, Thornhill, ON L3T 7P5, Canada,
yasrebi@geomaple.ca

Abstract. Rapid urban growth is pushing transport and utility infrastructure underground, so that tunnels are increasingly built at shallow depth in soft, variable and water-bearing ground beneath sensitive structures. This keynote paper examines how such ground uncertainty can be converted into manageable construction risk. Soft ground is treated as a behavioural category governed by stiffness, strength, drainage and disturbance, and groundwater is identified as a primary design parameter. The principles of the New Austrian Tunnelling Method (NATM) are revisited as an observational design philosophy that links behaviour-based ground classification, support classes, trigger levels and contractual flexibility. Experience from the urban tunnel programme of Tehran is then summarised through four case histories: a 31 m wide bifurcation of the Niayesh tunnel, the cross-passage intersection of the Hakim tunnel, a two-storey tunnel with 3.5 m of cover beneath the Modarres highway, and the 2016 collapse on Tehran Metro Line 6. The cases show that three-dimensional analysis, appropriate constitutive models and monitoring-based back-analysis are needed to predict ground movements reliably. In the two-storey tunnel, only the combination of fore-poling, micro-piles and nailing satisfied the 25.4 mm settlement criterion, reducing the predicted surface settlement by about 51.5%. Finally, a closed-loop digital workflow is outlined in which monitoring, numerical models and data-assisted tools shorten the time between observation and engineering decision.

Keywords: Urban tunnelling, NATM, Ground uncertainty, Observational method, Numerical back-analysis, Digital twin.

1 Introduction

Urban growth, increasing demand for mobility, limited surface space, congested utility corridors and the objectives of sustainability and resilience are moving the infrastructure of megacities underground. As a consequence, tunnelling increasingly takes place in difficult ground and beneath sensitive infrastructure: existing buildings, bridges, highways, lakes and buried services. Under these conditions the performance of a tunnel is governed by the interaction among soil, water, support, construction method and workmanship, rather than by any one of these factors in isolation.

The central question addressed in this paper is how uncertainty in the ground can be converted into manageable construction risk. The discussion follows the sequence *uncertainty* → *control* → *adaptation*. Section 2 describes the sources of ground and groundwater uncertainty in soft-ground tunnelling. Section 3 revisits the principles of the New Austrian Tunnelling Method (NATM) and their implementation through support classes. Section 4 introduces Tehran as a megacity laboratory for urban tunnelling, and Section 5 presents four case histories covering large spans, intersections, very shallow cover and a failure. Section 6 discusses monitoring, numerical back-analysis and digital transformation, and Section 7 summarises the main lessons.

2 Ground Uncertainty and Groundwater in Urban Tunnelling

2.1 Soft Ground as a Behavioural Category

"Soft ground" is a behavioural category rather than a single soil type. It includes soft clays and silts, loose saturated sands, fill and made ground, and mixed ground. Its response to excavation is governed by four behaviours: *stiffness* (low stiffness and limited stand-up time), *strength* (stress-path dependence and non-linearity), *drainage* (dewatering and consolidation effects) and *disturbance* (sensitivity, remoulding and cyclic loading). Urban fill may contain voids, debris and undocumented utilities, and mixed ground can create uneven and locally unstable zones at the face. Design must therefore address a credible range of conditions, not a single deterministic profile.

2.2 Uncertainty in the Ground Model

Ground uncertainty is the first source of tunnel risk. Stratigraphy varies between investigation points; urban ground contains abandoned foundations, wells, voids and services; and groundwater regimes change seasonally and during construction. A useful discipline is to separate explicitly what the site investigation tells us, what must be interpolated between boreholes, and what can still surprise us — voids, utilities, old foundations and changes in permeability. Regional geology defines the framework, but local investigation defines the design.

The history of the city is part of the ground model. Fig. 1 shows an example from Tehran: a watercourse that is visible on a 1956 aerial photograph had been filled with man-made soil by 1966 and later lay across a tunnel alignment. Old waterways, *qanats* (traditional underground water channels) and man-made fill of this kind constitute hidden tunnelling risk unless historical records are systematically included in the investigation.

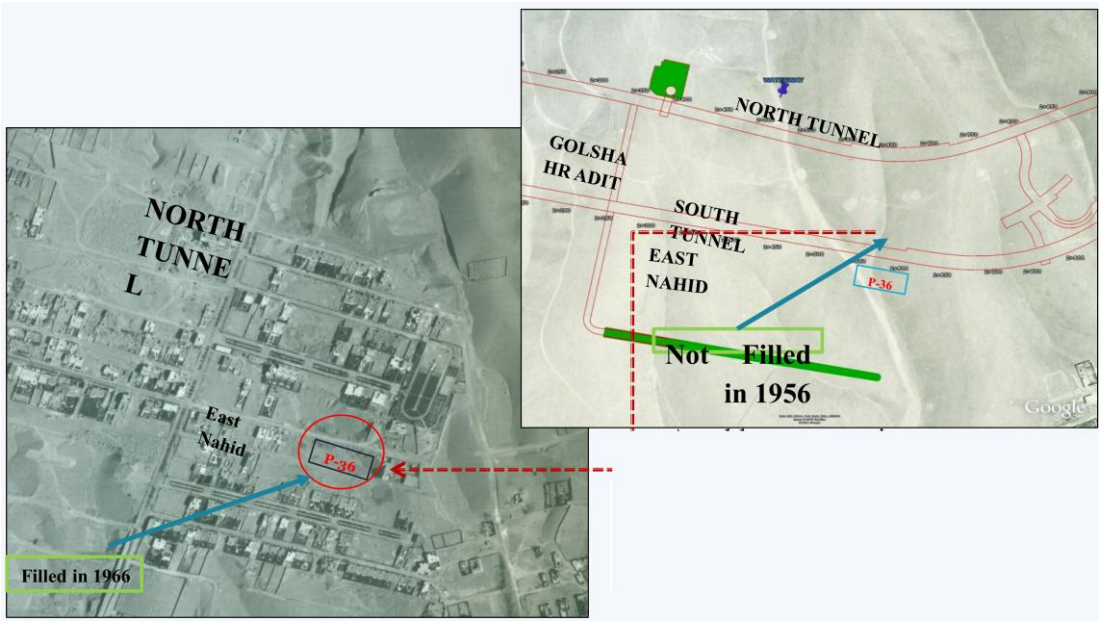

Fig. 1. Urban history as part of the ground model: an old waterway that was open in 1956 and filled with man-made soil by 1966 (aerial photographs) crossing a tunnel alignment in Tehran.

2.3 Groundwater as a Governing Hazard

Groundwater controls four mechanisms of instability in urban tunnels: face instability, piping and internal erosion, drawdown settlement, and blowout or hydraulic fracture. Drawdown increases the effective stress in the surrounding ground and therefore the settlement risk for adjacent structures, even where the tunnel itself remains stable [1, 2]. Groundwater should

therefore be treated as a primary design parameter that is investigated, modelled, controlled and monitored throughout construction.

2.4 The Geotechnical Baseline Report

The Geotechnical Baseline Report (GBR) is one of the most important contractual documents in modern tunnelling because it turns uncertainty into contractual clarity [3]. Its purpose is to define the expected ground conditions, allocate contractual risk, reduce claims, improve communication between the parties and support construction planning. A GBR typically describes the ground and groundwater, states the baseline assumptions, identifies risk zones and sets out the construction expectations. Engineering geology, groundwater, stress redistribution, settlement and site investigation collectively govern tunnel performance and should guide both design and construction decisions.

3 NATM as an Observational Design Philosophy

The New Austrian Tunnelling Method was developed in Austria between 1957 and 1965 by Ladislaus von Rabcewicz, Leopold Müller and Franz Pacher [4]. NATM is a design and construction philosophy, not a fixed excavation sequence or a specific set of excavation and support techniques. The term NATM refers to this philosophy; the sequential excavation method (SEM) describes the sequential excavation approach; sprayed-concrete-lined (SCL) tunnelling is a terminology for the lining technology; and the centre diaphragm method (CDM), side-drift and top heading–bench excavations are excavation sequences. The underlying cycle is: excavate → ground responds → install support → measure → compare with prediction → adjust. Seven principles can be distinguished:

- **Preserve and mobilise ground strength.** Excavation removes confinement; a stress arch forms around the opening when the ground can mobilise its shear resistance, whereas excessive relaxation causes yielding, loosening and a larger support demand. Face effects are three-dimensional and cannot be fully represented by a plane-strain model.
- **Control, not eliminate, deformation.** Too little deformation leads to high support loads; too much leads to deterioration of the ground and surface settlement.
- **Early support and rapid ring closure.** Support is installed close to the face, unsupported time is minimised and the invert is closed early; in shallow soft ground, support timing can be as important as support capacity.
- **Minimise unsupported length and closure time.**
- **Observational method: prediction to action** [5]: predict → monitor → compare → trigger → modify → verify.
- **The contract must permit adaptation**, by defining support classes and decision authority, triggers for changes and commercial mechanisms for approved changes.
- **Behaviour-based ground classification**, in which ground, water, overburden, face stability, deformation potential and nearby assets together determine the support class.

On site, these principles are implemented through a zoning plan of excavation and support classes: investigation → geotechnical zones → expected behaviour → support class → field verification. Table 1 summarises the classes used for the Niayesh tunnel in Tehran, which has a total main-tunnel length of 8100 m, an overburden of 4.7–40 m (18 m on average) and a maximum longitudinal slope of 4.5%. The tunnels were excavated by mechanical excavator following NATM; fan-shaped forepoling (length 6 m, diameter 76 mm) was arranged in the roof in loose ground, and the face was sealed with 3 cm of shotcrete only in poor ground. A modified horseshoe shape was used for the 1.5- and 2.5-lane sections and a mouth-shaped section for the 3.5- and 4-lane sections.

Table 1. Excavation and support classes of the Niayesh tunnel (shotcrete C25/30).

Excavation class	1.5 lanes	2.5 lanes	3.5 lanes	Bifurcation[a]
Area (m²)	87	136	186	470
Width (m)	10.80	14.40	18.00	30.60
Height (m)	9.80	11.90	12.60	19.60
Traffic lanes[b]	1	2	3	4
Shotcrete, main wall (cm)	25	30	35	45–55
Shotcrete, temporary wall (cm)	–	20	25	25
Shotcrete, temporary invert (cm)	25	20	–	20
Shotcrete, main invert (cm)	25	30	35	45–55
Round length, top heading (m)	1–1.5	1–1.5	1–1.5	1
Round length, bench (m)	3–4.5	3–4.5	3–4.5	2

[a] Maximum width and height in the bifurcation area. [b] Main tunnels have one additional 2.5 m wide emergency lane.

4 Tehran: A Megacity Laboratory for Urban Tunnelling

Tehran has an urban area of about 686 km² (approximately 30 km × 25 km), some 10 million residents and about 3 million daytime commuters. The city generates around 15 million trips per day, of which 2.5 million are made on highways, with about 3.5 million cars. The metro network currently spans 310 km with 7 lines and 160 active stations and has carried a total of 820 million trips; the long-term plan aims to extend it to 430 km with eleven lines by 2040. The urban highway tunnels summarised in Table 2 illustrate the range of constraints encountered.

Table 2. Urban highway tunnels in Tehran discussed in this paper.

Tunnel	Total length (m)	Governing constraints
Niayesh	8100	Large spans and bifurcations; bridges, a lake, a highway and high-rise buildings above
Amir Kabir	4060	Shallow cover (4.5–8.5 m) beneath the historic bazaar district
Hakim	1012	Intersections; low cover beneath a sensitive urban park
Arash–Esfandiar	1532	Highway under-passing; commercial buildings, qanats, old waterways and voids

Even small structures can be demanding. The Valiasr underpass, 160 m long with eleven inlets and outlets, was built with only about 3 m of cover beneath one of the busiest intersections of the city. Carefully staged excavation, rapid support installation, protection of adjacent infrastructure and real-time monitoring were essential to maintain both stability and surface serviceability.

5 Case Histories

5.1 Large-Span Bifurcation of the Niayesh Tunnel

The bifurcation chambers of the Niayesh tunnel are about 31 m wide and 19 m high, with an overburden of only 11–14 m. Because of the large span and excavation volume, controlling ground deformation and structural stability was the main challenge. The combination of large span, low cover and non-prismatic geometry produces genuinely three-dimensional behaviour. The chambers were therefore excavated in a multi-stage sequence (Fig. 2), with the excavation and support class selected according to the risk and monitoring plan and verified by back-analysis with PLAXIS models and monitoring data.

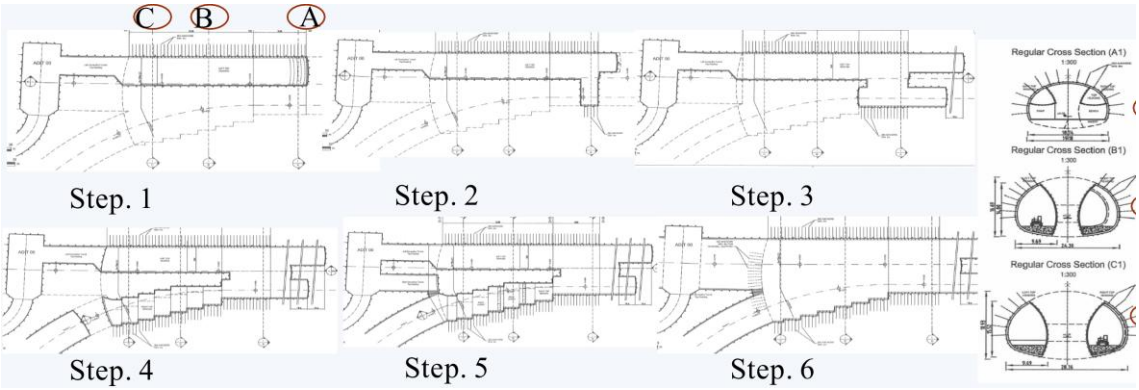

Fig. 2. Six-step excavation sequence for the 31 m bifurcation of the Niayesh tunnel and the regular cross-sections A, B and C.

The study focused on the influence and effectiveness of rib elements during the NATM construction of the bifurcation, built in three phases: pile excavation, rib excavation, and enlargement with final-lining construction. Both 2D and 3D numerical analyses were carried out, and the surface settlements recorded by monitoring were used to assess and validate the 3D predictions (Fig. 3). 3D analysis was necessary because of the non-prismatic geometry, the staged excavation with ribs and the longitudinal load transfer; it showed that the ribs reduced settlement and redistributed the initial-lining forces. Numerical models are predictions; monitoring provides the validation.

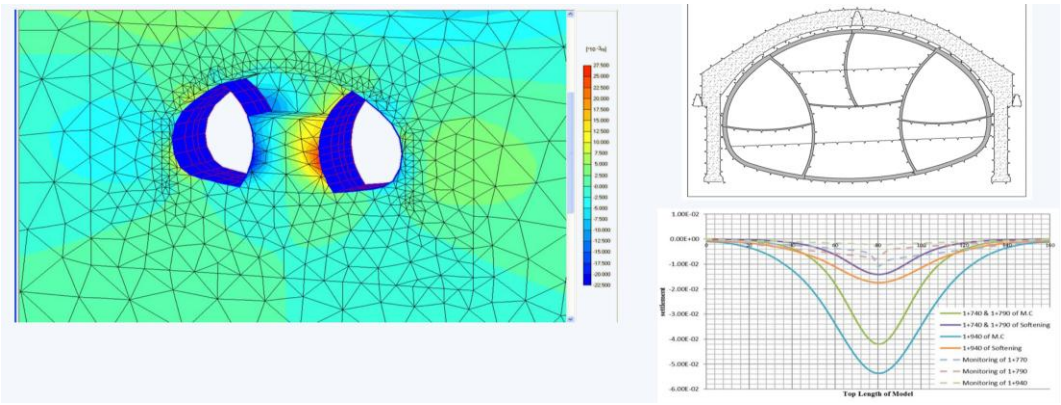

Fig. 3. Numerical modelling of the Niayesh bifurcation (left: 3D model; right: 2D section and comparison of predicted and monitored surface settlement profiles).

Along the alignment, critical positions included the under-passing of the Kurdistan bridge, passages beneath the lake of Mellat Park and beneath the Modarres highway, a cinema and residential high-rise buildings. Beneath the Modarres highway (span of about 18 m and cover of about 5 m), risk was controlled by five integrated measures: a rigid frame, fore-poling, consolidation grouting, short excavation rounds and portal stabilisation with a soil-nailing system.

5.2 Selection of the Constitutive Model

The choice of constitutive model is a crucial and debated aspect of numerical simulation, because it can control the prediction. Tunnelling in cemented soils with strain-softening behaviour is particularly demanding: such materials have distinct peak and residual strength parameters, strength reduces with increasing strain, and the high stiffness of unloading paths around the tunnel combined with the low strain of cemented soils further affects the results [6].

Three questions should be asked of any candidate model: Can it reproduce unloading stiffness? Can it reproduce strain softening? Can its parameters be obtained reliably?

Fig. 4 compares surface settlements recorded at three monitoring sections with predictions from a softening model and from an elastic–perfectly plastic Mohr–Coulomb (MC) model, taking the monitoring records as the reference. The MC model predicted final settlements of roughly 42–54 mm, whereas the softening model predicted about 14–18 mm, much closer to the monitored values. A single elastic modulus or a basic MC parameter set may be adequate for screening, but inadequate for the prediction of movements.

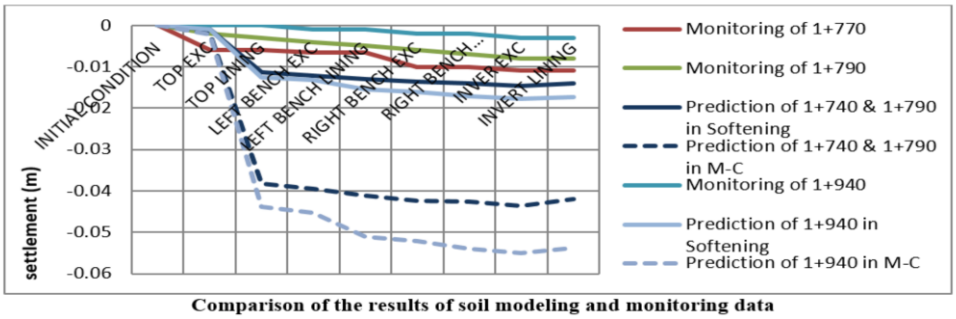

Fig. 4. Surface settlement during the construction stages: monitoring records at chainages 1+770, 1+790 and 1+940 compared with predictions of the softening and Mohr–Coulomb (M-C) models.

5.3 Cross-Passage Intersection of the Hakim Tunnel

The intersection between a cross passage and the main tunnel of the Hakim tunnel (main tunnel about 17.6 m wide and 12.6 m high) has a complex geometry that requires staged 3D analysis, and construction tolerance and sequencing are critical. The analysis also showed that the interaction between the initial and final linings changes the load path. For an 18 m wide, 10.9 m high section (186 m²) with a 35 cm initial lining and a 50 cm final lining, the construction-stage analysis gave a maximum axial force of about 140 t in the initial lining, while the final lining carried a maximum axial force of about 90 t after the assumed degradation of the initial lining. Interface conditions and installation timing strongly influence the final-lining forces and should be modelled explicitly to avoid unrealistic load distributions. The 3D predictions were compared with monitoring data, and the portal was analysed as a three-dimensional boundary problem, since reduced confinement, changing geometry and staged excavation make portals inherently three-dimensional.

5.4 Two-Storey Tunnel beneath the Modarres Highway

The two-storey tunnel of the Arash–Esfandiar project, 13 m high and 12.2 m wide, passes beneath the Modarres highway with only 3.5 m of overburden in fill. The very low cover, large section, relatively straight floor and walls, high walls and the highway above made this the most demanding of the cases. The construction strategy was to reinforce before excavating: fore-poling, micro-piles and nails were installed, followed by staged excavation, structural works and waterproofing (Fig. 5).

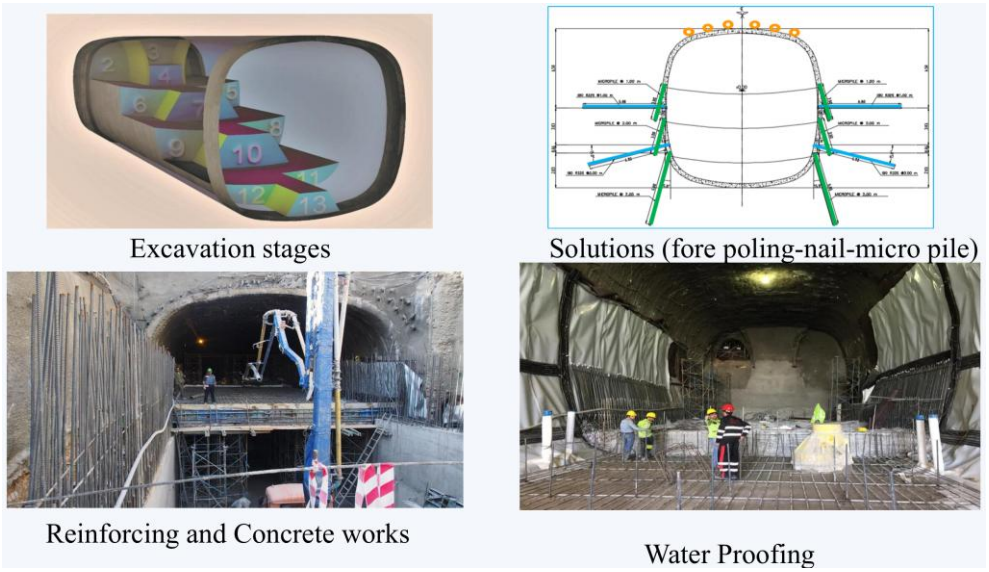

Fig. 5. Construction strategy for the two-storey tunnel: excavation stages, pre-support and reinforcement (fore-poling, nails and micro-piles), reinforcing and concrete works, and waterproofing.

Five numerical cases were evaluated against a maximum surface settlement of 25.4 mm: a baseline without additional support, fore-poles only (60 fore-poles in two rows, 6.0 m long), micro-piles only, nails only, and the combination of all three. The results are listed in Table 3. Only the combined system satisfied the settlement criterion, with a predicted surface settlement of 24.9 mm, a reduction of about 51.5% compared with the baseline. The individual measures reduced settlement by only 10.8–24%.

Table 3. Settlement and initial-lining forces for the five numerical cases of the two-storey tunnel (allowable surface settlement 25.4 mm).

Case	Fore-pole	Micro-pile	Nail	Surface settl. (mm)	Ratio to allow.	Settl. reduct.	Axial force (kN/m)	Bending moment (kN·m/m)	Moment reduct.
1	–	–	–	51.35	2.02	–	603.25	165.39	–
2	✓	–	–	39.03	1.54	24%	651.44	116.25	29.7%
3	–	✓	–	40.41	1.59	21%	712.33	158.34	4.3%
4	–	–	✓	45.79	1.80	10.8%	607.41	148.56	10.2%
5	✓	✓	✓	24.93	0.98	51.5%	714.51	89.95	45.6%

Settlements and axial forces are given as magnitudes. The maximum shear force was practically unchanged (161–164 kN/m) in all cases.

The internal forces show that support does not simply reduce forces but redistributes them: the combined system reduced the maximum bending moment of the initial lining by 45.6%, while the maximum axial force increased from 603 to 715 kN/m and the shear force remained almost constant. During construction, the measured settlements were compared with the predictions of the combined model; the differences between prediction and measurement reveal the remaining uncertainty in the ground model and are used to update it.

5.5 When Control Is Lost: The 2016 Failure on Tehran Metro Line 6

On 17 June 2016, a failure of the tunnel face and lining on Tehran Metro Line 6 produced a sinkhole about 26 m by 17 m in plan, which ruptured a gas pipeline and caused an explosion

(Fig. 6). Three people were killed and the project was delayed by six months. Monitoring records before the failure showed a progressive increase in settlement.

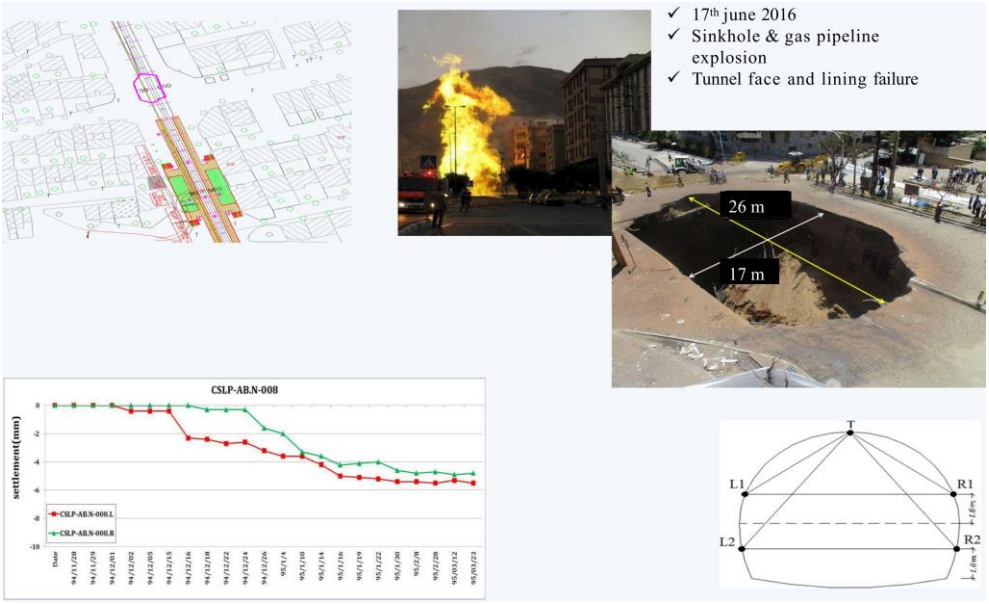

Fig. 6. Failure on Tehran Metro Line 6 (17 June 2016): location plan, gas pipeline explosion, sinkhole of about 26 m × 17 m, and settlement monitoring records before the failure.

After the failure, P.O.R. Consulting Engineers was commissioned to design the excavation and support for passing through the failure zone, to review the design of the rest of Line 6 and to supervise the construction of the temporary and final linings. The design changes included an excavation and support zoning plan based on risk assessment and monitoring results; extensometer and inclinometer monitoring; pre-support by forepoling, micro-piles and face grouting through the failure zone; an increase in face subdivision from two to six drifts; shorter advance lengths; and back-analysis by 3D finite element analysis (FEA) in FLAC under a strict monitoring regime. With a strictly applied risk and monitoring plan, the tunnel was successfully driven through the failure zone. The main lesson for contractor and client was the need for a rigorous monitoring plan and for attention to the risk notes of the consultant.

6 Monitoring, Back-Analysis and Digital Transformation

Monitoring must trigger action and not simply record movement. Trigger levels organised as alert → alarm → action connect monitoring trends, such as crack development on building façades, to predefined engineering responses, which is the practical core of the observational method [5]. After the Line 6 failure, this principle was extended into a closed-loop workflow: physical tunnel → digital model → live data → decision and action. The *physical tunnel* comprises the excavation, support, ground, groundwater and nearby assets; the *digital representation* combines BIM geometry with the geotechnical and numerical models; the *live data* include instrumentation, face mapping, construction progress and support installation; and the *decision layer* contains thresholds, forecasts, scenario testing and corrective actions.

In practice, the workflow is ground model → prediction → monitoring → back-analysis → decision. Near-real-time comparison of predicted and measured deformation, trigger levels linked to engineering actions, and continuous improvement of model parameters by back-analysis increase confidence in the prediction as excavation advances. Data-assisted tools, including artificial intelligence (AI), can add value in three areas: pattern recognition for early warning by identifying abnormal trends and correlations; updating of settlement and risk forecasts as excavation progresses; and comparison of construction alternatives and support

scenarios. AI assists engineering judgement but does not replace it. Digitalisation adds value when it shortens the time between observation and engineering decision.

7 Conclusions

The experience summarised in this paper leads to five conclusions for tunnelling in rapidly developing cities:

- Ground and groundwater govern behaviour; design must address a credible range of conditions, including those inherited from the urban history of the site.
- Deformation must be controlled, not only stability; in shallow soft ground, support timing is as important as support capacity.
- The construction sequence is part of the design, and large spans, intersections and portals require three-dimensional analysis.
- Numerical models predict and monitoring verifies; the constitutive model and its parameters can control the predicted settlement.
- Risk management requires decisions and action, supported by contracts that permit adaptation and by trigger levels linked to predefined responses.

Urban tunnelling therefore requires active control of ground behaviour rather than the execution of a fixed design, following the cycle predict → monitor → compare → update → decide → verify.

Snow Damage Patterns at Solar Power Plants

Ahmet Turer[1]
[1] 0000-0002-2214-1387, Middle East Technical University, Department of Civil Engineering, Ankara, Türkiye, aturer@metu.edu.tr

Abstract. Türkiye's solar capacity reached 25.8 GW in January 2026, representing 20.9% of national installed capacity and supporting its 2053 net-zero strategy. At high-altitude ground-mounted photovoltaic plants (Güneş Enerji Santralleri GES), however, snow may govern structural design. Designers and consultants commonly apply TS498 directly, although it is a "building-based" provision and do not represent the aerodynamic snow behavior of open-frame solar arrays. This study examines root cause of a large number of damage cases and recurring failures documented through field investigations and insurance claims. Wind generally removes snow from exposed roofs, except for local accumulation in roof valleys. On the contrary, wind transports snow from the surrounding ground over the panels at ground mounted GES sites. Once the snow thickness reaches the 0.7-0.8m ground clearance under panels, successive long GES rows act as snow fences, accumulating extra snow on and between arrays. The resulting accumulated and nonuniform snow load can greatly exceed capacity, unlike the TS498 building roof-based loads. Modelling cold-formed C-sections with one-dimensional frame elements cannot capture local plate buckling, torsional instability, eccentricity or connection-region stresses, requiring shell-based representations. Under-torqued bolts in slotted holes, inappropriate self-tapping screws, inadequate detailing, and representing discrete panel reactions as uniformly distributed loads further increase vulnerability. These assumptions and deficiencies cause local and global buckling, connection yielding, and panel bending-punching failure. Assessment of wind-driven snow accumulation, consideration of torsional instability, better connection detailing, and adoption of contemporary provisions such as ASCE 7-22, EN 1991-1-3:2025 for reliable GES in snow-prone regions are underlined.

Keywords: GES; Snow Drifting; Collapse; Buckling, TS498.

1 Introduction

The rapid growth of solar power generation in Türkiye has resulted in the construction of numerous ground-mounted photovoltaic (GMPV) power plants, commonly referred to as Güneş Enerji Santralleri (GES), in regions having widely different climatic, topographic, and geotechnical conditions. Many of these systems consist of lightweight and highly repetitive structural tables assembled from photovoltaic modules, cold-formed steel C-shaped purlins, similar sectioned beams, columns, braces, slotted bolted connections, and driven steel posts. Although their structural layout may appear simple, their response can become considerably more complex when they are installed close to the ground in high-altitude regions exposed to severe snow and wind.

The field evidence examined in this study is based on seven insurance-commissioned forensic investigations conducted by the author between 2017 and 2026, including cases in Kahramanmaraş, Adıyaman, Ağrı, Van, and Bitlis, together with the METU M.S. thesis by Temel [1] concerning the Turkish ground snow-load map and snow-damage prevention for

solar power plants. The most recent investigations were performed at an Ağrı GES in 2025 and at GES facilities in Van and Bitlis in 2026. The investigated portfolio included a plant located above an elevation of 3,100 m and another located adjacent to a ski resort where seasonal snow depths exceeding one meter are common.

Despite differences in structural configuration, elevation, terrain, row spacing, and damage intensity, the investigated facilities exhibited a recurring common feature. Wind-snow interaction caused successive PV rows to behave as snow-retaining obstructions. Snow transported from the surrounding ground and redistributed from the panel surfaces accumulated between the rows and around their lower edges. Sliding snow aggravated the loading condition by faster closing the gap between the ground and lowest panel edge. The resulting snow depths and load distributions could not be represented adequately by applying only a conventional uniformly distributed roof snow load obtained from TS498. In some occasions, designers further reduced the load by factors like C_e (TS EN 1991-1-3 [2]) completely making the structures vulnerable to accumulated snow.

The field observations also showed that 'underestimated' excessive snow accumulation was seldom the sole deficiency but accompanied by other mistakes. Snow demand interacted with thin-walled open C-sections, shear-center eccentricities, concentrated clamp reactions, insufficiently restrained purlins and beams, single-bolt 'slotted connections', construction irregularities, beams connected only by a web plate, and driven posts installed without concrete footings. These interactions produced recurring damage patterns ranging from local member deformation to global buckling modes, PV fracture, and progressive collapse.

The present paper therefore has three principal objectives: (i) to inform designers - engineers regarding the wind induced accumulation of ground mounted GES, evaluate the applicability and limitations of the available Turkish and international design provisions; (ii) to classify the principal structural damage patterns observed during the forensic investigations; and (iii) to identify the physical and structural mechanisms responsible for these failures and propose practical preventive measures. The paper treats the regional ground snow load as an essential climatic input, but not necessarily as the final load magnitude or distribution acting on a low-clearance, multi-row GMPV structure. Wind induced snow accumulation, statistical analysis of 20-50 years satellite based snow data, and General Directorate of Meteorology closest station records must be considered for the GES design.

2 Available National and International Design Provisions

2.1 Turkish Codes

TS498:2021 constitutes the principal starting point for determining snow actions in Türkiye [3]. It provides the regional and elevation-dependent basis for snow loading and refers to TS EN 1991-1-3 for the treatment of roof geometry, balanced and unbalanced loading, and wind-induced snow accumulation [2]. However, its snow-load formulation is primarily framed around roofs of building-type structures. It does not define a dedicated load model for low-clearance, open-frame, multi-row GMPV arrays exposed to snow transported at ground level.

Consequently, TS498 remains necessary for establishing the regional snow hazard, but it should not be regarded as a sufficient stand-alone procedure for determining the final load on a ground-mounted PV array. In particular, the direct application of the commonly used 0.8 roof shape coefficient becomes questionable once the lower edge of the array is obstructed by accumulated snow. The validity of this reduction and the transition from a snow-shedding surface to a snow-retaining obstruction are examined in Section 4.

TS EN 1991-1-3 provides load arrangements for snow drifting at roof steps, parapets, obstructions, valleys, and multi-span roofs [2]. Its provisions for accumulation between successive roof ridges are physically relevant to rows of inclined PV panels because both

configurations contain repeated high points and sheltered zones. Nevertheless, these provisions were developed for building roofs and cannot be transferred directly to GMPV arrays without considering ground proximity, permeability, row spacing, upwind fetch, and the volume of snow that may be transported from the surrounding terrain.

The structural members and connections are generally assessed under the Turkish Regulation on the Design, Calculation and Construction Principles of Steel Structures [4]. Cold-formed members also require the application of TS EN 1993-1-3 [5] or an equivalent thin-walled steel design specification. These provisions are particularly important for the open C-sections widely used as purlins, beams, and columns in GES structures.

The Turkish Regulation on the Design, Calculation and Construction Principles of Light-Gauge Steel Buildings, published in 2026, applies to cold-formed steel sheets having net thicknesses between 0.45 and 4.00 mm [6]. The regulation addresses local, distortional, torsional, flexural-torsional, and lateral-torsional buckling, as well as the separation between the centroid and shear center. Its stated scope is limited to light-gauge steel buildings, and it enters into force on 1 January 2027. It is therefore not a directly governing GES design code for the investigated cases. Nevertheless, the mechanical principles it contains are directly relevant to the cold-formed C-sections used in these systems.

2.2 International Codes

The second-generation EN 1991-1-3:2025 represents an important development because it explicitly considers snow accumulation around rows of tilted PV panels installed on flat roofs [7]. It also relates drift geometry to obstruction height and wind exposure and requires special consideration for low structures to which snow may be transported from the ground. However, its PV provisions are intended primarily for roof-mounted systems. A ground-mounted solar farm may receive snow transported over a much larger terrain than the roof catchment area assumed in such models. The 2025 document is therefore a valuable physical reference but not a complete prescriptive solution for extensive GMPV arrays.

Other international standards and guidelines address individual parts of the problem, as summarized in Table 1.

Table 1. Applicability of principal design documents to ground-mounted PV structures.

Code	Description	Limitation
TS 498:2021 [3]	Regional and elevation-dependent snow action; conventional roof loading	No specific multi-row, ground-level snow-transport model
TS EN 1991-1-3 [2]	Balanced, unbalanced, obstruction and multi-span roof drift loads	Developed principally for building roofs
EN 1991-1-3:2025 [7]	Tilted PV rows on flat roofs; drift related to panel height and exposure	Roof-mounted PV model; not a complete ground-mounted array procedure
ASCE/SEI 7-22 [8]	Risk-targeted ground snow loads and general roof-drift procedures	No dedicated row-to-row drift model for GMPV plants
O'Rourke (2025) [9]	Ground-mounted panels; obstructed and unobstructed lower edges; snow-shedding clearance	Excludes ground snow travelling up a drift and over the module surface
IEC TS 62738 [10]	General design guidance for utility-scale ground-mounted PV plants	Snow recommendations are mainly qualitative
IEC 62938 [11]	Non-uniform module testing with additional loading near the lower edge	Module test only; excludes supporting steel, connections, foundations and row drift
JIS C 8955/NEDO guidance [12, 13]	PV-specific structural and ground-mounted array guidance	Not directly binding in Türkiye but useful for comparison

ASCE/SEI 7-22 provides general snow-load and roof-drift procedures [8]. The more recent ASCE publication Design Snow Loads for Ground Mounted Solar Panels provides a more directly applicable framework by distinguishing unobstructed, partially obstructed, and fully obstructed leading edges [9]. It also relates the required ground clearance to the volume needed to store snow shed from the panels. However, the publication explicitly excludes the mechanism in which ground snow moves up an existing drift and onto the module surface, which is consistent with the mechanism suggested by several of the Turkish field observations.

IEC TS 62738 provides general recommendations for utility-scale ground-mounted PV plants and draws attention to snow accumulation, sliding snow, site conditions, and protection of electrical equipment [10]. It does not prescribe the magnitude or distribution of wind-driven row-to-row drift loads. IEC 62938, in contrast, defines a non-uniform laboratory snow-load test for framed PV modules, including additional loading toward the lower module edge [11]. This test is valuable for module qualification but cannot verify the complete module-clamp-purlin-beam-column-foundation system under site-specific accumulation.

The available documents therefore provide important but separate components of the design problem. None provides a complete procedure integrating regional snow hazard, ground-level snow transport, progressive obstruction of the lower panel edge, row-to-row accumulation, concentrated module reactions, thin-walled member stability, connection slip, and soil-foundation response. A simple approach for considering snow load on GMPV arrays is suggested in the conclusions section.

3 Major Damage Patterns Observed in Ground-Mounted PV Plants

This section classifies the principal physical damage patterns recorded during the forensic investigations. The classification is intentionally based on observable deformation and failure modes. The snow-transport mechanisms, analytical simplifications, and detailing deficiencies that produced or amplified these patterns are discussed separately in Section 4.

Purlin bending and lateral-torsional deformation is the most commonly observed structural damage. The purlins used in GES are commonly made by ‘inclined’, thin-walled open C-sections. Field observations included violently buckled sections (lateral torsional buckling LTB), torsional buckling of the cantilever portion, large vertical and lateral displacement, almost always twisting of the cross-section, rolling deformation towards the slope as the web rotates, and local damage caused at connections such as near module clamps and primary transition between beams. Although snow pressure acts over the module surface, the module transfers this action to the purlins through discrete clamps. The actual purlin loading therefore consists of concentrated or short patch reactions rather than a ‘continuously’ distributed line load as assumed in the FEM. When these reactions act eccentrically relative to the shear center of an inclined C-section, combined bending and torsion will develop. C-sections are usually weak against torsion stresses as they are open channels. The poor connection between purlins add to the poor structural response. Several systems contained purlin splices in which only the thin web of the C-section was connected (Fig. 1). Such details do not provide continuity for the flange forces and very limited resistance to cross-sectional rotation and torsion; they act like moment releases changing the bending moment distribution. Large and multiple slotted holes with lengths in the order of 5*d on the C channel flanges reduced bending capacity and stability of the purlins. Inclined or poorly aligned purlins further increased secondary bending and local force concentrations at these connections.

The primary beams usually support purlins and have suffered similar damage. The beams are connected to the columns in an eccentric manner and some cases used only one bolt. The eccentricity between the beam and column caused rotation, the weakened bema cross section

by slotted hole rotated and torn away from the column. The beam especially suffered more towards the shorter column, since the snow load on that region was higher. Unlike TS498 prediction of even snow load on building-like roofs, the GMPV plants are closer to the ground and snow accumulation is high at the shorter column side. The torn away and buckled beams caused PV to get closer to the columns which are often times contacted, punched through PV, and caused short-circuit and local burning of the panels (Fig. 2 and Fig. 3). The main beams had highest load on the bottom cantilever part as the snow accumulated deeper on that side. Lateral torsional buckling of the cantilever part was dominant in all cases since the analysis did not consider (a) snow accumulation caused by wind on GMPV plants, (b) 1D frame element did not model the shear center being outside the C-channels. Concentrated load applied by the purlins had damaging effects on the beams and purlins. Local buckling was mainly at the short column to beam connection as the shear and bending moment were highest at that connection. The discrete and eccentric purlin reactions, together with insufficient lateral restraint, caused the beams to respond in combined bending and torsion. Concentric beam models may estimate global bending moments but cannot reliably represent torsion and LTB unless the actual load offsets, restraint conditions, connection flexibility, warping, and geometric imperfections are included.

The lower-edge cantilever region of the PV tables was one of the most frequently damaged zones. PV usually connected using 4 pin supports. The bottom row of PV is closest to the ground and wind accumulated snow thickness is highest at this region. The PV panels at the very top are usually exposed because the wind carries snow (unlike even snow assumption by TS498 or designers) and just the opposite side has a lot of snow depth and load acting on it as the snow fills the gap between the ground and lowest row of PVs, then keep on piling meters deep. Most of the GMPV plants had about 25-degree inclination and about 2m vertical height difference between the bottom and top edges. The snow accumulated by wind is compacted denser at the bottom but compaction puts more load on the panels. The PV panels are rated to 5.40 kN/m² and they are mostly cracked in the bottom row, indicating the snow load exceeded this threshold. Since the top row was always exposed, it is not the snow load reached that value evenly throughout the solar field. It was mostly the rows closest to the edge of the solar field where the dominant wind was coming from. Typical evidence included downward displacement of the lower panel line, permanent deformation of the supporting members, separation between adjacent modules, and fracture of module glass or frames. Usually, a few rows work like snow fences and not all of the GMPV rows experience the same snow load. The spatial concentration of damage supports wind-driven redistribution rather than uniform regional overloading. The wind carried snow accumulation has to be considered in the design.

Column punching through PV modules were frequently observed. This was presented as how strong the columns were by the designers; however, it was the weak beam column connection torn apart by poorly evaluated snow accumulation and inadequate connection aggravated by eccentric load transfer and local buckling caused by weakened member using slotted holes causing PV panels to come down and contact with the columns. Beam-column connection slipped, rotated, or tore under load. Many of the examined connections used a single bolt passing through a slotted hole with uncertain torque level (Fig. 4). Once slip or hole elongation occurred, the frame developed a kinematic mechanism and the relative position of the column, beam, and module changed. In several cases, the upper end of a column or an adjoining structural component came into hard contact with the rear surface of a module and penetrated or fractured it. Besides the structural damage, this failure mode damages cables and conductive components and consequently cause insulation failure, short circuits, arcing, and local fire.

Fig. 1. Typical purlin damage (a) poor connection between purlins, (b) combined bending, twist, rolling of inclined cold-formed C-purlins with discrete module-clamp reactions (LTB) and downward movement of PV panels.

Fig. 2. (a) Rotational buckling of the lower-edge cantilever; (b) PV module fractured by column punching with local buckling, connection tearing, slotted single-bolt beam-column connection.

Fig. 3. (a) lateral-torsional deformation of a primary beam, purlin-beam and column-beam interaction; (b) downward penetration of lower columns in softened winter soil, punching of PV.

Fig. 4. (a) buckling of diagonal members as they slide until the end of slotted connections and (b) a long slotted hole with a big head opening on the purlins.

Downward penetration or settlement of driven columns into the soil are observed in a few occasions. GES are like any other load carrying system and the load transfer mechanism is similar to a chain: the system is as strong as the weakest link in a chain. Snow load acts on the PV panels, transferred through pins to purlins, from purlins to beams, beams to columns and to the ground. Some cases where the columns, especially the short ones with the highest axial force, were found to be driven into the ground if the foundation was on weak soil. The columns are generally driven into the ground by impact or axial force during construction. However, the ground conditions during construction are different than the above freezing conditions at the footing level during spring under snow load. As the snow still not fully melted and a lot of snow load acting on the columns, melting snow makes the soil soft and columns on the shorter side may start to penetrate into the ground under snow load. At some facilities, the steel columns or posts without footing, under wet winter/spring conditions, moved vertically by the soil softening. Some posts consequently penetrated further into the ground, settled differentially, or rotated. This movement altered the table geometry and caused all kinds of additional problems with the rest of the members.

4 Wind Induced Snow Accumulation and Conclusions

The damage mechanisms described in Section 3 were amplified by recurring errors in load assessment, structural modelling and connection detailing. Designers frequently applied TS498 roof loads without evaluating ground-level wind-snow redistribution, although wind may remove snow from exposed roofs while successive PV rows trap snow transported across the ground. Structural demand was further underestimated when simplified concentric one-dimensional frame models were used for cold-formed C-sections without adequately representing shear-center eccentricity, torsion, local-global buckling, and concentrated module-clamp reactions. Slotted holes, inadequate washers and complications with bolt torque levels additionally permitted connection slip and rotation. These deficiencies produced recurring rather than genuinely unforeseen damage. As an example, the proportion of damaged PV modules increased from approximately 20% in 2025 to 70% in 2026 at Ağrı GES, because the repairs did not address the governing loading and structural mechanisms. This recurrence demonstrates the need for root-cause design correction rather than repeated component replacement or reliance on insurance recovery.

Site-specific statistical assessment is essential for high-altitude GMPV plants because TS 498 was developed primarily for building roofs and does not represent ground-level snow transport and row-to-row accumulation. On exposed roofs, wind may reduce snow loading; at GMPV sites, however, it redistributes snow across the ground while successive rows act as obstructions that trap the transported mass. Consequently, characteristic ground snow action should be determined from long-term gridded reanalysis SWE and nearby station records, without unjustified exposure reductions, and combined with a separate accumulation model for the obstructed-array condition.

Statistical analysis of satellite-based snow depth at 0.1 degree closest to the GES site indicates that water equivalent snow load on the ground almost every year surpasses the design values provided by TS498 and used in PV load calculations. Some of the designers used factor like exposure coefficient C_e=0.8 to further reduce the snow load and make a more 'economical' design. The ERA5-Land gridded reanalysis estimates of snow water equivalent (SWE) since 1950 is consistently higher than the S_k value used for design during the pre-event period of 1950 – 2024 [14]. The reported characteristic ground snow load in one of the recent studies, S_k = 1.725 kN/m², corresponds to 175.9 mm of snow water equivalent (SWE). This threshold was exceeded in 69 of the 75 years giving an empirical mean recurrence interval of 1.09 years; therefore, it is not an unexpected snow load S_k value, which is expected to be exceed almost every year. The return period of 1.725 kN/m² is about 1.09 years and such a loading cannot be used for design.

When the amount of load for 20 and 50 years return period for Van GES station were calculated, $S_{20,SWE} \approx 4.81\ \mathrm{kN/m^2}$ and $S_{50,SWE} \approx 5.54\ \mathrm{kN/m^2}$ were obtained. These values are 2.79 to 3.21 times larger than the values used considered in the design. Reduction coefficients of 0.8 applied twice for μ_1 and C_e caused a design deviation of about 5 times. Now, considering the snow accumulation and increased snow density adds on top of this deviation since the snow height on the panels are thicker than the snow on the ground because of wind induced accumulation effect.

The climatic record quantifies the snow mass available on the ground, whereas the structural demand on the PV system is governed by its wind-driven redistribution. Blowing snow is transported by creep, saltation and suspension, and is deposited where obstructions or separated-flow regions reduce wind velocity and transport capacity [15]. In the investigated GMPV arrays, the initial 0.70 - 0.80 m clearance allowed airflow beneath the modules and storage of shed snow; however, snowfall, sliding snow and wind-transported deposits progressively closed this gap. Once the lower edge became buried, the snow surface and inclined modules formed a nearly continuous obstruction, causing the rows to behave as

inclined snow fences and promoting further deposition, compaction and filling between successive rows, potentially up to the approximately 2.5 m upper-module elevation (Fig. 5). Perimeter rows intercepted the incoming snow flux first and consequently experienced earlier burial and more severe loading than interior rows. For scale, a 2.5 m drift with an average density of 200 kg/m^3 contains approximately 500 kg/m^2, corresponding to a load of about 4.90 kN/m^2. Design must distinguish between an open-clearance snow-shedding regime and a foreseeable obstructed regime requiring consideration of row-to-row drifting, lower-edge loading and stability of the complete skeletal system.

The forensic evidence indicates that low-clearance GMPV arrays in severe snow climates must be designed for an obstructed condition whenever burial of the lower panel edge is foreseeable. Unless a validated site-specific wind-snow analysis demonstrates a lower demand, the space beneath and between successive arrays should conservatively be assumed to fill with compacted snow up to the upper panel corner, and the resulting non-uniform, lower-edge-dominant actions should be transferred through the complete skeletal load carrying system. Direct application of TS498 roof loads, coefficients, particularly exposure reductions, does not represent this mechanism adequately. Cold-formed open C-sections should be avoided for primary purlins and beams unless their connections, restraints and member stability are explicitly designed for eccentric clamp reactions, combined bending and torsion, local and distortional buckling, warping, and lateral-torsional buckling. Slotted single-bolt connections and concentric frame models that suppress these governing failure modes should not be accepted. If the statistically derived characteristic ground snow depth obtained from ERA5-Land or similar database exceeds the lower panel-edge elevation but remains below the upper panel-edge elevation, loss of the lower-edge clearance should be assumed and the inter-row space should conservatively be considered filled with partially compacted snow at about the upper panel edge level (Fig. 5).

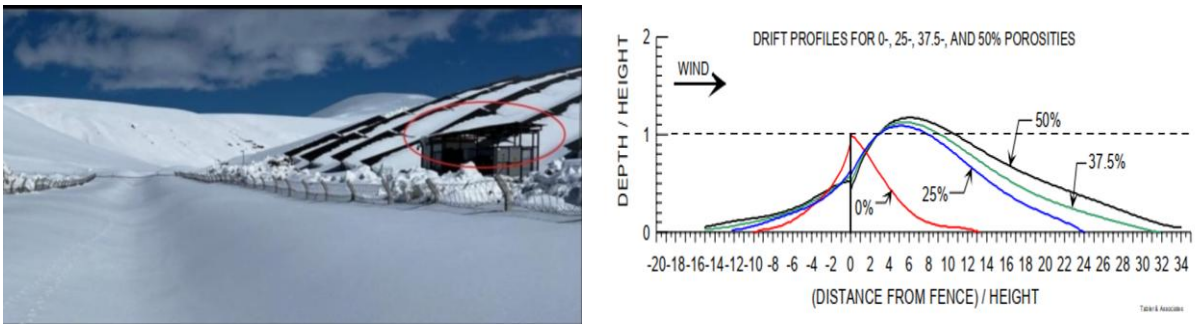

Fig. 5. (a) GMPV rows buried by non-uniform snow approaching 2.5 m, while the adjacent roof remained largely snow-free (b) effect of snow-fence drift profiles over flat terrain (reproduced from Tabler [15], Fig. 3.57).

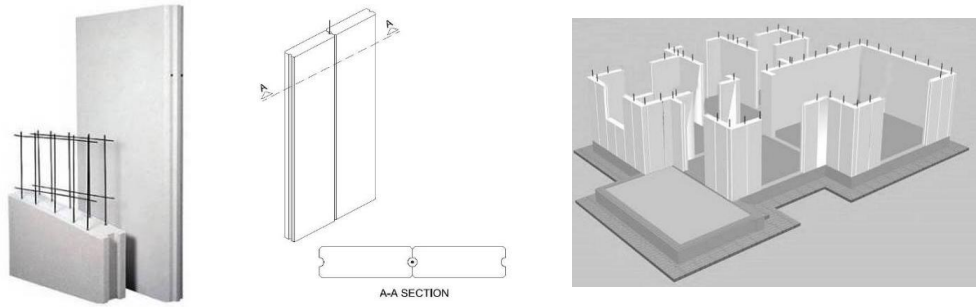
Abstract. Autoclaved Aerated Concrete (AAC) is a versatile cementitious material used to produce both masonry block units and reinforced wall panels. Due to its low self-weight, reinforced AAC load-bearing panel wall systems are particularly suitable for low-rise construction in seismically active regions. This paper presents an experimental investigation of the cyclic in-plane behavior of AAC load-bearing walls comprising two, four, and six panels. The specimens were tested under various axial stress levels and subjected to cyclic displacement reversals. The experimental results showed that the response initiated with separation of the panel bases from the leveling mortar in the form of uplift, followed by visible separation between adjacent panels at lateral drift ratios between 0.50% and 1.00%. In the six-panel specimens, several adjacent panels exhibited monolithic behavior at early drift levels, transitioning to individual panel rocking as the drift increased. The lateral load-carrying capacity of the walls was found to increase with both the applied axial stress and the number of panels. The two-panel walls exhibited a predominantly flexural response, whereas the four- and six-panel walls exhibited a combined flexural–shear response. Overall, the specimens sustained considerable drift demands while maintaining their structural integrity, displaying satisfactory deformation capacity.



Keywords: AAC panel; load-bearing wall; cyclic experiment

1 Introduction

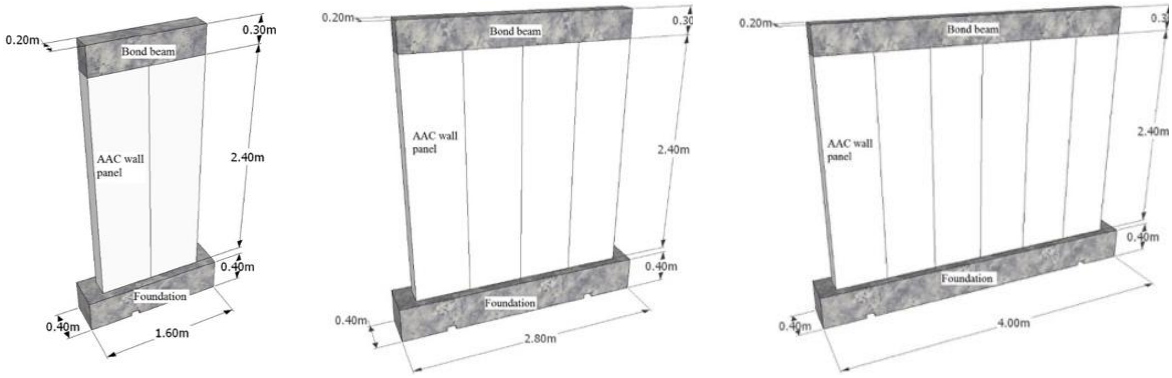
AAC is a versatile cementitious material used to produce both masonry block units and reinforced panels incorporating wire mesh reinforcement to resist out-of-plane forces (Fig. 1a). Beyond its structural applications in load bearing and infill walls, cladding, floor systems, and insulation boards, it is also distinguished by its lightweight nature, which facilitates rapid construction. Furthermore, AAC offers significant advantages in thermal performance and fire safety.

Structures of two to three stories can be constructed using load-bearing AAC panels alone. In accordance with Turkish Building Earthquake Code (TBEC) [1], the total height of buildings constructed with these panels cannot exceed 10.5 m. When two panels are erected side by side (Fig. 1b) on a foundation over a leveling mortar, the end profiles of the panels form a cylindrical gap between them. Vertical reinforcement bars extending from the foundation run through these gaps to the full height of the wall, after which the gaps are filled with grout. Once all walls are completed (Fig. 1c), a bond beam is cast on top, into which the vertical reinforcement is

embedded via lap splices. AAC floor and roof panels are then laid on these bond beams to form floors and roof.

(a) (b) (c)

Fig. 1. (a) AAC reinforced panel, (b) side by side connection of load-bearing AAC wall panels and (c) Formation of the first story walls [2]



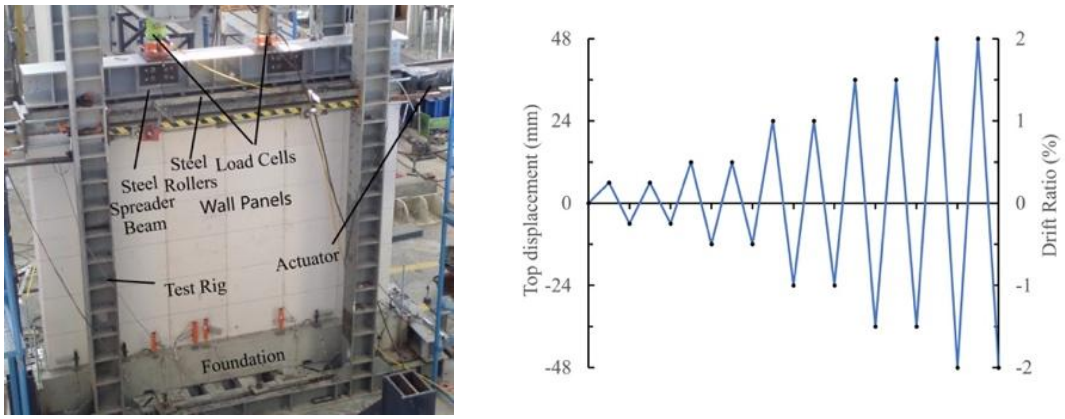
Buildings constructed with this practice in Türkiye since 1970s have exhibited satisfactory seismic performance [3, 4], which is largely attributed to their relatively low self-weight. Several studies have investigated the seismic behavior of AAC load-bearing wall panel systems. Bayulke [5] reported separation of orthogonal walls and corner crushing in a one-story building, while the structure maintained self-centering with minimal residual drift. Tanner [6, 7] and Cancino [8] conducted cyclic in-plane tests on vertically and horizontally oriented panels, recommending the design of vertical panels in interconnected groups. Varela [9, 10] proposed simplified modeling approaches and suggested seismic design factors. Numerical studies using the Concrete Damaged Plasticity model [11] showed good agreement with experiments [12]. Ugurlu et al. [2] reported a significant lateral drift ratio of 2.0%, with a strength degradation of 20% occurring at a drift ratio of 1.5%. Taghipour et al. [13] presented results from the tests conducted at Middle East Technical University (METU), observing ultimate lateral drift ratios of 1.0% and failure modes dominated by flexural and sliding behavior. Gokmen et al. [14] reported an ultimate lateral roof drift ratio of 0.35%, and determined a structural behavior factor (R) of 2.35. More recent studies [15–17] further expanded the experimental database by examining different panel configurations, openings, and boundary conditions under cyclic loading. Despite this growing body of international research, experimental investigation of the seismic behavior of AAC structures within Türkiye had remained limited; prior to 2015, only a single shaking table test [5] had been conducted domestically. To address this gap, a comprehensive research program was initiated in 2015 through a collaboration between Istanbul Technical University (ITU) and Middle East Technical University (METU), funded by Turkish AAC Association (TAACA). This paper presents a part of the results from the experiments carried out as ITU's contribution to that initiative. While a more comprehensive version of this work has been published in Ugurlu et al.[18], the present paper focuses on the experimental observations of the cyclic in-plane behavior, damage progression, and lateral load-carrying capacity of AAC load-bearing panel walls with varying panel configurations and axial stress levels.

2 Experimental Study

2.1 Specimen Geometries and Configuration

Six wall specimens were constructed in the Structural and Earthquake Engineering Laboratory of ITU. The specimens consisted of two, four, and six loadbearing AAC wall panels, each 600 mm in width, designated W2, W4, and W6, respectively (Fig. 2). For each configuration, two identical wall specimens were tested under two different constant axial stress levels (the lower and higher axial stress levels are distinguished by the suffixes -1 and -2, resulting in specimens

W2-1, W2-2, W4-1, W4-2, W6-1, and W6-2). The lower axial stress level was 0.2 MPa and the higher axial stress level was 0.5 MPa. During transportation of W2-1, a cracking sound was heard, which may be indicative of damage sustained prior to testing. Therefore, for this specimen only, the axial stress level was reduced to 0.1 MPa in order not to induce further damage.



(a) (b) (c)

Fig. 2. Wall specimens (a) Two-panel, (b) Four-panel and (c) Six-panel.

2.2 Specimen Testing and Instrumentation

After construction, the specimens were transported to the test rig (Fig. 3a). Lateral displacements were applied by a hydraulic actuator with a force capacity of 1000 kN and a displacement range of 400 mm, following the loading protocol illustrated in Fig. 3b. The test rig was designed to prevent out-of-plane displacements and foundation uplift. A constant axial load was applied using vertical actuators (one for the W2 specimens and two for the W4 and W6 specimens) and transferred to the specimen through a steel spreader beam. Steel rollers placed beneath the spreader beam allowed free lateral movement of the specimen during testing. Linear potentiometers were used to measure in-plane lateral displacements, panel and foundation uplift and out of plane displacements.

(a) (b)

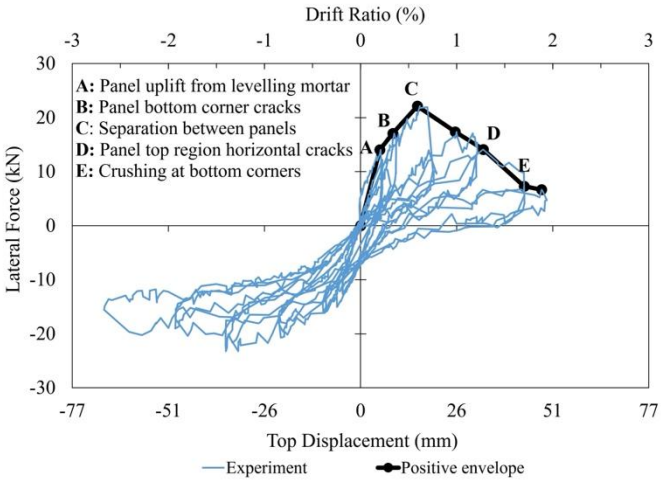
Fig. 3. (a) Test rig and (b) loading protocol (modified from [18]).

2.3 Test Results

The experimental results are presented as load–displacement curves in Figs. 4,6,8,10,12 and 14. The damage states and the corresponding lateral drift levels are marked on these curves. The damage states are labelled with capital letters from A to E, in chronological order from the earliest to the most advanced damage as the drift amplitude increased. For clarity, these annotations are shown only on the positive envelope, since the damage progression on the negative side was similar and occurred at comparable drift levels. The crack patterns at selected

drift levels for each specimen are illustrated in Figs. 5,7,9,11,13 and 15. In these figures, cracks that developed during the pushing (positive) half-cycle are shown in blue, whereas those that developed during the pulling (negative) half-cycle are shown in red. The measured crack widths in millimeters, are indicated next to each crack or opening. The vertical green lines and the blue dots denote the separation between adjacent panels and the locations of spalled AAC material, respectively. The double-headed arrow indicates the location and direction of the applied lateral load.

W2-1. The load–displacement response of W2-1 is presented in Fig 4. The peak lateral force of 22 kN was attained at a lateral drift ratio of 0.6%, beyond which the strength gradually degraded, and the specimen lost 20% of its load-carrying capacity at a drift ratio of 1.0%.



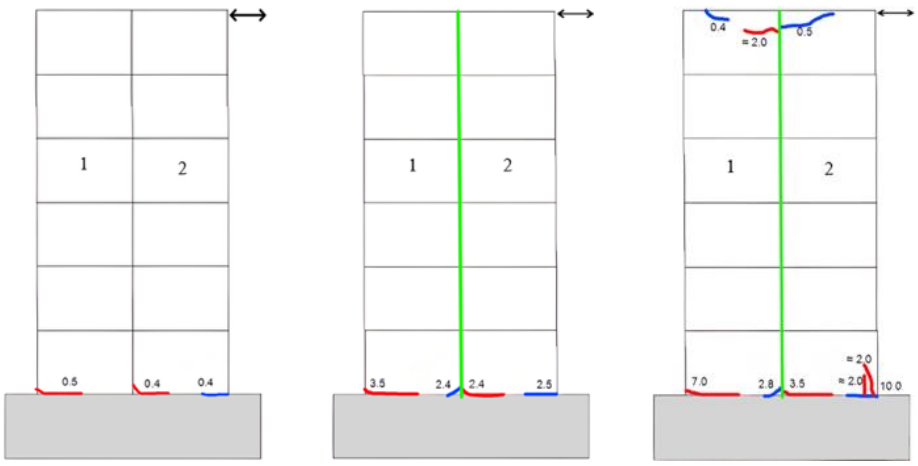


Fig. 4. Lateral load vs. top displacement curve of W2-1 with damage states superimposed (modified from [18]).

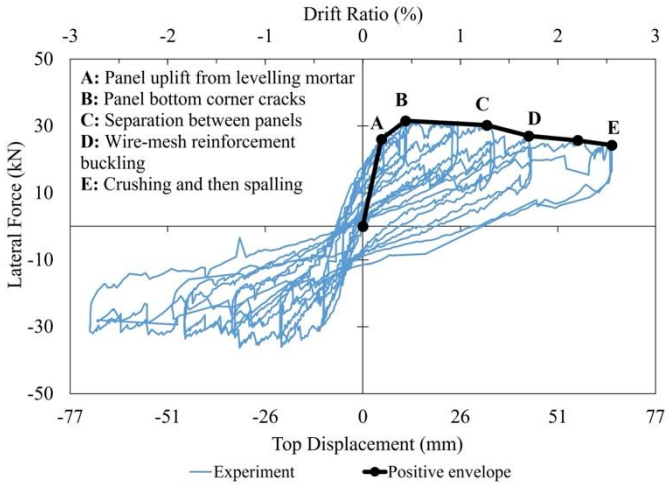
The progression of damage in W2-1 is illustrated in Fig. 5. The earliest observed damage was the separation of the panel bases from the leveling mortar, accompanied by uplift at a lateral drift of 0.25 %. The opening associated with this uplift widened progressively as the lateral drift increased. Subsequently, diagonal cracks developed at the bottom corners of the panels. At a target drift ratio of 1.00%, panel-to-panel interface openings along the vertical joints became discernible. As the drift was further increased to 1.50 %, horizontal cracks formed in the upper regions of the panels, and the previously observed corner cracks evolved into localized crushing. No web-shear cracking was observed across the central portion of the panels

(a) (b) (c)

Fig. 5. Observed crack patterns of specimen W2-1 at lateral target drift ratios of (a) 0.25%, (b) 1.00%, and (c) 1.50%.

W2-2. The load–displacement response of W2-2 is presented in Fig. 6. The peak lateral force of 31.5 kN was attained at a lateral drift ratio of 0.5 %, beyond which the strength gradually degraded. The specimen lost 20 % of its load-carrying capacity at a drift ratio of 2.3 %.



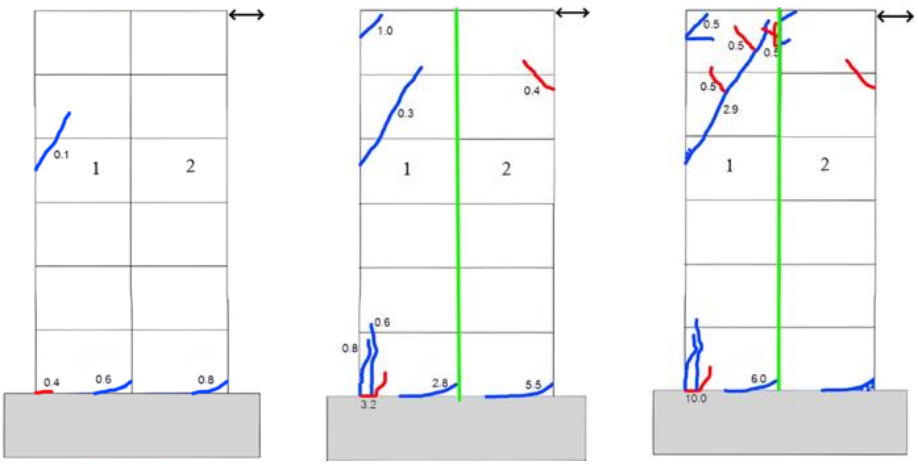


Fig. 6. Lateral load vs. top displacement curve of W2-2 with damage states superimposed (modified from [18]).

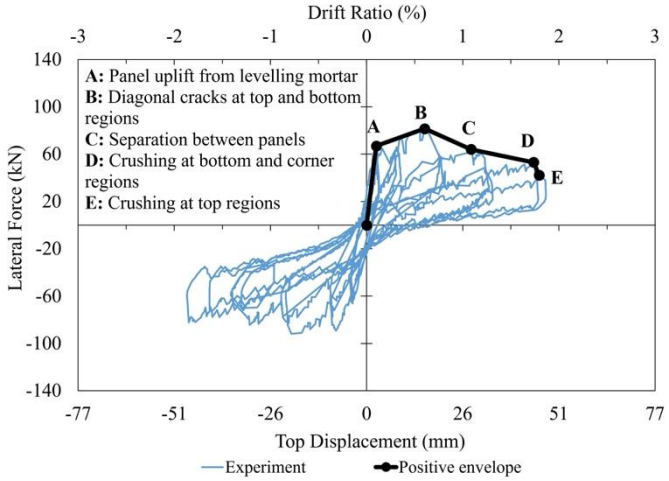
The progression of damage in W2-2 is illustrated in Fig. 7. Similar to W2-1, the earliest observed damage at 0.25 % lateral drift, was the separation of the panel bases from the leveling mortar, accompanied by uplift, which widened as the lateral drift increased. Subsequently, diagonal cracks developed at the bottom corners of the panels. At a target drift ratio of 0.50 %, a diagonal shear crack formed near the vertical mid-height of the first panel, on the side opposite to the hydraulic actuator. At the same drift level, panel-to-panel interface openings along the vertical joints became discernible, confirming individual panel rocking behavior, while upper-corner cracks continued to develop and propagate with increasing drift. At a lateral drift ratio of 2.00 %, buckling of the wire mesh reinforcement was observed in the regions where the AAC had crushed and spalled.

(a) (b) (c)

Fig. 7. Observed crack patterns of specimen W2-2 at lateral target drift ratios of (a) 0.25%, (b) 1.00%, and (c) 2.00%. (modified from [18]).

W4-1. The load–displacement response of W4-1 is presented in Fig. 8. The peak lateral force of 81.5 kN was attained at a lateral drift ratio of 0.6 %, beyond which the strength gradually degraded. The specimen lost 20 % of its load-carrying capacity at a drift ratio of 1.1 %.



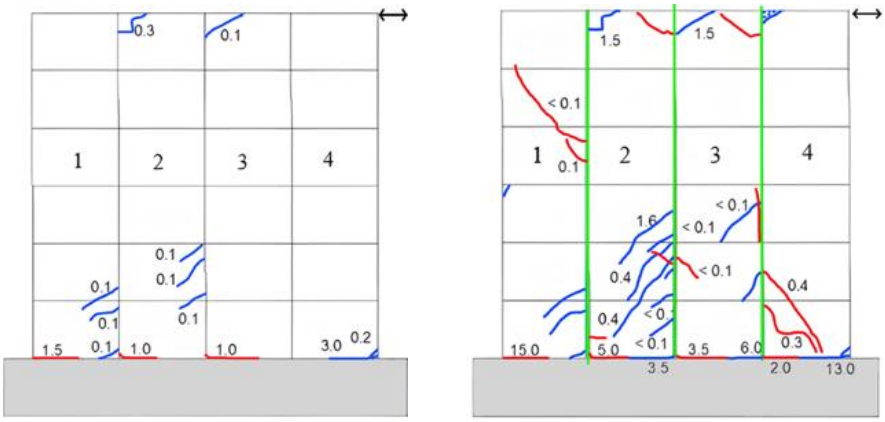


Fig. 8. Lateral load vs. top displacement curve of W4-1 with damage states superimposed (modified from [18]).

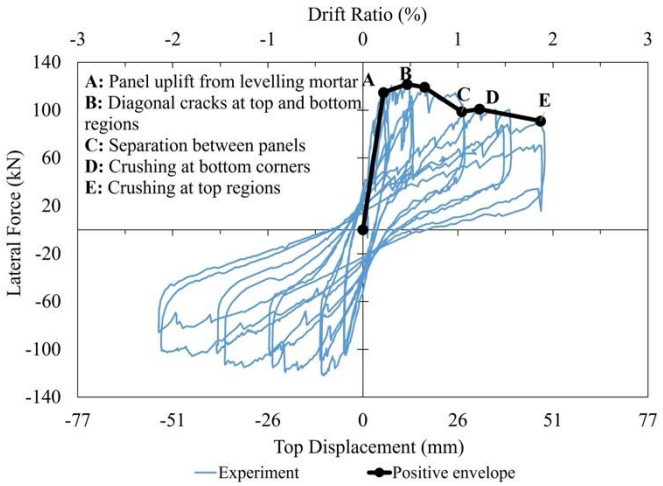
The progression of damage in W4-1 is illustrated in Fig. 9. The earliest damage in W4-1 consisted of the separation of the panel bases from the leveling mortar, accompanied by uplift. At a drift ratio of 0.50 %, cracks formed at the upper corners of the panels, and diagonal cracks developed in the lower half of the first and second panels, between the mid-height and the base. As the drift increased to 1.00%, panel-to-panel interface openings became discernible along the vertical joints, while the previously observed cracks grew in both width and number. At a drift ratio of 1.50 %, the diagonal cracks at the mid-height regions and at the upper and lower corners of the panels propagated further, accompanied by crushing at the top and bottom of the panels.

(a) (b)

Fig. 9. Observed crack patterns of specimen W4-1 at lateral target drift ratios of (a) 0.50% and (b) 1.50% (modified from [18]).

W4-2. The load–displacement response of W4-2 is presented in Fig. 10. The peak lateral force of 121.6 kN was attained at a lateral drift ratio of 0.5 %, beyond which the strength gradually degraded. The specimen lost 20 % of its load-carrying capacity at a drift ratio of 1.5 %.



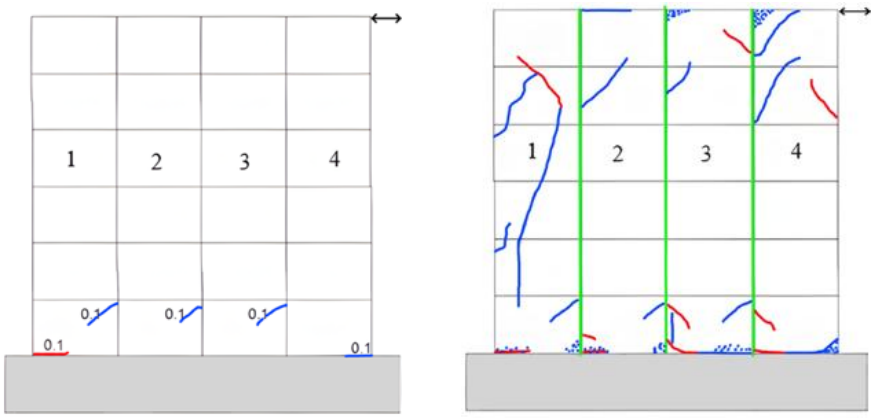


Fig. 10. Lateral load vs. top displacement curve of W4-2 with damage states superimposed (modified from [18]).

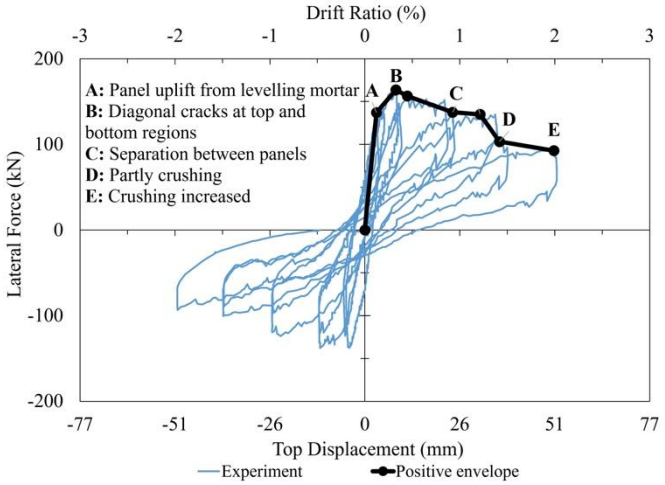
The progression of damage in W4-2 is illustrated in Fig. 11. The earliest damage in W4-2 was observed at a drift ratio of 0.25 % and consisted of the separation of the panel bases from the leveling mortar, accompanied by uplift. At a drift ratio of 0.50 %, diagonal cracks were concentrated in the lower and upper regions of the panels. As the drift increased to 1.00%, panel-to-panel interface openings became discernible along the vertical joints, the previously observed cracks grew in both width and number, and new diagonal cracks emerged in the upper regions. At a drift ratio of 1.50 %, the size and number of cracks increased further, and crushing and spalling initiated at the lower and upper corners. At a drift ratio of 2.00%, crushing and spalling intensified, particularly at the lower and upper corners.

(a) (b)

Fig. 11. Observed crack patterns of specimen W4-2 at lateral target drift ratios of (a) 0.25% and (b) 2.00% (modified from [18]).

W6-1. The load–displacement response of W6-1 is presented in Fig. 12. The peak lateral force of 163.6 kN was attained at a lateral drift ratio of 0.3 %, beyond which the strength gradually degraded. The specimen lost 20 % of its load-carrying capacity at a drift ratio of 1.3 %.



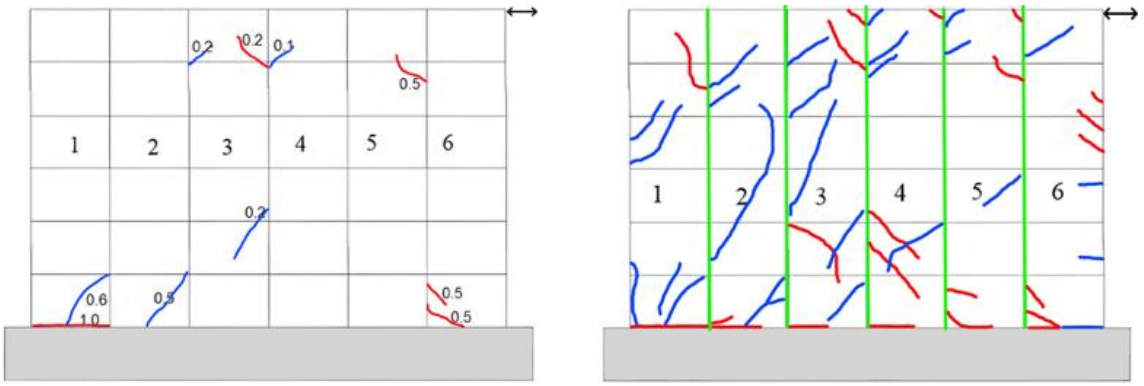


Fig. 12. Lateral load vs. top displacement curve of W6-1 with damage states superimposed (modified from [18]).

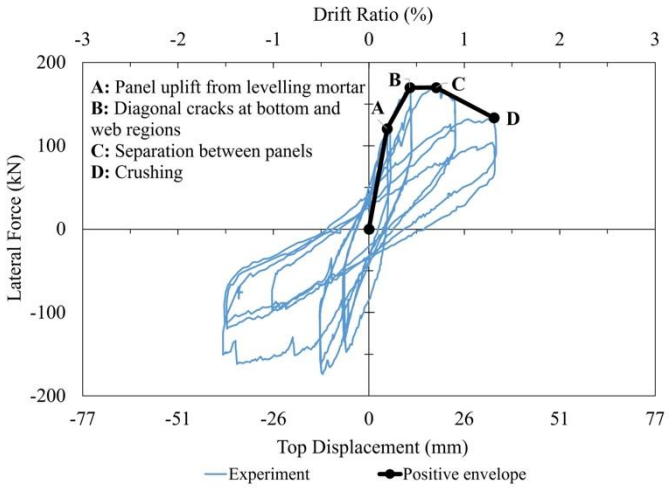
The progression of damage in W6-1 is illustrated in Fig. 13. The earliest damage in W6-1 was observed at a drift ratio of 0.25 % and consisted of the separation of the first, second, and sixth panel bases from the leveling mortar, accompanied by uplift. At the same drift level, diagonal cracks formed in the lower and upper regions of the panels. As the drift increased to 0.50 %, these cracks grew in both width and number and propagated into the remaining panels. In addition, web-shear cracks formed in the central regions of the panels, and all panels except the two central ones had separated from the leveling mortar. At a drift ratio of 1.00%, the two remaining central panels also separated from the leveling mortar, the previously observed cracks further increased in both width and number, and panel-to-panel interface openings became discernible along the vertical joints. At a drift ratio of 1.50%, crushing was observed at the panel bases.

(a) (b)

Fig. 13. Observed crack patterns of specimen W6-1 at lateral target drift ratios of (a) 0.25% and (b) 1.50% (modified from [18]).

W6-2. The load–displacement response of W6-2 is presented in Fig. 14. The peak lateral force of 170.0 kN was attained at a lateral drift ratio of 0.4 %, beyond which the strength gradually degraded. The specimen lost 20 % of its load-carrying capacity at a drift ratio of 1.3 %.



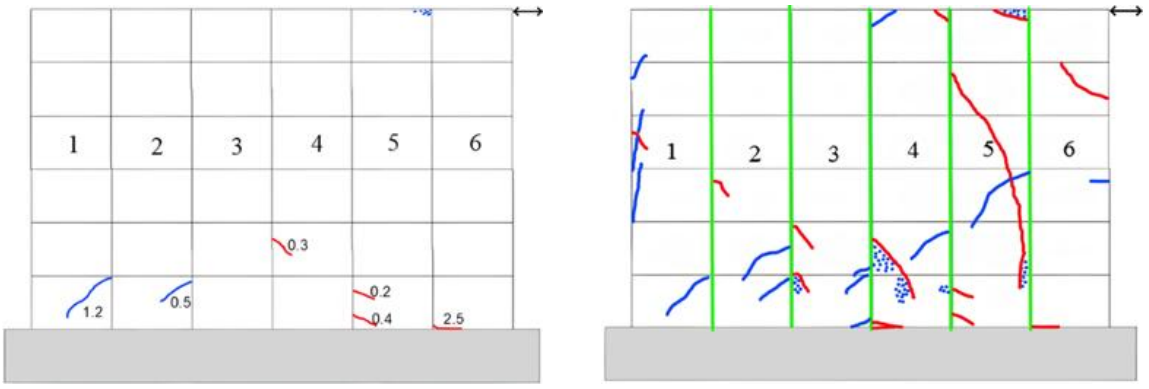


Fig. 14. Lateral load vs. top displacement curve of W6-2 with damage states superimposed (modified from [18]).

The progression of damage in W6-2 is illustrated in Fig. 15. The earliest damage in W6-2 was observed at a drift ratio of 0.25% and consisted of the separation of the panel bases from the leveling mortar, accompanied by uplift. At the same drift level, diagonal cracks formed in the lower regions of the panels. As the drift increased to 0.50%, these cracks grew in both width and number and propagated towards the mid-height of the panels and the upper corners. In addition, web-shear cracks formed in the central regions of the panels. At a drift ratio of 1.00%, the previously observed cracks intensified, panel-to-panel interface openings became discernible along the vertical joints, and crushing and spalling initiated at the lower, mid-height, and upper regions of the panels. At a drift ratio of 1.50%, the crushing and spalling progressed further.

(a) (b)

Fig. 15. Observed crack patterns of specimen W6-2 at lateral target drift ratios of (a) 0.25% and (b) 1.50% (modified from [18]).

2.4 Discussion

In all specimens, the earliest damage was the separation of the panel bases from the leveling mortar, accompanied by uplift, first recorded at a drift ratio of 0.25%, except in W4-1 where this occurred at 0.50%. Corner cracks developed and widened as the uplift increased with drift. At 1.00% drift, panel-to-panel interface openings became discernible along the vertical joints in all specimens, confirming individual panel rocking behavior. Crushing was observed at 1.50% drift, progressing to spalling at 2.00% drift, particularly in the higher axial stress specimens. In W4-2, spalling was concentrated at the panel corners, whereas in W6-2 it

occurred both at the corners and in the vicinity of the diagonal cracks extending toward the central region.

The two-panel specimens exhibited a predominantly flexural response, with damage concentrated at the panel corners and bases. Web-shear cracks developed in the four- and six-panel specimens alongside corner cracking and crushing, indicating a combined flexural–shear response. The more flexural character of the two-panel response may partly reflect the use of a single vertical actuator for axial load application, which provided less rotational restraint to the bond beam compared with the two-actuator configuration used for the four- and six-panel specimens.

In W6-1 and W6-2, diagonal cracks in several adjacent panels followed a similar orientation and extended across panel boundaries up to a drift ratio of 0.50%, suggesting monolithic behavior between these adjacent panels at early drift levels. This tendency was more pronounced in W6-2. As the drift increased, panel-to-panel interface openings became discernible, marking the transition from monolithic to individual panel behavior.

Higher axial stress consistently resulted in greater peak lateral force across all configurations. The peak lateral force increased as the number of panels increased, ranging from 22–31.5 kN for two-panel walls to 163.6–170.0 kN for six-panel walls.

All specimens sustained considerable drift demands while maintaining their structural integrity, with 20% loss of load-carrying capacity observed at drift ratios of 1.0% or greater. The hysteretic response of all specimens remained stable throughout the tests, with no sudden loss of load-carrying capacity, although noticeable pinching was observed particularly after diagonal cracking and interface opening.

3 Conclusions

This study investigated the cyclic in-plane behavior of autoclaved aerated concrete (AAC) load-bearing panel walls consisting of two, four, and six panels through experimental testing. The principal findings are summarized below.

The experimental results confirmed that AAC load-bearing panel walls respond as individual rocking units under cyclic lateral loading, with base separation and panel-to-panel interface opening observed at low drift levels. An exception was noted in the six-panel specimens, where adjacent panels exhibited monolithic behavior up to 0.50% drift before transitioning to individual rocking.

The failure mode was influenced by the panel configuration. Two-panel walls exhibited a predominantly flexural response, while four- and six-panel walls displayed a combined flexural–shear response. It is noted that the difference in the number of vertical actuators used for axial load application may have contributed to this distinction.

Both axial stress level and number of panels had a significant influence on the lateral load-carrying capacity, with higher values of each parameter consistently yielding greater peak lateral force.

All specimens sustained considerable drift demands while maintaining their structural integrity, with 20% loss of load-carrying capacity observed at drift ratios of 1.0% or greater. The hysteretic response remained stable throughout the tests, with no sudden loss of load-carrying capacity, although noticeable pinching was observed after diagonal cracking and interface opening.

Given that the observed response involves both flexural and shear mechanisms, the design of such walls should account for both failure modes and their potential interaction.

Abstract. Cliff-mounted glass observation platforms (GOPs) are increasingly constructed as landmark tourist structures; however, their slender steel support systems, low inherent damping, elevated deck mass, and deformation-sensitive circular framing make them vulnerable to near-fault earthquake effects. This study presents a performance-based seismic retrofit approach for a steel GOP using optimized fluid viscous dampers (FVDs) and targeted local strengthening. The GOP in Bursa Province, Türkiye was selected as an example. A three-dimensional structural model was developed in SAP2000 using frame elements. The seismic response was evaluated through bidirectional direct-integration time-history analyses under selected near-fault ground motions from the 2023 Kahramanmaraş earthquake sequence. The proposed retrofit procedure is governed by member-level demand-to-capacity ratios, with a target acceptance limit of $D/C \leq 0.80$. A MATLAB-based iterative design routine was used to update damper coefficients after each time-history analysis until the prescribed performance criterion was satisfied. Within this framework, two practical retrofit alternatives are emphasized: a sequential damper installation strategy, in which the primary support system is first controlled and deck dampers are subsequently optimized, and a hybrid strategy combining FVDs with local cross-sectional enhancement of critical circular ring beams. The results show that the unretrofitted structure develops excessive displacement demand and non-uniform deck deformation, particularly around the outer ring and ramp-connected region. The sequential damper strategy provides a balanced reduction in displacement, acceleration, and base-shear demand, making it attractive when global response control and foundation demand are governing design considerations. In contrast, the hybrid retrofit strategy provides the most effective control of local deck distortion and torsion-sensitive deformation by combining supplemental damping with increased sectional stability of critical deck members. These findings indicate that retrofit design for GOPs should not be based solely on global response reduction, but should also consider local deck deformation, force transfer to the support system, and damper utilization efficiency. The proposed framework provides a practical design-oriented methodology for seismic retrofit of slender steel GOPs located in near-fault regions.

Keywords: Glass observation platform; Viscous damper; Near-fault earthquake; Seismic retrofit

1. Introduction

GOPs have rapidly become landmark tourism structures because they combine scenic visibility, lightweight steel framing, and transparent deck systems. In Türkiye and worldwide, these structures are commonly configured as cliff-mounted or elevated decks with long cantilevered components and irregular plan geometry. Such architectural advantages may also produce low lateral stiffness, low inherent damping, and torsion-sensitive vibration characteristics. Similar lightweight transparent pedestrian and glass-bridge systems have been discussed in recent vibration-serviceability studies [1-3]. Two representative glass observation platforms are shown in Fig. 1.

a) Kirazlıdere glass observation platform (Isparta Province, Türkiye)

b) Ulubey Glass Terrace (Uşak Province, Türkiye)

Fig. 1. Representative glass observation platforms (GOPs)

Despite their growing use in seismically active regions, the seismic retrofit of steel GOPs has received limited attention compared with conventional buildings and bridges. The problem is particularly important for near-fault earthquakes, where strong acceleration pulses and velocity-sensitive demand may simultaneously amplify support-level actions and local deck deformation. Therefore, retrofit design should consider not only global displacement reduction, but also force transfer, torsion-sensitive deck response, and member-level capacity exceedance. This study introduces an iterative viscous-damper optimization framework together with a hybrid retrofit concept that combines supplemental damping with localized section enhancement of critical circular ring beams. To the authors' knowledge, this is the first study to systematically investigate the retrofit of an observation deck using viscous dampers, with particular emphasis on improving seismic performance and controlling dynamic demand in critical structural components.

2 Case Study and Numerical Model

The selected case study is the Oylat GOP located in the İnegöl district of Bursa Province, Türkiye. The platform has an approximate area of 250 m² and is situated on a rocky hilltop. The structure consists of a circular steel deck supported by a spatial lattice tower and connected to the terrain through an access deck. The circular deck is composed of inner and outer ring beams, radial beams, circumferential joists, and primary deck members. Because the deck mass is elevated and the ramp connection introduces geometric eccentricity, the platform is expected to exhibit coupled lateral-torsional behavior under earthquake loading.

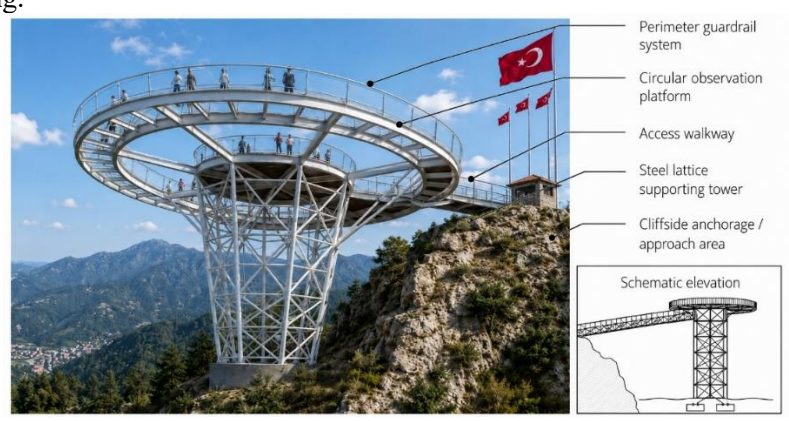

Fig. 2. Oylat GOP and the three-dimensional SAP2000 model

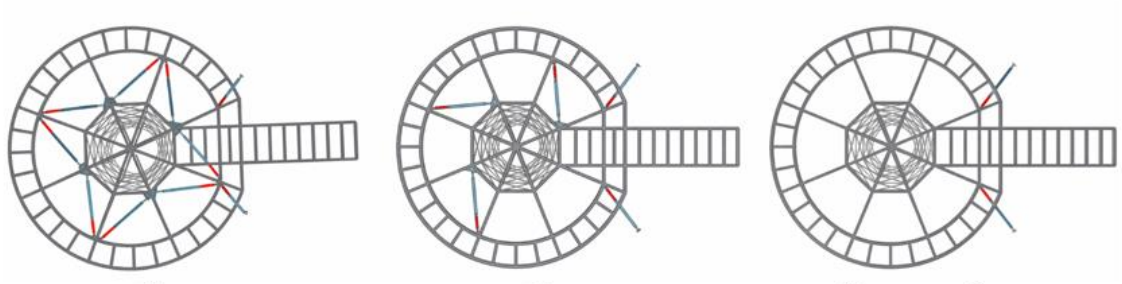
A three-dimensional SAP2000 model was developed using frame elements. The superstructure was mainly represented by HE-series members, whereas the supporting lattice system was modeled using circular hollow sections. In line with the original model description, S275JR steel was assigned to the deck and ramp members, while S235JR steel was assigned to the lattice support members. The model was used for modal analysis and bidirectional direct-integration time-history analyses. Steel member performance was evaluated by the demand-to-capacity (D/C) ratio obtained from member capacity checks. A target D/C limit of 0.80 was adopted as a conservative retrofit acceptance criterion so that all alternatives could be compared using a common performance index [4, 5].

3 Retrofit Strategies and Damper Optimization

Four retrofit strategies were evaluated in order to distinguish the effects of damper distribution, installation sequence, force-transfer control, and local member strengthening. The discussion below summarizes the design logic followed for each strategy before the common optimization procedure and layout figures are presented.



i) Strategy I - distributed damper layout: In this strategy, VDs were placed in a relatively distributed manner between the circular deck system and the supporting members. The purpose of this strategy was to reduce local member demand by increasing energy dissipation at several deck-support interaction points. Therefore, the procedure mainly followed a localized demand-reduction logic: critical regions were identified from the initial D/C distribution, dampers were assigned to these regions, and the damping coefficients were updated iteratively until the target D/C <= 0.80 criterion was approached. This strategy is useful for examining the effect of a broad damper layout, but it may also introduce a less controlled force-transfer mechanism because several dampers act simultaneously around the deck.

ii) Strategy II - sequential column-to-deck optimization: Strategy II was developed as a more systematic damper-only alternative. In this case, the support/column system was controlled first, and the deck-level dampers were optimized after the primary load path had been stabilized. This sequential logic was adopted to prevent the deck dampers from being designed before the main support demand was sufficiently reduced. After each time-history analysis, the MATLAB-based routine updated the damper coefficients and the model was reanalyzed. Compared with Strategy I, this approach provides a clearer design sequence and a more balanced control of displacement, acceleration, and base-shear response.

iii) Strategy III - column-priority damping: Strategy III focused primarily on protecting the main load-bearing support system. The damper layout was therefore more concentrated on the column/support side, while a certain level of deck demand was allowed to remain. This strategy represents a damage-tolerant or support-priority design philosophy in which the main objective is to reduce force demand transferred to the foundation and support members. However, because the circular deck and ramp-connected region are not directly strengthened, this strategy is expected to be less effective in controlling torsion-sensitive local deck deformation.

iv) Strategy IV - hybrid damping and section enhancement. Strategy IV used the practical damper-placement philosophy of Strategy III but added targeted local strengthening of the critical inner and outer circular ring beams. In this hybrid strategy, supplemental viscous damping was used to reduce seismic demand, while section enhancement was used to improve the stiffness, stability, and capacity of the deck members that remained critical after the damper-only stages. The design sequence therefore included column control, deck demand evaluation, section enhancement, and a final coupled verification stage. This strategy directly addresses the main limitation of damper-only schemes by combining global response reduction with local deck-performance improvement.

The strategy layouts and an implementation view of the viscous dampers are given in Figs. 3 and 4. The same D/C-based performance criterion was used in all strategies so that the alternatives could be compared within a consistent performance-based framework.

(b) Str#1 (c) Str#2 (d) Str#3 and Str#4

Fig. 3. Damper layout configurations for the investigated retrofit strategies.

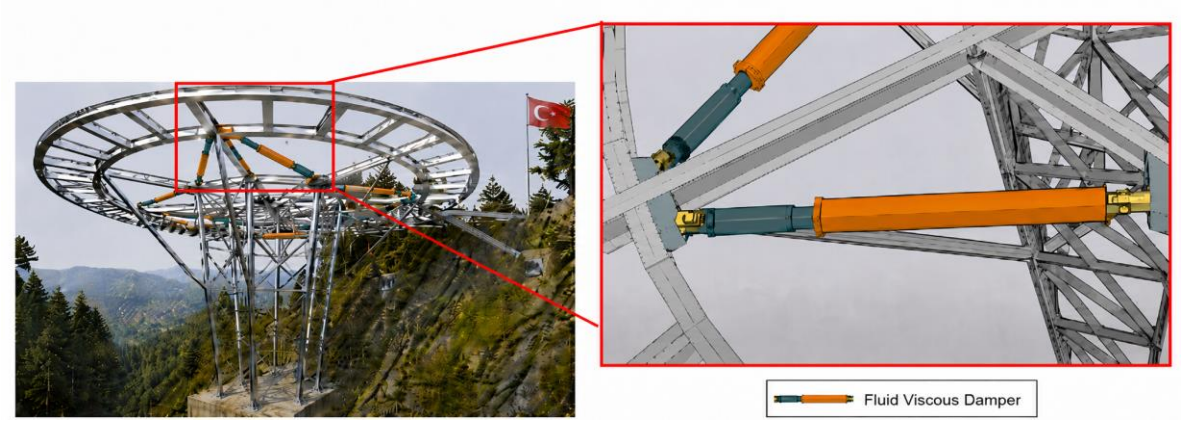


Fig. 4. Applied fluid viscous damper configuration on the observation platform.

The damper force was modeled as a velocity-dependent response using damper-exponential link elements. The viscous dampers were represented by a Maxwell-type link formulation with the damping coefficient treated as the main optimization variable. A MATLAB-based iterative routine was used to update the damping coefficients after each time-history analysis. The loop was repeated until the governing D/C demand satisfied the target threshold. For Strategy 4, the procedure also included a section-enhancement phase and a coupled verification stage, as summarized in Fig. 5.

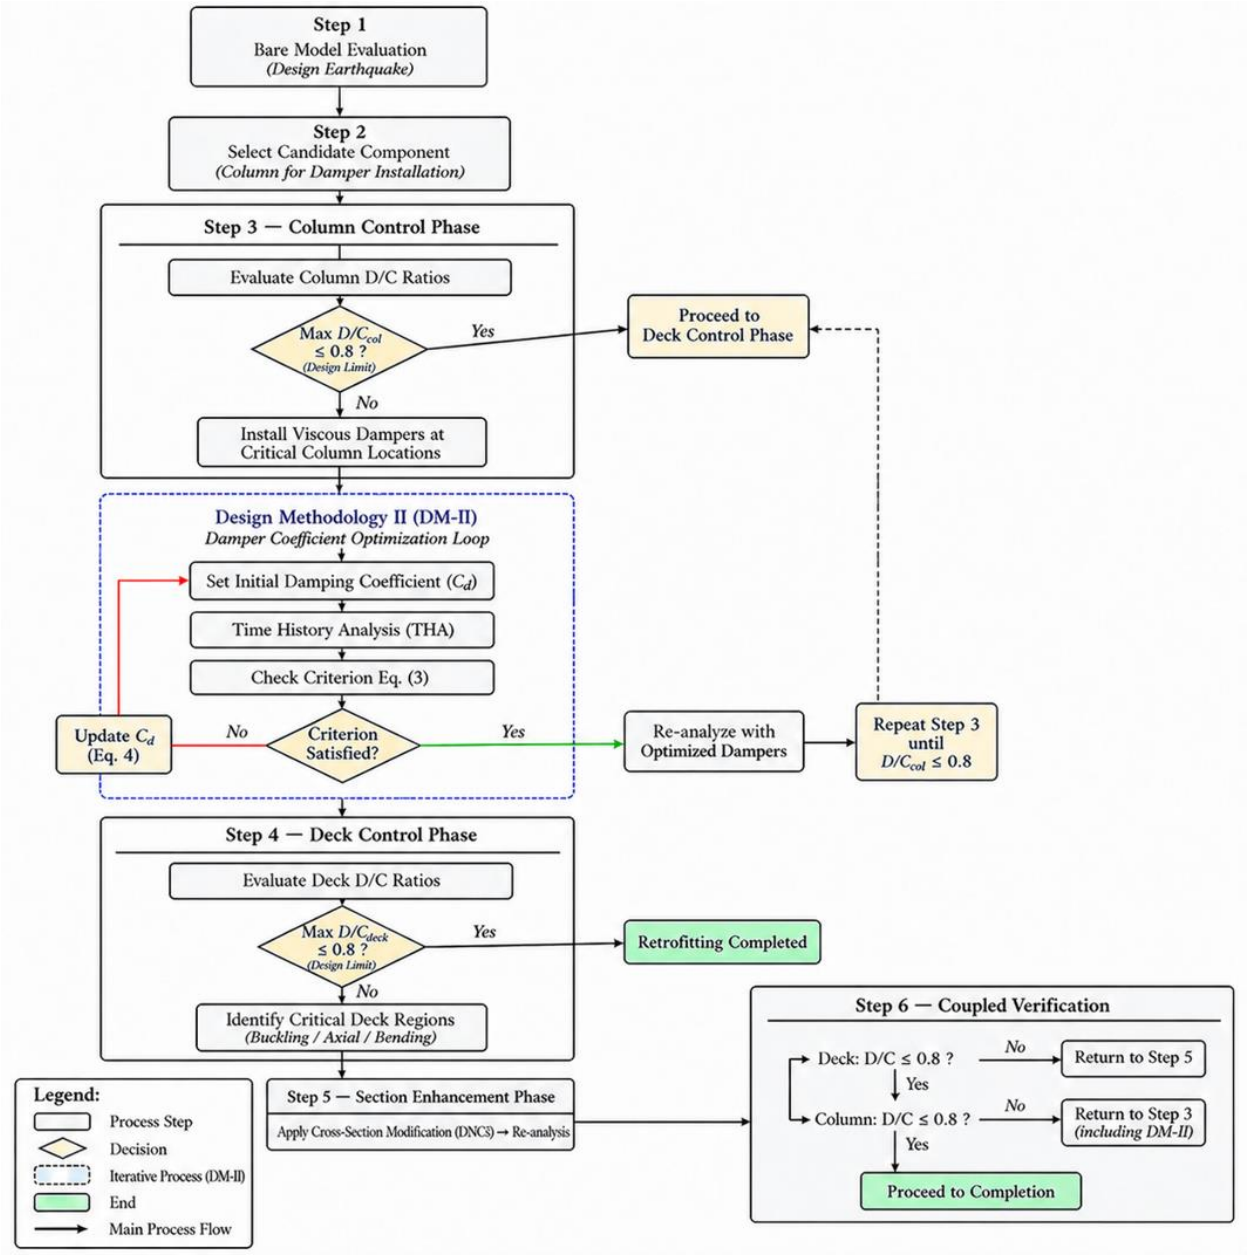

Fig. 5. Flowchart of the proposed Strategy 4 hybrid retrofit methodology.

4 Ground Motions

Three near-fault records from the 2023 Kahramanmaraş earthquake sequence were used: S4614 Pazarcık, S2718 Pazarcık, and S4614 Elbistan, as shown Fig 6. These records were selected to represent near-source conditions and pulse-related demand characteristics relevant to flexible observation platforms [6,7]. The rupture distances range from 2.10 to 8.25 km; S4614 Pazarcık is relatively acceleration dominated, whereas S2718 Pazarcık and S4614 Elbistan have larger PGV/PGA ratios and stronger velocity-sensitive characteristics. The accelerograms were spectrally matched to the target design spectrum using SeismoMatch. The adopted wavelet-based matching procedure follows established response-spectrum matching formulations and was used to obtain spectrum-compatible records while retaining the general time-domain characteristics of the original motions [8-10].

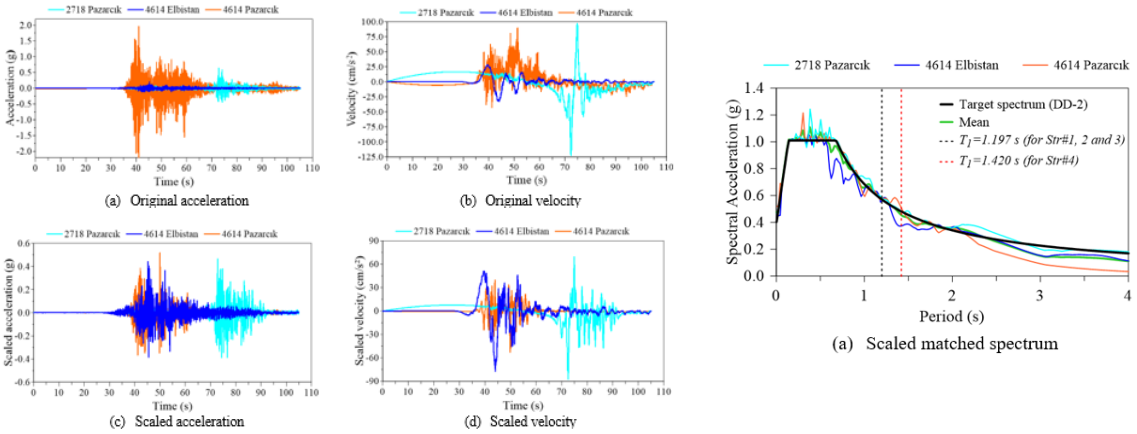

Fig. 6. Ground-motion histories and matched response spectra used in the analyses.

5 Results and Discussion

Fig 7. compares the peak responses of the bare model and the four retrofitted configurations under the selected earthquake records. The bare model developed the highest global response demands and showed extensive member-level D/C exceedance, especially in the circular deck system. This indicates that local deck vulnerability is a governing issue for cliff-mounted observation platforms. Strategies 1 and 2 substantially reduced displacement and acceleration demands. Strategy 2 also provided a balanced base-shear response because the support system was stabilized before the deck dampers were optimized. However, the member-level checks indicate that global response reduction alone is not sufficient unless the circular deck members also satisfy the adopted D/C limit. The peak response results show two distinct retrofit objectives. Strategy 4 achieved the lowest displacement demand, with peak values approximately reduced from about 28-29 cm in the bare structure to about 5-6 cm. However, Strategy 2 provided the most balanced damper-only response in terms of displacement, acceleration, and base-shear reduction. This confirms that peak displacement alone is not sufficient for selecting the optimum retrofit scheme.

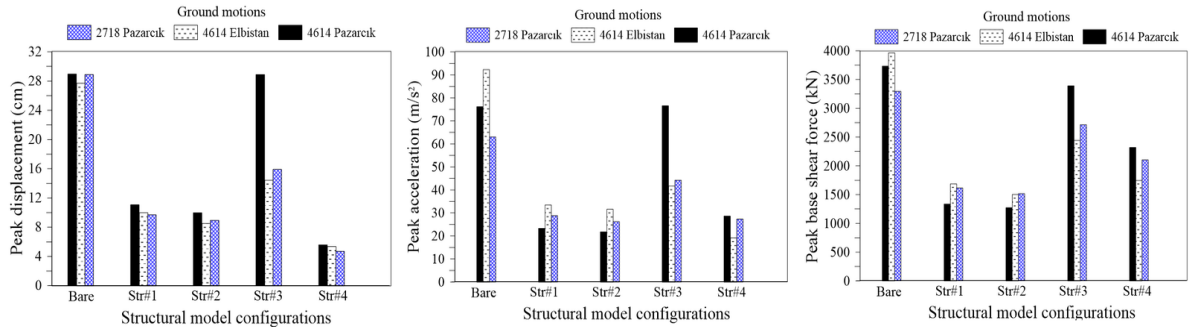

Fig. 7. Peak displacement, acceleration, and base-shear response of the bare and retrofitted configurations.

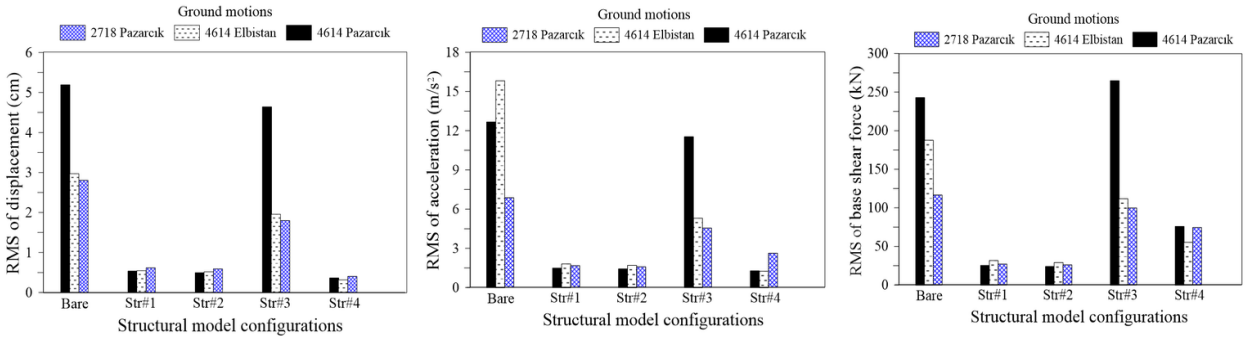
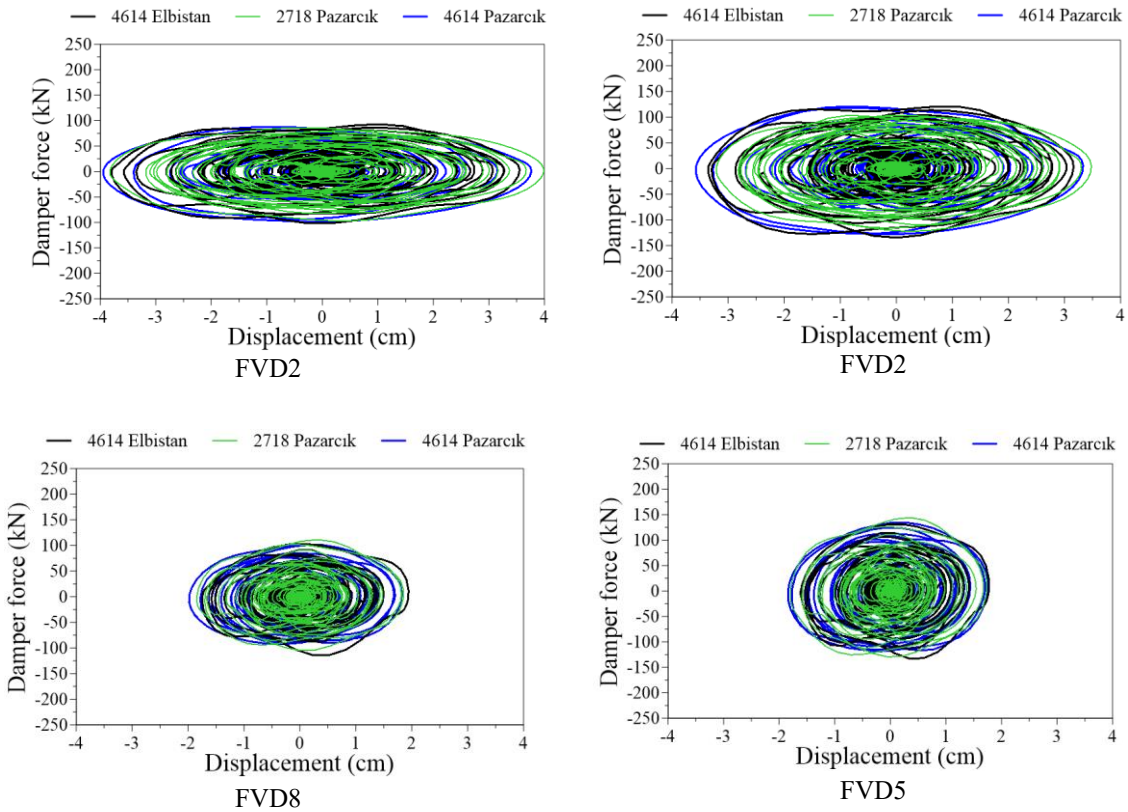
Fig. 8 presents the RMS values of displacement, acceleration, and base shear for all structural configurations. RMS-based results further indicate that Strategies 1, 2, and 4 reduce the sustained vibration intensity of the platform, whereas Strategy 3 remains less effective. The damper force and hysteresis results confirm that viscous dampers were effectively engaged during the analyses. The hysteresis loops were stable, indicating repeatable energy dissipation and meaningful damper utilization rather than a simple redistribution of structural stiffness.





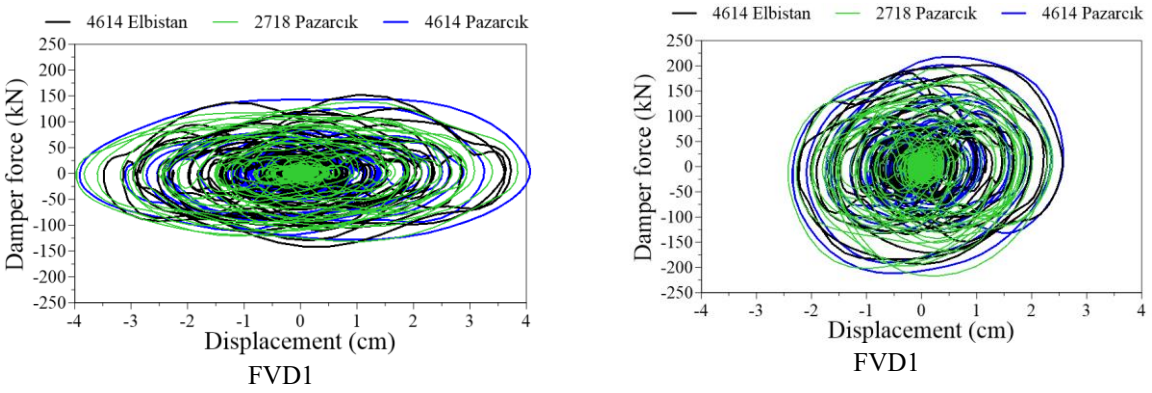


Fig. 8. RMS displacement, acceleration, and base-shear response for the analyzed configurations.

Error! Reference source not found. 9. shows the force–displacement hysteresis behavior of the dampers used in the four retrofit configurations. In all cases, the loops are stable and well developed, indicating that the dampers are effectively engaged and are dissipating seismic input energy in a repeatable manner. For Str#1 and Str#2, the hysteresis loops of the different devices suggest that the damping demand is distributed over more than one response-critical location. The wider loops observed for FVD2 indicate greater displacement demand, whereas the more compact loops of FVD8 and FVD5 indicate more localized motion demand combined with effective force development. This is consistent with the iterative placement logic of the retrofit methodology, in which dampers are assigned according to local structural response rather than uniformly distributed throughout the system. For Str#3 and Str#4, both configurations are represented by FVD1, yet the loop shapes differ noticeably. Str#4 exhibits a more vertically developed hysteretic pattern, which implies a more efficient force response within a relatively controlled displacement range.

Fig 10 presents the displacement distribution along the outer circular radial beam line and is arguably the most informative figure regarding local deck behavior. The bare model exhibits large and highly non-uniform oscillatory deformation around the perimeter, indicating pronounced local amplification and torsion-sensitive deck response. Deck-level deformation profiles provide the clearest evidence for the advantage of the hybrid retrofit. The original structure exhibited non-uniform deformation around the outer ring and ramp-connected region. Strategy 4 reduced this irregular deformation by combining supplemental damping with local stiffness and capacity enhancement in the strengthened circular ring beams.

6 Conclusions

This study developed a performance-based hybrid retrofit strategy for cliff-mounted steel GOPs exposed to near-fault seismic demands. The main contribution lies in combining fluid viscous dampers with selective cross-sectional strengthening of vulnerable circular deck members within a single retrofit scheme. The Oylat GOP was selected as a representative case to evaluate the feasibility of the proposed approach using a three-dimensional SAP2000 model and bidirectional direct-integration time-history analyses. In addition to the hybrid solution, three damper-oriented retrofit configurations were investigated as comparative alternatives. These benchmark cases were used to assess the effectiveness of Str#4 in terms of global seismic response reduction, control of local deck deformation, improvement of member-level capacity, and limitation of force transfer to the supporting system.

- The unretrofitted platform was vulnerable under the selected near-fault records, with excessive displacement demand and local D/C exceedances concentrated in the circular deck system.
- Damper-only strategies reduced global seismic response, but their efficiency depended strongly on damper placement and the resulting force-transfer mechanism.
- The sequential damper strategy provided the most balanced damper-only solution when base-shear limitation and global response reduction were governing objectives.
- The hybrid Strategy 4 provided the best local deck-performance improvement by combining energy dissipation with increased sectional stiffness and stability of critical circular ring beams.
- For steel glass observation platforms, retrofit decisions should combine global response measures, local deck deformation, damper utilization, and member-level capacity indices rather than relying only on peak displacement.

ABSTRACT

Although Special Central Braced Frames (SCBFs) are widely used in the design of multi-story steel structures in high seismic risk areas, they have disadvantages such as element buckling under compression and limited energy dissipation capacity. Buckling-Restrained Braced Frames (BRBFs), exhibiting symmetric hysteretic behavior, offer a superior seismic solution to these structural problems. In this study, the seismic design of a seven-story steel structure was carried out with SCBF and BRBF alternatives according to AISC 341-22 capacity design principles and ASCE 7-22 regulations; The research findings showed that the high coefficient of behavior ($R = 8$) in the BRBF system provided a 25% reduction in the total base shear force seismically. It has been determined that this global seismic demand reduction and the decrease in the unbalanced vertical force (P_{ub}) in the chevron configuration from 558 kN to 117.8 kN prevented mandatory oversizing in beam cross-sections (reduction from HEB 600 profile to HEB 240/340 range) and provided a material optimization of 11.2 tons (19%) in the weight of the frame without braces. In the context of capacity design philosophy, it has been proven that despite the increased excessive strength demand $\Omega_0 = 2.5$), the HEM 360 cross-section can be safely used instead of HEM 400 in the columns thanks to the compensatory effect of the reduced base shear force. In conclusion, this study; Quantitative data demonstrate that the BRB system, with its dramatic material savings and seismic repairability potential offered within a cross-free frame, is an extremely rational and reliable design alternative in high seismic risk areas.

INTRODUCTION

As a country located within a highly active seismic zone, Türkiye faces a critical need to enhance the seismic resistance of its structures to minimize loss of life and property. Recent earthquakes such as the M_w 7.5 Kahramanmaraş Earthquake in 2023 and the M_w 6.2 Istanbul Earthquake have highlighted the necessity for innovative structural systems capable of improving the seismic performance of the existing building stock. In steel structures, Moment-Resisting Frames (MRFs) and Braced Frames are among the most employed lateral force-resisting systems. MRF systems are designed such that beams and columns are connected through moment-resisting joints, providing both stiffness and ductility against lateral loads. Special Moment Frames (SMFs) dissipate seismic energy primarily through the plastic deformation of structural members. However, under severe earthquake loading, large inelastic deformations inevitably result in permanent structural damage and residual deformations, which may adversely affect the post-earthquake functionality and resilience of the structure.

The seismic design philosophy of SMFs is fundamentally based on utilizing the inelastic deformation capacity of structural steel to dissipate earthquake-induced energy.Special Concentrically Braced Frames (SCBFs), on the other hand, enhance the stiffness and strength of structures by transferring lateral loads to the foundation through bracing members installed within the frame. Depending on architectural constraints and stiffness requirements, these systems may be configured in various geometries, including X-bracing, diagonal bracing, and inverted-V (Chevron) bracing. Among these alternatives, X-bracing is generally preferred due to its more effective energy dissipation characteristics at the connection regions under cyclic tension-compression loading. The fundamental design principle of SCBFs is the transformation of lateral loads into axial tensile and compressive forces within the brace members. A distinctive characteristic of SCBF systems is their asymmetric behavior under tension and compression loading. The seismic response of these systems is highly dependent on brace slenderness and differs significantly between tensile and compressive load states. Under tensile loading, brace members undergo strain hardening, whereas under compressive loading, buckling occurs once the critical buckling load is exceeded. Following buckling, a sudden and substantial reduction in load-carrying capacity is observed. Under cyclic loading conditions, the re-straightening of buckled braces results in stiffness degradation, leading to pronounced pinching effects in the force-displacement hysteresis loops and a significant reduction in energy dissipation capacity. Previous studies have concluded that brace slenderness is one of the most influential parameters governing the hysteretic behavior of conventional braces. While tensile loading promotes strain hardening, compressive loading induces buckling once the critical load threshold is exceeded (Figure 1'a). This phenomenon reduces the overall energy dissipation capability of the system and limits its seismic performance. Consequently, conventional braces are unable to dissipate a substantial portion of earthquake energy, and their strength deteriorates rapidly with increasing loading cycles, a phenomenon commonly referred to as strength degradation. Such behavior compromises the seismic safety of structures and may lead to global stability problems, particularly in systems utilizing highly slender braces. Due to these unfavorable behavioral characteristics, modern seismic design provisions, including AISC 341 and the Turkish Building Earthquake Code (TBEC 2018), impose specific limitations on the use of conventional bracing systems. In regions requiring high ductility, brace slenderness ratios are restricted, and special detailing requirements are imposed at connection regions to accommodate brace rotations during buckling, such as the provision of adequate gusset plate free-bending lengths. These limitations and performance concerns have ultimately led to the development of Buckling-Restrained Braces (BRBs), which exhibit stable and symmetric behavior under both tensile and compressive loading. Unlike conventional braces, BRBs eliminate the tendency of brace members to buckle under axial compression, thereby enabling nearly identical hysteretic responses in tension and compression (Figure 1b). As a result, BRBs provide stable energy dissipation, superior ductility, and significantly improved seismic performance under cyclic loading conditions.

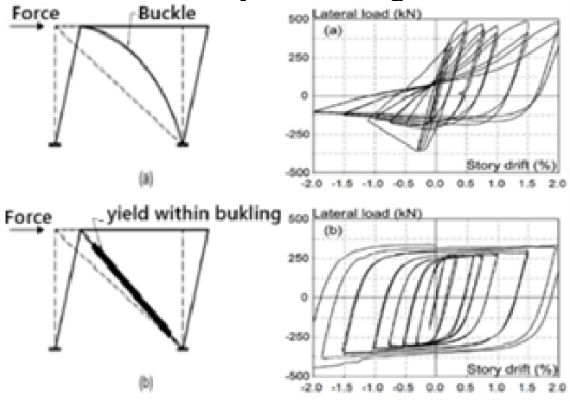

Fig. 1. Lateral load–story drift relationships of (a) a conventional brace (CB) and (b) a buckling-restrained brace (BRB) with diagonal configuration [1].

Buckling-Restrained Braces (BRBs) consist of three primary components: the steel core (SC), the buckling restraint mechanism (BRM), and an unbonded interface layer located between the SC and the BRM. The SC is the component responsible for carrying the axial load. As illustrated in Figure 2, various SC cross-sectional configurations have been proposed and investigated in previous studies. A review of the literature reveals that rectangular [2–4], cruciform [5,6], and H-shaped [7,8] core sections are among the most adopted configurations.The primary function of the BRM is to prevent buckling of the SC under axial compressive loading, thereby enabling the core element to undergo stable post-yield plastic deformation under both tensile and compressive loading conditions. Through this mechanism, the BRB effectively dissipates seismic energy imparted to the structure. BRMs may be manufactured by infilling concrete or mortar into steel tube sections [9], entirely from steel plates [10], or by utilizing advanced composite materials such as glass-fiber-reinforced polymers (GFRP) [11] and carbon-fiber-reinforced polymers (CFRP) [12].The purpose of the unbonded interface layer is to prevent load transfer from the SC to the BRM and to eliminate additional stresses generated by friction between these components during cyclic loading. To achieve this objective, previous studies have investigated methods for determining optimum interface dimensions [13] as well as the use of isolation materials such as butyl tape [14] and silicone sheets [15]. Recent developments in BRB technology have resulted in the emergence of innovative configurations tailored to specific performance requirements. For instance, several studies have proposed replaceable BRB systems in which damaged steel core elements can be readily replaced following a major seismic event [16–18]. Other investigations have introduced all-steel BRB designs incorporating metamaterials and perforated core elements with negative Poisson's ratios [19,20]. Furthermore, dual stage BRB systems have been developed to accommodate large axial deformations without causing structural damage while maintaining stable energy dissipation capabilities at prescribed design drift levels under frequent and moderate earthquake excitations. These advancements demonstrate the continuous evolution of BRB technology toward enhanced seismic resilience, improved reparability, and superior energy dissipation performance compared with conventional bracing systems.

METOT

In this study, two alternative lateral force-resisting systems suitable for multi-story steel buildings located in regions of high seismic hazard were comparatively evaluated. A typical seven-story office building, consisting of six regular stories and one roof level, was selected as the reference structure. The regular story height was taken as 3.5 m, while the roof level height was 2.6 m, resulting in a total building height of 23.6 m. The building has four bays in the X-direction, each with a span length of 9 m, yielding a total plan dimension of 36 m in this direction. Moment-Resisting Frames (MRFs) were employed as the lateral force-resisting system along the X-axis. In the Y-direction, the structure consists of three bays, each measuring 7.5 m in length, resulting in a total building dimension of 22.5 m. The typical floor plan of the building is presented in Fig. 3.

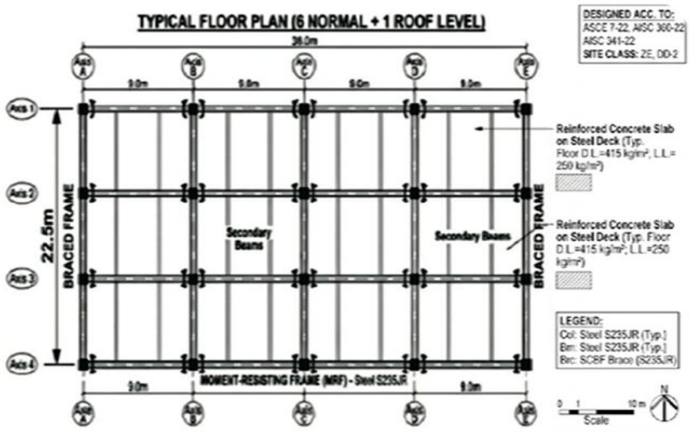

Fig. 3. Typical floor plan.

S235JR structural steel was adopted for the design of the primary load-carrying columns, beams, and bracing members. This steel grade was selected due to its widespread use in construction practice, ease of procurement, cost-effectiveness, and adequate corrosion resistance. Structural analysis and member sizing were performed using the Load and Resistance Factor Design (LRFD) methodology in accordance with the provisions of AISC 360-22 and the seismic detailing requirements of AISC 341-22. Equivalent seismic loads were determined based on the procedures specified in ASCE 7-22. For the comparative analysis, the response modification coefficient was taken as $R = 6$ for the Special Concentrically Braced Frame (SCBF) system and $R = 8$ for the Buckling-Restrained Braced Frame (BRBF) system. Accordingly, the design base shear forces (V_y) were calculated and distributed over the building height. In the capacity design of columns, the system overstrength factors (Ω_0) prescribed by the relevant standards were adopted as 2.0 for the SCBF system and 2.5 for the BRBF system. Within the scope of this study, the DD-2 seismic hazard level, corresponding to a 10% probability of exceedance in 50 years, was selected as the design earthquake level. Furthermore, the ZE site class, representing highly unfavorable soil conditions from a seismic perspective, was adopted. When integrating the seismic parameters defined in the Turkish Seismic Hazard Map into the ASCE 7-22 framework, the structure was assumed to belong to a high seismic risk category corresponding to Seismic Design Category D (SDC D). The design spectral accelerations were taken as $S_{DS} = 1.0g$ and $S_{D1} = 0.6g$.The applied gravity loads consisted of a dead load of 4.07 kN/m^2 and a live load of 2.45 kN/m^2 for typical floors, while the roof level was assigned a dead load of 3.19 kN/m² and a live load of 0.98 kN/m^2. In addition, an exterior cladding load of 0.74 kN/m^2 was considered. Based on these assumptions, the design base shear force in the Y-direction was determined using the Equivalent Lateral Force (ELF) procedure, after which the equivalent seismic story forces and story shear forces were calculated. According to AISC 341-22, the design and detailing requirements for SCBF systems in regions of high seismic hazard (DD-2, SDC D) are governed by stringent provisions intended to ensure satisfactory structural performance and controlled collapse mechanisms. Therefore, the bracing configurations adopted along Grid Lines A–A and E–E were selected to achieve both code compliance and structural economy's 341-22 places restrictions on certain bracing configurations and requires additional design checks to account for unbalanced forces that may develop following brace buckling. In Chevron (V- or inverted V-type) bracing systems, when the compression brace buckles, the force carried by the tension brace generates a significant unbalanced vertical load at the beam intersection point. Consequently, capacity design requirements may lead to substantial beam overdesign. In contrast, the use of a two-story X-

brace configuration allows the tensile and compressive brace forces to balance each other at the connection region, thereby eliminating large, unbalanced forces acting on the beam and resulting in a more economical structural solution. Following this optimization strategy, the brace configuration and member sections were determined first. Subsequently, the brace-to-gusset plate connections, primary beam and column sections, and connection details were designed. The SCBF and BRBF systems located along Grid Lines A–A and E–E are illustrated in Figure 4. After completing the design of the SCBF system, the design of the BRBF system was undertaken. Accordingly, the geometric configuration of the bracing system was modified to better accommodate the unique seismic behavior and performance characteristics of BRBF structures.

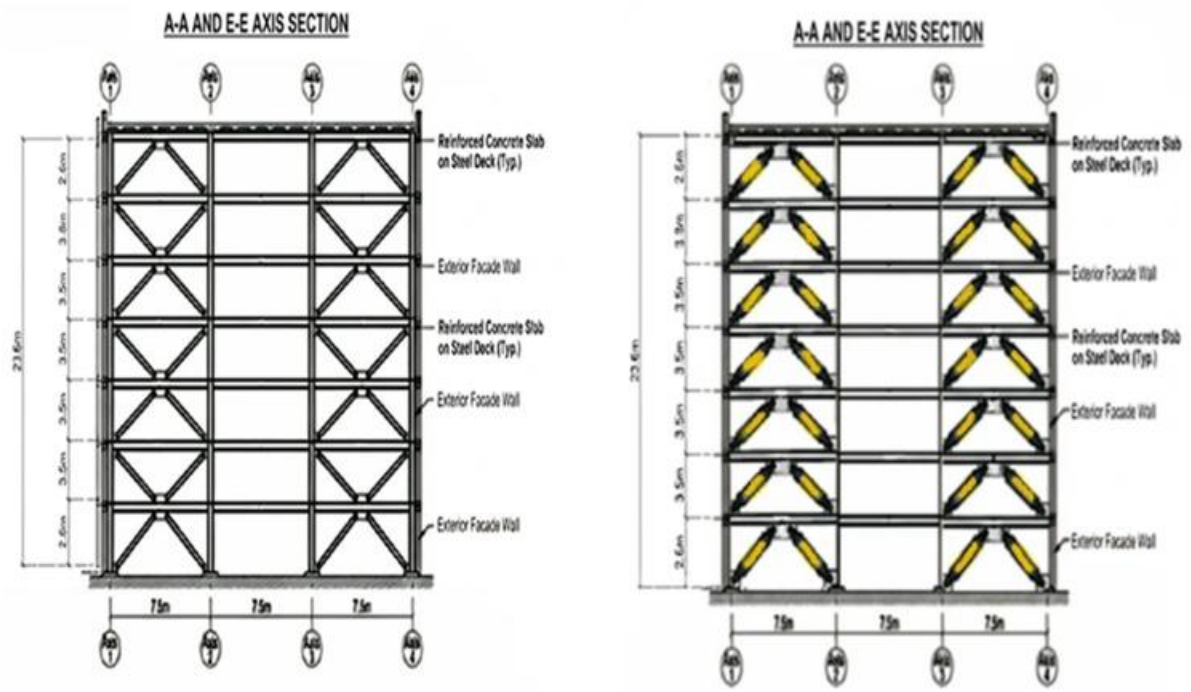

Fig. 4. (a) SCBFs located along Grid Lines A–A and E–E, and (b) BRBFs located along Grid Lines A–A and E–E.

The most significant characteristic of BRB members is their ability to maintain their load-carrying capacity under compressive loading without experiencing global buckling. In a Chevron-configured BRBF system, when one brace reaches its maximum compressive capacity while the opposing brace reaches its maximum tensile capacity, the forces acting at the beam–brace intersection largely balance each other. The remaining force imbalance, typically on the order of 10–15%, is transferred to the beam as an unbalanced vertical force. Consequently, beam sections can be substantially reduced compared to those required in conventional SCBF systems. To provide greater architectural flexibility, Chevron-configured BRBFs were employed in the exterior bays (Bays 1 and 3), while the middle bay was intentionally left unbraced. Although numerous BRB configurations have been proposed in the literature, a conventional BRB system was adopted in this study under the assumption that commercially manufactured BRB units would be procured. This configuration consists of a rectangular steel core encased within a hollow structural section, with the remaining void filled with concrete or mortar. Upon completion of the BRBF design, the brace-to-gusset plate connections were detailed, the primary beam and column sections were selected, and the beam-to-column connections were designed.

RESULT AND DISCUSSION

The analyses revealed significant differences between the SCBF and BRBF systems in terms of seismic force distribution and member sizing requirements. According to ASCE 7-22 (Table 12.2-1), the response modification coefficient (R) is specified as 6 for SCBF systems and 8 for BRBF systems. This difference indicates that BRBFs possess a higher ductility capacity and can dissipate seismic energy more effectively than SCBFs. Based on the Equivalent Lateral Force (ELF) procedure, the design base shear force was calculated as $4048.8\ kN$ for the SCBF system and $3036.6\ kN$ for the BRBF system. Therefore, replacing the SCBF system with a BRBF system resulted in a 25% reduction in the total seismic demand acting on the structure. This reduction directly decreased the seismic demands imposed on all primary structural members, including beams and columns, and enabled significant reductions in member sizes, leading to a more economical design while remaining consistent with capacity design principles. The selection of braced bays was considered a critical aspect of the design due to its influence on both torsional stiffness and architectural functionality. Providing braces in all three bays was expected to produce excessive lateral stiffness and increase overturning demands at the foundation level. To preserve architectural accessibility for corridors, doors, and windows while maintaining structural symmetry, braces were installed only in the exterior bays (Bays 1 and 3), whereas the middle bay (Bay 2) was left unbraced. Furthermore, placing the braces in the exterior bays maximizes the lever arm resisting overturning moments and consequently minimized uplift forces transmitted to the foundation. For the SCBF system, a two-story X-brace configuration was employed throughout the regular floors, while a Chevron configuration was adopted at the roof level where gravity load demands were relatively lower. In contrast, the principal advantage of BRB members lie in their nearly identical tensile and compressive capacities. Owing to this stable hysteretic behavior, considerably more flexible architectural configurations can be achieved without generating large, unbalanced forces in beams. Accordingly, BRB members were also placed in the exterior bays (Bays 1 and 3), while the middle bay remained unbraced for the same structural and architectural reasons adopted in SCBF design. A Chevron bracing configuration was selected for all stories because it provides symmetric lateral stiffness and offers significant practical advantages in fabrication and erection due to the simplicity of the central beam–brace connection. In the SCBF system, the maximum story shear force occurred at the first story. Consequently, the seismic demands acting on the first-story braces governed the brace design. The required axial design force for the first-story braces was determined as $P_u = 692.3\ kN$. Hollow Structural Sections (HSS) with square geometry were selected because they provide identical buckling resistance about both principal axes. An HSS 150×150×10 section was initially chosen as the trial brace section. Subsequent evaluations performed in accordance with AISC 341-22, including axial compression resistance, axial tension resistance, and seismic compactness (local slenderness) checks required for highly ductile members, demonstrated that the selected HSS 150×150×10 section satisfied all applicable limit-state requirements. Unlike conventional brace design in SCBF systems, the steel core areas of BRB members can be adjusted with high precision according to the reduction in story shear forces along the building height. This capability enables highly efficient material optimization. The variation of story shear forces (V_x), steel core cross-sectional areas (A_{sc}), and the dimensions of the square HSS casing sections used as the BRB restraining units throughout the building height are summarized in Table 1.In accordance with the capacity design provisions of AISC 341-22, the maximum expected tensile and compressive strengths of each BRB were calculated based on the selected steel core areas. These calculations incorporated the effects of the strain-hardening adjustment factor ($\omega = 1.4$) and the compression strength adjustment factor ($\beta = 1.15$), thereby accounting for the expected inelastic behavior of the BRB members during severe seismic loading.

Table 1. Cross-sectional distribution of BRB members per story

Story	Story Shear Force ($Vx - kN$)	SC Area ($Asc - (mm^2)$)	SC Plate ($w \times thk - mm$)	SHS outer Casing Dimensions (mm)
7 (roof)	682.2	500	50×10	100×100×5
6th	1396.5	1200	60×20	120×120×6
5th	1975.4	1600	80×20	140×140×6
4th	2423.0	2000	80×25	140×140×6
3rd	2744.3	2250	90×25	150×150×8
2nd	2945.8	2400	100×25	150×150×8
1st	3036.6	2500	100×25	160×160×8

According to the requirements of AISC 341-22, beam design in the SCBF system was categorized into two distinct groups. The first category consisted of beams located in the unbraced middle bay, where the design was governed primarily by gravity loads (dead and live loads). The second category comprised beams located within the braced exterior bays, where design was controlled not only by gravity loads but also by the net unbalanced force transferred to the beam following the buckling of one of the brace members.This concentrated force acting at the beam midpoint generated significant shear forces and bending moments. Although the use of a two-story X-brace configuration effectively reduced force imbalance in the typical stories, the maximum unbalanced force occurred at the roof level where a Chevron bracing configuration was employed. To satisfy these seismic demands, HEB sections, which possess greater cross-sectional area and superior lateral buckling resistance than slender IPE profiles, were selected. For the middle-bay beams (Category 1) and the braced-bay beams in the regular stories (Category 2), HEB 300 sections satisfied all LRFD strength and serviceability requirements. However, for the Chevron-braced roof beam, the excessive unbalanced vertical force ($P_{ub} = 558\,kN$) resulting from one brace reaching its yielding capacity while the opposing brace buckled necessitated the use of an HEB 600 section. Like the SCBF design, beam design in the BRBF system was also divided into two categories in accordance with the capacity design provisions of AISC 341-22. The primary function of the middle-bay beams (Category 1) was to support gravity loads from the floor system and to act as collectors transmitting diaphragm-induced seismic forces to the braced exterior frames. Although HEB 240 sections were found to be adequate when only bending demands were considered, HEB 300 sections were ultimately selected as a standard solution to ensure sufficient stability and reliable transfer of the large axial collector forces generated through beam-column interaction. Even though gravity loads were lower at the roof level, HEB 300 sections were retained in the middle bay to ensure adequate diaphragm force transfer. According to the capacity design philosophy of AISC 341-22, beams located within braced bays are not designed directly for seismic forces; instead, they are proportioned to resist gravity loads together with the net unbalanced vertical forces generated by the connected BRB members at their expected capacities. Consequently, the exterior-bay beams in the regular stories were designed to resist both floor loads and the unbalanced vertical forces associated with the Chevron-configured BRBs. The largest unbalanced vertical force ($P_{ub} = 117.8\,kN$) occurred in the first-story beam. To accommodate the resulting bending and shear demands, an HEB 340 section was selected. At the roof level, however, both the gravity loads and the story shear force were significantly reduced, resulting in smaller BRB capacities and correspondingly lower bending demands. Therefore, an HEB 240 section was found to provide adequate strength for the roof beam. Column design in SCBF systems represents one of the most demanding consequences of the AISC 341-22 capacity design philosophy in terms of structural weight. SCBF columns must

remain stable and capable of resisting the maximum axial forces transmitted through the brace connections after brace yielding and buckling during severe seismic events. To model this critical condition, AISC 341-22 requires seismic loads to be amplified by the system overstrength factor ($\Omega_0 = 2.0$) and included in the governing load combinations. The analyses revealed that the amplified seismic loading condition ($\Omega_0 \, P_{EQ}$) generated extremely large axial compression demands, reaching $6118\,kN$ in the first-story exterior columns. To satisfy the global buckling resistance requirements (KL/r_y) and seismic compactness limits prescribed for highly ductile members ($\lambda_h d$), the use of heavy HEM 400 sections became necessary. The superior energy dissipation capability of the BRBF system results in a higher response modification coefficient ($R = 8$), thereby significantly reducing the design base shear force acting on the structure. Nevertheless, AISC 341-22 requires an even larger overstrength factor ($\Omega_0 = 2.5$) to ensure that columns remain elastic when BRB members develop their maximum expected tensile (T_{max}) and compressive (P_{max}) capacities during severe earthquakes. Despite this stricter overstrength requirement, analyses conducted under the amplified seismic load combination ($\Omega_0 \, P_{EQ}$) indicated that the maximum axial compression demand in the first-story exterior columns was $5833\,kN$, which remained lower than that obtained for the SCBF system. Consequently, HEM 360 sections were sufficient to satisfy both the global buckling resistance requirements (KL/r_y) and the seismic compactness criteria for highly ductile members without compromising structural safety or seismic performance. The findings clearly demonstrate that BRBF systems, owing to their superior energy dissipation capabilities, provide a more robust, reliable, and efficient structural solution for both the design of new steel buildings and the seismic retrofitting of existing structures, particularly in regions exposed to high seismic hazard. Furthermore, the substantial reductions achieved in beam and column sizes highlight the significant economic advantages that can be realized through the adoption of BRBF systems while simultaneously improving seismic resilience and post-earthquake functionality.

The Effect of Steel Fiber Length and Content on the Some Flexural Behavior Properties of the High-strength Concrete Beams

Hamdi ÖZTÜRK[1]
[1] 0000-0003-1015-2932, Karadeniz Technical University, Trabzon Vocational Collage, Trabzon, Türkiye
hozturk@ktu.edu.tr

Abstract. It is well known that the brittleness with low tensile strength and strain capacities of high-strength concrete (HSC) can be overcome by the addition of steel fibers. This paper presents research results of ten high-strength steel fiber concrete beams with steel fiber content of 0.75% and 1% (59 and 78 kg/m^3) by volume. Hooked-end and straight steel fibers with two different length (50 mm and 60 mm) were selected. This research shows that length and volume of steel fibers have significant effect on the load carrying capacity, flexural displacement, maximum strains, energy dissipation capacity, rigidity, and ductility.

Keywords: Flexural behavior, High strength concrete, Steel fiber

1 Introduction

Fiber-reinforced concrete is increasingly being used in civil engineering and taking importance as a structural material. Therefore, there is significant amount of research being carried out to investigate the effect of adding fibres to HSC. The toughness of fibre-reinforced concrete (FRC) materials can be considered as their energy absorption capacity, which is usually characterized by some portion of the area under the load-displacement curve obtained during a flexure test.

A lot of researchers, depending on Romualdi's works [1-2], have showed the usage of the steel fibers in industrial area, at the beginning of 1960. Swamy [3], showed that the addition of steel fibers improves tension, compression, flexural, and first cracking strength of the concrete. Taylor et al.[4], investigated the changes in the strength and toughness of traditional and high strength concrete including steel fibers. They implied that the effects of using steel fiber in the traditional and high strength concrete are similar. Aarup and Jensen [5], showed the possible ductility in the concrete by using short and heavy steel fibers. Materschlager and Bergmeister [6], presented the benefits of the using steel fiber in civil engineering. They investigated some mechanical properties of steel fiber concrete such as changes of ductility, compression and tensile strengths. They implied that using steel fiber-reinforced concrete provides affirmative results on the construction in the seismic areas. Ashour and Wafa [7], implied that using steel fibers in the concrete decreases the crack width while increases the crack number. They observed increasing ductility and delaying ultimate crushing in the concrete. They also implied that dispersion of fibers affects the crack propagation and development and that steel fibers increase the length of plastic hinges. Casanova et al., [8], made some experimental studies investigating the first cracking stress and tensile strength. According to their work, steel fibers increase the tensile strength capacity, which could be explained by the formation of micro cracks and progressing macro cracks. Özyurt et al., [9] showed that steel fiber aspect ratio and content made significant effect on the behavior after the peak stress. Fractural energy enhanced using increasing hooked-end steel fiber. Öztürk [10], Öztürk and Ayvaz [11-13], investigated the flexural behavior of steel-fiber high performance concrete beams. It was showed that steel fibers have significant effect on the load carrying capacity, displacement, maximum strains, energy dissipation capacity, rigidity change, and ductility. Chunxiang and Patnaikuni [14]

implied that the addition of steel fibers can also reduce the deflection of reinforced high strength concrete beams and improve post-cracking behavior significantly.

In this study, it was worked about flexural behavior of test beams made of steel fiber concrete have no reinforcing bars. So, after the work it was able to understand the flexural properties of steel fiber high-strength concrete beams and to compared in as much as for the load carrying capacity, displacement, load-strain variation, energy dissipation capacity, rigidity change, and ductility each other and with non-fibrous concrete beams.

2 Experimental Work

2.1 Materials

Ordinary Portland cement conforming to TS EN 19 [15], with a 28-day compressive strength of 42.5 MPa, crushed limestone sand and aggregate with maximum size of 16 mm, tap water for mixing and curing were used. Silica fume used was a commercially available with a specific gravity of 2.2, a bulk density of 6.0 kN/m^3, and a specific surface of 23 m^2/g, which improved concrete properties in fresh and hardened states. To improve the workability of concrete, a high-range water-reducing admixture (superplasticizer) was employed during mixing operation. The cement, silica fume, water, superplasticizer, crushed limestone sand and aggregate of 500, 50, 150, 13.75, 740 and 903 kg/m^3 were used to make HSC. The slump of the concrete with water/binder (W/B) ratio of 0.27 was 80 mm. Round, hooked-end and straight steel fibers having tensile strength of 1100 MPa were used in this study. The fibers have an average length of 50 and 60 mm with the two volume fractions of 0.75% and 1%. These fibers were available in bundles of about 30 fibers, which were fibrillated with water-soluble glue to ensure immediate dispersion in concrete during mixing.

2.2 Preparation of steel fiber concrete and testing beams

The dry cement and aggregates were mixed for 1 min. in a 0.06 m^3 laboratory mixer. The mixing was continued for further 1 min. while about 80% of water was added. The mixing was continued for another 1 min. and the fibers were then added continuously to the mixer for a period of 2-3 mins.. Finally, the remaining water (or remaining water including super plasticizer) was added and the mixing was continued for an additional 2 mins.. The freshly mix steel steel fiber-reinforced concrete was placed in two equal layers into a beam mold to cast the testing beams for a flexure strength test. Each layers was consolidated using a external vibration. At the end of 24 h after consolidating, the specimen was removed from the mold and cured in laboratory conditions for 28 days. And then flexure tests were performed.

The series of non-fibfous concrete beams (S1), concrete beams (S2) including steel fiber having length of 50 mm with the volume fraction of 0.75%, concrete beams (S3) including steel fiber having length of 60 mm with the volume fraction of 0.75%, concrete beams (S4) including steel fiber having length of 50 mm with the volume fraction of 1%, and concrete beams (S5) including steel fiber having length of 60 mm with the volume fraction of 1% were tested in the experimental study. Each testing beams series, listed in Table1, contains two beams, which have identical cross-section. All the beams have a constant cross-section of 100 mm x 200 mm (width x height) and constant length of 2100 mm. For the purpose of having the same quality concrete, the same concrete mix were used in the production of all test beams produced at different times. Furthermore, it was observed that small changes in concrete compressive strength occurred because of different casting. The average concrete compressive strength was approximately 60 MPa.

Table 1. Steel fiber properties of the test beams

Beam series	Steel fiber	
	Length (mm)	Volume fractions (%)
S1	-	-
S2	50	0.75
S3	60	0.75
S4	50	1
S5	60	1

2.3 The test set-up

The testing beams were simply supported at the both ends and subjected to two-point loads. The distance between the two-point loads was kept constant to be 560 mm. The test set-up used for loading the beam is shown in Figure 1. In this test set-up, the test beams were loaded with increment of 1 kN load by controlling load magnitude. Loading was applied until the load carrying capacity of the test beams was exceeded. In this test set-up, the load is applied to the beam by means of a 200-kN hydraulic testing machine and a dial gauge determines the displacement at the center of the axial line of the test beams. At the end of each load increment, observations and measurements were recorded for the midspan deflection, straingauge readings, and crack development and propagation on the beam surfaces.

Fig.1. A view from the test set-up

3 Results and Discussion

The results obtained from the test beams are given in the following subsections in tables and graphs to compare the results of the beams including the steel fibers having different length and volume fractions with each other and with the results of S1. The comparisons are made separately for the load carrying capacity, displacement, load-strain variation, energy dissipation capacity, rigidity change, and ductility.

3.1 Load-displacement

In this study, high strength non-fibrous concrete beams and steel fiber high-strength concrete beams subjected to flexure were investigated. For the test beams, average loads and displacements at first cracking, at the peak, and at failure are given in Table 2. Load-displacement curves of the test beams including steel fiber are seen in Figure 2.

Table 2. Applied loads and corresponding displacement of the test beams

Test beams	Load (kN)			Displacement (mm)		
	at first cracking	at peak	at failure	at first cracking	at peak	at failure
S1	5.7	5.7	5.7	-	-	-
S2	6.1	6.7	4.3	2.3	3.9	6.4
S3	7.2	8.2	3.8	2.3	6.8	25.4
S4	6.8	7.9	5	2.4	4.6	7.6
S5	8.7	11.2	3.9	2.5	8.2	32

As seen from Table 2 and Figure 2, the load carrying capacities of fibrous concrete beams increase with increasing fiber volume at the first cracking, at the peak, and at failure. Load carrying capacities of S3 and S5 beams are higher than those of S2 and S4 beams, except at failure. Test beams with long fiber were able to carry flexure loads more than those of the test beams with short fiber. So, S3 and S5 beams continued to carrying decreasing loads from peak point to failure. As also seen from the same table and figure, displacements of fibrous concrete beams are almost the same at the first cracking. The displacements of S3 and S5 beams are higher than those of the S2 and S4 beams. In other word, displacement of test beams with long fiber are higher than those of the test beams with short fiber. Displacements of fibrous concrete beams increase with increasing fiber volume at the peak load, and failure.

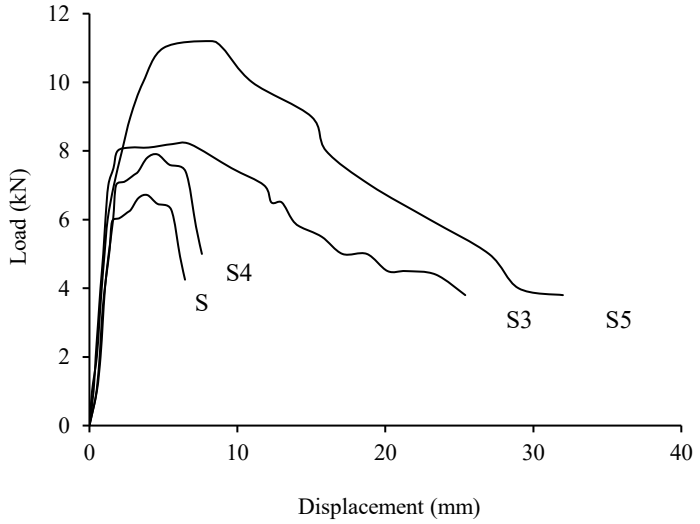

Fig. 2. Load-displacement curves of S2, S3, S4, and S5

3.2 Load-strain

In this study, strains at the center of bottom and top faces of the beams were measured. For the test beams, maximum strains are given in Table 3.As seen from Table 3, the strains of concrete beams increase with increasing steel fiber volume fraction and the fiber length. These strains are higher than that of non-fibrous concrete beam. Maximum strains of concrete beams with long fiber are higher than those of concrete beams with short fiber. Strains of the concrete at the top faces of the beams (compression strains) are higher than those of the concrete at the

bottom faces of the beams (tension strains). The test beams without fiber collapse suddenly after first crack occur, the test beams with fibers do not collapse after the first crack occur. They behave in a ductile manner. That means that steel fibers change the failure pattern of concrete beams from brittle to ductile.

Table 3. Maximum strains of top and bottom faces of concrete beam

Test beams	S1	S2	S3	S4	S5
Strain at the bottom face of beam (10^4 ε)	0.55	1.6	1.8	2.6	3.7
Strain at the top face of beam (10^4 ε)	0.60	1.80	3.30	4	4.3

3.3 Energy dissipation capacity

The energy dissipation capacities of the test beams were determined by calculating the area under the load-displacement curve for each beam. The energy dissipation capacities of the all test beams including steel fibers are given in Table 4.

Table 4. Energy dissipation capacities of the test beams

Test beam	Energy dissipation capacity (kN.mm)
S2	11.50
S3	47
S4	15.50
S5	73.50

As seen from Table 4, energy dissipation capacities of the test beams with long fiber are higher than those of the test beams with short fiber. Energy dissipation capacities of the test beams increase with increasing steel fiber volume fractions. Energy dissipation capacity of S5 is 56.4% higher than that of S3 with respect to that of S3. Energy dissipation capacity of S4 is 34.8% higher than that of S2 with respect to that of S2. Energy dissipation capacity of S3 is 308.7% higher than that of S2 with respect to that of S2. Energy dissipation capacity of S5 is 374.2% higher than that of S4 with respect to that of S4.

3.4 Rigidity change

Rigidity is defined and obtained as the slope of the line drawn from the origin of the load-displacement curve to the intersection of the horizontal line drawn from load chosen with the load-displacement curve. Rigidities of the test beams at the origin, at the first cracking, at the peak, and at failure and decreases in rigidity up to the first cracking, peak, and failure with respect to rigidity at origin are given in Table 5.

As seen from Table 5 and Figure 2, all test beams have the same rigidities at the origin. The rigidities of the fibrous test beams are close to each other for each steel fiber length at the first cracking, at the peak, and at failure. Decreases in rigidities are almost at the same level for each of steel fiber length up to peak load, and failure, except up to the first cracking. The test beams including long fiber lost more rigidity than the test beams including short fiber up to peak and failure, but the test beams including long fiber lost less rigidity than the test beams including short fiber up to the first cracking.

Table 5. Rigidity variations of the test beams

Test beams	Rigidity (kN/mm)				Decrease in rigidity (%)		
	At origin	At first cracking	At peak	At failure	To first cracking	To peak load	To failure
S1	4.2	-	-	-	-	-	-
S2	4.2	2.652	1.718	0.665	36.86	59.09	84.17
S3	4.2	3.130	1.205	0.149	25.48	71.31	96.45
S4	4.2	2.833	1.717	0.658	32.54	59.11	84.33
S5	4.2	3.480	1.374	0.122	17.14	67.28	97.09

Decrease in rigidities of the all test beams change between 17.14% and 36.86% from origin to the first cracking, between 59.09% and 71.31% from origin to peak load, and between 84.17% and 97.09% from origin to failure.

3.5 Ductility

Ductility is one of the main parameters of a structural member under flexure, because the different types of failure patterns for these members are dependent on the reinforcement ratio, and the end restraints.

It is well known that ductility can be expressed by the ductility coefficient. In this study, ductility coefficients given in Table 6 were determined as the ratio of displacement at failure to the displacement at the first cracking. These displacements are determined at the mid-point of the axial line of the test beams. As seen from Table 6, the ductility coefficients take the values from 1 to 12.8. As also seen from this table, the ductility coefficients of the test beams with fibers are larger than those of the test beams without fibers. The same coefficients of the test beams with long fiber are larger than those of the test beams with short fiber.

Ductility coefficients of S2, S3, S4, and S5 are 178%, 1004%, 217%, and 1180% higher than the ductility coefficient of S1, respectively, with respect to ductility coefficient of S1. Ductility coefficient of S5 is 15.94% higher than that of S3 with respect to that of S3. Ductility coefficient of S4 is 14.02% higher than that of S2 with respect to that of S2. Ductility coefficient of S3 is 297.12% higher than that of S2 with respect to that of S2. Ductility coefficient of S5 is 303.78% higher than that of S4 with respect to that of S4.

In addition, steel fibers at the compression zone have delayed the crushing of concrete. So, the test beams including steel fibers can carry additional flexural loads depending on steel fiber volume fractions. Therefore, these test beams displace more up to failure. This means that, as mentioned before, steel fibers change the failure pattern of concrete beams from brittle to ductile.

Table 6. Ductility coefficients of the test beams

Test beams	Displacement at first cracking δ (mm)	Displacement at failure δ_u (mm)	Ductility coefficient δ_u/δ
S1	-	-	1*
S2	2.3	6.4	2.78
S3	2.3	25.4	11.04
S4	2.4	7.6	3.17
S5	2.5	32	12.80

* Since S1 collapses when the first cracking occurs, $\delta_u = \delta$.

4 Conclusions

The main conclusion drawn from the results obtained in this study are given below.

1. Load carrying capacities of the test beams including long fiber are higher than those of the test beams with short fiber. Load carrying capacities increase with increasing fiber content.
2. The displacement of the test beams decreases with increasing steel fiber volume. The maximum displacement of the test beams with long fiber are higher than those of the test beams with short fiber at the peak and the failure.
3. Strains of the test beams increase with increasing steel fiber length and volume fraction. These strains are higher than that of non-fibrous concrete beam.
4. Energy dissipation capacities of the test beams with long fiber are higher than those of the test beams with short fiber and energy dissipation capacities of the test beams increase with increasing steel fiber volume fractions.
5. The test beams including long fiber lost more rigidity than the test beams including short fiber up to peak and failure, but the test beams including long fiber lost less rigidity than the test beams including short fiber up to the first cracking.
6. Test beams with long fiber showed more ductile behavior.

Acknowledgments

The Effect of Rigid Basement Shear Walls on Seismic Behaviour of Reinforced Concrete Structures according to TBEC 2018

Hurmet Kucukgoncu[1]
[1] 0000-0001-5148-8753, Abdullah Gül University, Civil Engineering Department, Kayseri, Türkiye, hurmet.kucukgoncu@agu.edu.tr

Abstract. Some buildings are designed with a basement in the architectural plan for various reasons. Since structures with a basement are directly connected to the soil, the interaction between the structure and the soil must be considered when analysing such structures. Thus, interactions between the structure and soil that significantly affect the structure should be considered in the analysis. Therefore, it is common practice to construct rigid shear walls around basement floors. In this application, the seismic behaviours are decoupled due to the rigidity of the basement walls and the higher flexibility of the superstructure relative to the basement floors. However, since the superstructure and basement floors are components of the same structure, they are structurally interconnected and dynamically interact. In the latest Turkish Building Earthquake Code 2018 (TBEC 2018), the calculation steps for structures designed with rigid basement walls differ, including the earthquake load reduction coefficients. For this reason, the building designed as a dual functional structural system with rigid basement shear walls, and the dual functional building designed without rigid basement shear walls were analysed using the mode superposition method in SAP 2000 software according to the TBEC 2018 provision. Both buildings have the same architectural and floor plan. Seismic properties, including period, frequency, interstory drift, storey displacements, storey shear forces, and base shear forces, obtained for both buildings were compared. As a result of the comparisons, rigid shear wall basements contributed positively to both the usable architectural space and seismic performance of the building.

Keywords: Mode superposition method, Rigid basement shear wall, Seismic behaviour, TBEC 2018

1 Introduction

Numerous reinforced concrete buildings feature basements for functional purposes like parking, machinery, storage, or shelter in Türkiye. Basement floors are surrounded by rigid shear walls for architectural and structural reasons, such as retaining the soil around the designed basement floors. Due to the rigid shear walls added to the basement floor, the strength, rigidity and seismic behaviour of the basement floors and the relatively more flexible superstructure are different from each other [1]. For this reason, although the substructure and superstructure of such buildings interact with each other through connections in earthquake codes, the Load-Bearing System Behaviour Coefficient (R) and the Excess Strength Coefficient (D), which are defined based on ductility, are considered at different values for the superstructure and the more rigid basements. Therefore, the specific design rules and foundational criteria regarding the calculation of structures with rigid shear wall basements are officially prescribed within the Turkish Building Earthquake Code 2018 (TBEC 2018) [2]. According to TBEC 2018 [2], structural analysis of configurations with basements can be conducted via the equivalent lateral seismic force technique or modal superposition methodologies; within this framework, the lower substructure and upper framework are modelled independently prior to their combined

evaluation. In this context, several studies have been conducted on modelling, design, and analysis of buildings with rigid basements [1,3-14]. Previous research on rigid basements shows their direct effects on the seismic behaviour of [4, 5, 8, 13]. Buildings with basements reduced the damage caused by earthquakes [4], and basement walls were shown to reduce roof or top displacements and base shear forces under seismic forces [5, 8, 13]. Furthermore, it was observed that the ductility demand was reduced and the effect of soft storey damage was lower [5]. In terms of load bearing, deformation, and practical usage, designing a basement in high-rise buildings provides significant advantages [13].

Different modelling approaches and seismic codes have been evaluated for structures with basements [1, 3, 9, 11, 14]. While these approaches minimally affected the superstructure's natural vibration period, variations occurred in storey shear forces and relative drift ratios [3]. Some studies performed response spectrum and time history analyses incorporating structure-soil interaction [8, 14], noting that nonlinear dynamic time history analysis factoring soil properties offers the most realistic approach. To model and design structures with rigid basements, previous studies evaluated international or national seismic codes, proposing distinct evaluation techniques, two-stage analyses, or complementary modal methods [1, 9, 11]. The seismic behaviour of high-rise buildings with large basement floors, common podiums, or shared basements with neighbouring buildings was also demonstrated [6, 7, 10]. Experiments and analyses reported that in order to obtain the seismic behaviour envelopes, the structure should be modelled and analysed separately and together with the common podium floors [6], or modelled together with neighbouring buildings [10]. Additionally, a single-tower model featuring partially fixed end restraints was found to overestimate internal forces within the podium floors [7]. Investigating the location and quantity of basement shear walls revealed that seismic wall moments decreased as more rigid basement walls were added [12].

As demonstrated, literature includes various studies evaluating basement-supported structures. Especially with the analysis methods added to TBEC 2018 [2] regarding structures with basements, studies in this direction have gained momentum. Conversely, existing literature predominantly examines the seismic response of deep-basement high-rise structures [3, 6, 10, 13] or relies on outdated seismic codes [1, 4]. Although TBEC 2018 is considered in some research [11], its application on low-to-medium rise buildings remains limited. However, low-to-medium rise buildings with the basements were investigated according to the older seismic codes [4]. This study examines seismic behaviour in a 5-storey building designed per TBEC 2018 [2]. The effects of rigid basement wall on the structural behaviour of a low-rise building, which was commonly found in the building stock located on a dangerous earthquake zone, were investigated after it was designed with rigid basement walls in the study. The differences between models with and without basements are analysed to evaluate the current code requirements for typical multi-storey structures. The mode superposition method was used among the different methods proposed for the analysis of rigid basement shear walls in TBEC 2018 [2]. Consequently, structural response parameters such as period, top displacement, storey shear forces, and interstory drifts were evaluated and compared for buildings with and without rigid basement shear walls.

2 Material and Method

In accordance with the Turkish Building Earthquake Code 2018 [2], this investigation models and analyses two structural systems that are architecturally identical, contrasting a building with rigid basement shear walls against a reference building without them.

2.1 TBEC 2018 Approach

To design structures with rigid basements, TBEC 2018 incorporates linear methods based on a two-stage analysis. Initially, the rigid basement is modelled as massless, whereas the superstructure retains its mass, which is exclusively considered in the first seismic analysis. The

Structural System Behaviour Coefficient, R_{top}, is used for the superstructure's seismic force calculation. During the subsequent stage, the superstructure is assumed massless, while the rigid basement is modelled including its own mass. Consequently, the analysis considers solely the mass of the rigid basement. According to the structural characteristics of the subsystem, seismic forces for the rigid basement are determined utilizing the behaviour coefficient R_{bottom} [2]. Subsequently, vertical and horizontal forces transferred from the superstructure are added to the rigid basement seismic forces calculated in this way.

First, the building base and height of rigid basement shear walls must be determined according to TBEC 2018 [2]. When both criteria (a) and (b) are fully satisfied, the building base is taken at the slab level right above the basement walls. Otherwise, this base level must be shifted down to the top of the foundation [2].

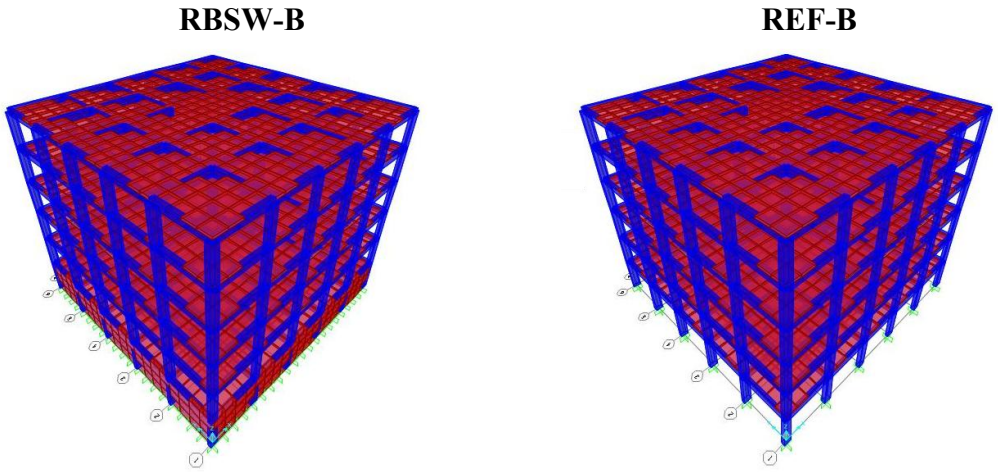
(a) The structural perimeter is enclosed by rigid basement walls on all sides or a minimum of three sides.

(b) In the dominant vibration mode along each orthogonal axis, the natural period computed for the complete structure ($T_{p,all}$) does not exceed 1.1 times the period obtained by neglecting all basement masses ($T_{p,top}$), satisfying the condition ($T_{p,all} \leq 1.1\ T_{p,top}$).

Two different Structural System Behaviour Coefficients (R) and Excess Strength Coefficients (D) are considered for the substructure and superstructure. The Seismic Load Reduction Coefficient (Ra) is calculated using *Equation 1* and *2*, where I is the Building Importance Coefficient, T is the natural period, and T_B is the spectrum corner period:

$$R_a(T)=\frac{R}{I} \qquad T>T_B \qquad (1)$$

$$R_a(T)=D+\left(\frac{R}{I}-D\right)\frac{T}{T_B} \qquad T\leq T_B \qquad (2)$$



Under these conditions, seismic analysis can employ either the mode superposition method or the equivalent lateral seismic force technique or mode superposition method. Since the mode superposition method is used in this study, its specific steps within the two-loading approach where the upper and lower sections are modelled together as a single system but analysed separately due to stiffness and vibration mode differences are detailed below [2]:

For the first loading scenario, the mode superposition method is applied considering only the superstructure masses. To establish a sufficient number of vibration modes, the effective mass participation ratios corresponding to the superstructure's total mass are evaluated. $(R_a)_{top}$ is calculated using R_{top} and D_{top}. Reduced internal forces are determined for both sections, and the superstructure design is conducted based on these forces for ductile behaviour. To accommodate non-ductile structural actions, the internal forces determined for the superstructure are amplified by D_{top}. These forces are amplified by the second order and equivalent base shear force amplification factors, if necessary [2].

For the second loading scenario, the superstructure is assumed massless, whereas the rigid basement is modelled with its own mass. To establish the number of vibration modes, evaluation relies on the effective mass participation ratios of the basement. $(R_a)_{bottom}$ is calculated by taking $R_{bottom}/I = 2.5$ and $D_{bottom} = 1.5$. To address the ductile performance of sub-grade components, design action values are established by superimposing the second-stage loading responses onto the forces extracted from the lower substructure during the initial loading phase. In the case of non-ductile behaviour, design forces are determined by combining the second loading forces amplified by D_{bottom} with the first loading lower section forces scaled by $0.6D_{top}$ [2].

2.2 Numerical Method

In this study, a building with 1 basement storey and 5 normal storeys was designed and analysed as rigid basement shear walls and without rigid basement shear walls (reference building). Throughout the study, the building with rigid basement shear walls is called RBSW-B and the building without rigid basement shear walls analysed as reference is called REF-B. The structures are identical in terms of both architectural plan, load-bearing system members, dimensions, reinforcement diameters, and amounts. The illustrations of both models are given in *Fig. 1*. The only difference is the rigid shear walls surrounding the basement floor on four sides. The reinforced concrete bearing system of the structure consists of frames and walls surrounding the core on three sides and is a dual functional bearing system. Along each orthogonal axis (x and y), the configuration comprises a total of 6 axes and 5 spans. The length between the axes in both directions is 4m. Both orthogonal plan dimensions of the structure measure 20 m. A uniform thickness of 300 mm is utilized for both the peripheral basement walls and the central core shear walls. A slab thickness of 15 cm is defined, with gravity loads specified as 2.5 kN/m² for dead load, 2.0 kN/m² for live load, and a roof-level snow load of 0.75 kN/m². The concrete class is C30/35, the reinforcement class is S420. The storey height is 2.85m. Since the condition of $T_{p,all} \leq 1.1T_{p,upper}$ given for buildings with rigid basements in TBEC 2018 [2] is met, the total height of the building is considered as 14.25 m. Column dimensions are 300x600 mm^2 and the column longitudinal reinforcement ratio is 0.0183. Beam dimensions are 300x500 mm^2 and the beam longitudinal reinforcement ratio is 0.0071. Dimensions and reinforcement arrangements of column and beam elements are given in *Fig. 2*.

Rigid Basement Shear Wall Building Reference Building

Fig.1. Building with rigid basement shear walls and building without rigid basement shear walls (reference) model.

Longitudinal Rebars: 10Ø20
Transverse Rebars: Ø10/100

Longitudinal Rebars: 5Ø16 (bottom) and 3Ø12 (top)
Transverse Rebars: Ø8/100

Fig. 2. Dimensions of the structural members' elements and reinforcement arrangements.

For the building models, the dimensions of all bearing members were selected by performing preliminary dimensioning calculations to meet the requirements of TBEC 2018 [2] and TS 500-2000 [15]. After the analyses using the SAP 2000-v22 [16], there is an A1 building irregularity in both directions and a B2 irregularity in the y-direction. In addition, the interstory drifts and second-order effects in the structure were also checked, and the necessary conditions were provided. The floor slabs were modelled as rigid diaphragms. To comply with TBEC 2018 [2], effective stiffness modifiers for the reinforced concrete structural components were also integrated into the software. Subsequently, mode superposition method was performed on the structural models in accordance with the TBEC 2018 [2] framework. *Table 1* presents the seismic parameters and response spectrum values of the building bearing system models.

Table 1. Seismic design parameters and response spectrum values.

Parameter and Definition	**Value / Coefficient**
Earthquake Ground Motion Level	DD2
Local Soil Class	ZC
Soil Parameters (T_A&T_B)	T_A = 0.0688 sn, T_B = 0.3439 sn
Seismic Coefficients (SDS&SD1)	SDS = 1.291g, SD1 = 0.444g
Building Classification	BKS = 3, I = 1, DTS = 1, BYS = 6
Bearing System Behaviour Coefficient (R)	R_{upper} = 7, $R_{basement}$ = 2.5
Excess Strength Coefficient (D)	D_{upper} = 2.5, $D_{basement}$ = 1.5
Sae - Elastic Superstructure (g)	Sae(T(x)) = 0.7274 g, Sae(T(y)) = 1.0176 g
Ra - Superstructure	Ra(T(x)) = 7, Ra(T(y)) = 7
SaR - Superstructure (g)	SaR(T(x)) = 0.1039 g, SaR(T(y)) = 0.1454 g
SaR - Basement (g)	$SaR_{basement}$ (T) = 0.2066 g

Assuming the structures are located in Istanbul's Bakırköy district, design spectrum parameters and spectral acceleration coefficients were derived based on this coordinate using data from the AFAD Turkish Earthquake Hazard Maps Interactive Web Application [17]. Spectrum curves were generated following the computation of both the horizontal elastic and reduced design spectral acceleration values. Separate reduced design spectra required for the modal superposition analysis were constructed for both the superstructure and the lower rigid basement section. Thus, the reduced design acceleration spectra obtained for the lower part and superstructure sections of the structure according to TBEC 2018 [2] are given comparatively in *Fig. 3*.

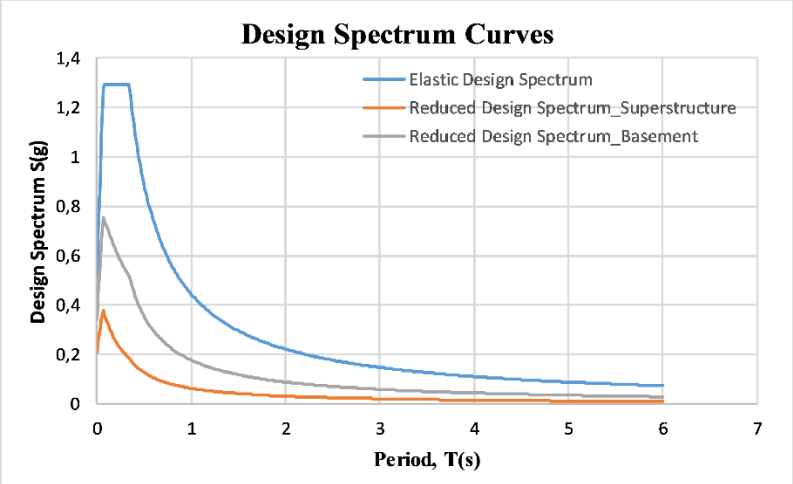


Fig. 3. Design acceleration spectra: elastic and reduced curves.

As mentioned above, both building models were created with the SAP 2000-v22 [16] software according to the mode superposition method principles within TBEC 2018 [2]. First, the first-case earthquake loading of the rigid basement shear wall building was performed. In this case, the modal analysis was performed with the help of the reduced design acceleration spectrum obtained for the superstructure in *Fig. 3*, with the upper section of the building having mass and the lower section having no mass. Then, the second-case earthquake loading was performed with the upper section of the building having mass and the lower section having mass. In this case, modal analysis was performed with the help of the reduced design acceleration spectrum obtained for the lower section in *Fig. 3*. Load combinations on the structure models were created separately for the design issues to be made according to ductile and non-ductile behaviour, considering the loading in both cases.

3 Results and Discussion

To evaluate the structural performance under both seismic directions and loading cases, numerical analysis yielded critical parameters—including period, frequency, top displacement, interstory drift, alongside storey and base shear forces—for both the reference structure and the model with rigid basement shear walls. The results obtained from the rigid basement shear wall building were shown with the name RBSW-B, and the rigid basement shear wall building analysed as the reference was shown with the name REF-B.

3.1 Building Period and Frequency

The modal analyses results, the dominant period and frequency values of both building models are given in *Table 2*. In addition, the period and frequency percentage difference of the rigid basement shear wall building compared to the reference building is also given in *Table 2*. Accordingly, the period value of the rigid basement shear wall building is smaller than the period value of the reference building, while the frequency value is slightly larger. The reason for this is the extra rigidity provided to the building by the rigid basement shear walls.

Table 2. Modal parameters of reference versus rigid basement-walled models.

Models	T(s)	f (1/s)	T%	f%
RBSW-B	0.610	1.638	-	-
REF-B	0.712	1.405	14.326	16.584

3.2 Storey Displacement and Interstory Drift

The top displacements are the maximum drifts obtained from the top storey of each model and are given in *Table 3*. Accordingly, the top displacements of the rigid shear wall basement structures are lower than the reference structure without a rigid shear wall. This difference between the top storey drifts is around 10% for both directions. This effect arises because the rigid basement inclusion significantly increases the overall structural stiffness.

Table 3. Maximum storey drift values of reference versus rigid basement-walled models.

Models	dx_{max} (m)	dy_{max} (m)	dx_{max}%	dy_{max}%
RBSW-B	0.02949	0.02998	-	-
REF-B	0.03296	0.03303	10.536	9.251

Table 4 shows the storey drifts of the lower part and the upper structure for both earthquake directions and the differences in the storey drifts of the rigid shear wall and basement building compared to the reference building. Accordingly, the storey drifts of the rigid shear wall and basement building are smaller than those of the reference building for both directions. While the difference is highest in the basement, this difference decreases as the number of storeys

increases. In particular, while this difference is around 90% in the basement, it decreases to around 10% on the top storey. Thus, the effect of rigid basement walls on storey drifts decreases as the storeys go up.

Table 4. Storey displacements of reference and rigid basement shear wall models.

Storey No	RBSW dx_{max} (m)	RBSW dy_{max} (m)	REF dx_{max} (m)	REF dy_{max} (m)	dx_{max}%	dy_{max}%
5	0.029491	0.029978	0.032964	0.033034	10.53574	9.251075
4	0.024752	0.024151	0.028432	0.027281	12.94316	11.47319
3	0.018903	0.017767	0.022903	0.021029	17.46496	15.51191
2	0.012407	0.01123	0.016774	0.014629	26.03434	23.23467
1	0.002095	0.005059	0.010402	0.008494	79.85964	40.44031
B	0.000346	0.000377	0.004224	0.003191	91.80871	88.18552

Interstory drifts, which express the difference in drifts between consecutive storeys, are given in *Fig. 4* and as can be seen from this graph, the relative storey drifts of the rigid shear wall basement building in the x direction are greater than the reference building. However, the difference in interstory drifts obtained in the y-direction is relatively low. This indicates that the interstory drifts of rigid basement walls increase in parallel with the displacement difference between storeys, especially with the increase in the number of storeys.

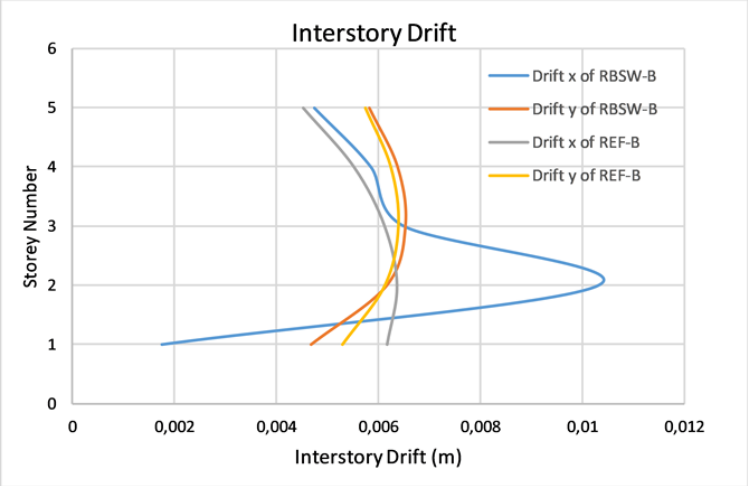

Fig. 4. Interstory drifts of reference and rigid basement shear walls buildings.

3.3 Shear Force

The base shear forces of the basement floor (lower part) for the building with rigid basement walls and the reference building are given in *Table 5*. As seen from *Table 5*, the base shear forces obtained from the building with rigid basement walls for both earthquake directions are smaller than those obtained from the reference building. The recorded deviations are 9% along the x-axis and 2% along the y-axis. By the addition of rigid basement walls to the structure, an average decrease of approximately 5% in the base shear forces was observed.

Table 5. Base shear forces of reference and rigid basement shear wall models.

Models	Vx (kN)	Vy (kN)	Vx%	Vy%
RBSW-B	6686.968	7674.671	-	-
REF-B	7303.719	7856.093	9.223	2.364

The induced superstructure lateral shear forces computed under each orthogonal seismic direction (x and y) for both structural configurations are summarized in *Table 6.* Accordingly, the shear forces acting on the storeys in the structure with rigid basement shear in both x and y directions are smaller than those in the reference building. Along the x-axis, this variance ranges from 4% to 7%, while it spans between 3% and 6% in the y direction. Rigid basement walls reduce the storey shear forces of the superstructure as they increase the rigidity of the structure.

Table 6. Storey shear forces of reference and rigid basement shear wall models.

Storey No	RBSW Vx (kN)	RBSW Vy(kN)	REF Vx (kN)	REF Vy(kN)	Vx%	Vy%
5	2376.278	2894.402	2541.47	3047.299	6.952	5.283
4	3792.884	4341.998	4003.125	4499.447	5.543	3.626
3	4757.928	5213.513	4995.379	5466.092	4.991	4.845
2	5568.364	6147.567	5884.682	6527.167	5.681	6.175
1	6334.26	7190.999	6613.993	7492.877	4.416	4.198

Figure 5 illustrates a graphical representation of the superstructure column shear forces, highlighting the lateral shear responses computed along both orthogonal axes (x and y) for the reference and rigid-basement structures. Accordingly, as the storey numbers increase, the shear forces on the storeys also increase proportionally. However, an increase in the total number of storeys for the rigid-basement configuration led to a more pronounced divergence between the lateral forces computed along both orthogonal axes (x and y). This difference is minimum at the base and maximum at the top storey. Although this difference is very small, it is greater in the reference building than in the building with rigid basement walls. Thus, rigid basement walls have slightly reduced the difference in storey shear forces between storeys.

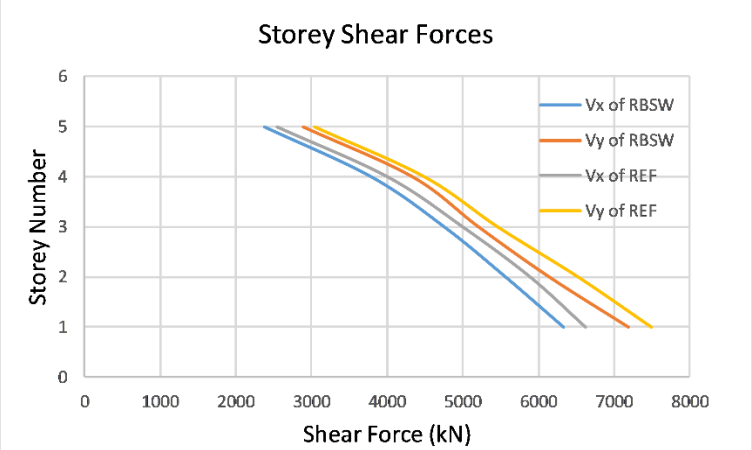

Fig. 5. Storey shear forces corresponding to columns of reference and rigid basement shear walls buildings.

4 Conclusion

In the study, two buildings with 5 normal storeys on a basement floor designed with and without rigid basement walls were analysed using the mode superposition method according to TBEC 2018. Following the computational analysis, critical structural responses—encompassing period, top displacement, interstory drifts, alongside storey and base shear forces—were extracted and evaluated across the investigated building models. In the light of this data, the following results were obtained.

- Adding rigid basement shear walls to the building reduces the period of the building and increases its frequency.
- Rigid shear walls reduce the top displacement of the top storey of the building by approximately 10%.
- The storey drifts of the superstructure have decreased with the addition of rigid basement shear walls to the structure. This amount is 10% on the top storey and approximately 90% on the basement floor.
- Rigid basement walls have reduced the base shear forces acting on the building by approximately 5%.
- Rigid basement walls have reduced the storey shear forces acting on the building storeys by an average of 5%.

As a result, the addition of rigid basement shear walls provided additional rigidity to the building, resulting in positive contributions to the seismic behaviour of the building. Even though this difference remains around 5%-10% in terms of seismic effects, it is important that rigid shear wall basements provide additional usage areas such as storage, parking, machine room, etc. to buildings, while also improving the seismic behaviour of the building. Thus, designing buildings with rigid basement walls according to TBEC 2018 offers various advantages in many aspects.

Abstract. Railway bridges are critical transportation infrastructure components which demand high structural resilience to maintain safe transit operations under earthquake loading conditions. Given that a significant portion of existing railway bridges were constructed nearly a century ago, assessing and enhancing their seismic capacity has become a critical concern. In this study, the seismic performance of a 100-m-span steel railway bridge was investigated by comparative simulations of two distinct structural states: the unretrofitted baseline configuration and the damped counterpart equipped with longitudinally oriented fluid viscous dampers (FVDs). A three-dimensional (3D) finite element model of the bridge was developed to capture its structural behavior under dynamic loading. The numerical analyses were performed in SAP2000 using a suite of scaled ground-motion records. Within the scope of this study, to evaluate the global structural behavior and identify potential failure mechanisms under seismic demand, the analysis results were assessed comparatively based on key response parameters, including acceleration, displacement, base shear force, and energy dissipation behavior. Results demonstrate that longitudinal FVDs significantly affect energy dissipation by converting seismic energy into heat. Even though middle-span displacements and deck accelerations experience only minor reductions, the FVDs can be shown to operate efficiently within their safe stroke limits without changing the period. As a structural response, total base shear demands were increased due to the added damper reactions transferred to the substructure.

Keywords: Steel Railway Bridge; Seismic Performance; Fluid Viscous Damper; Time History Analysis; Numerical Model;

1 Introduction

Long-span steel railway bridges face three primary structural weaknesses: destructive pounding, deterioration of track alignment, and the formation of a permanent plastic hinge under severe seismic loading. Pounding risk arises from excessive longitudinal displacements at support connections [1]. Dynamic mid-span deflections in railway bridges significantly degrade track alignment, thereby compromising running safety and increasing derailment risks [2]; furthermore, the manifestation of cyclic plastic hinging within the primary steel load-bearing members induces severe residual deformations and permanent structural damage, which further threatens long-term operational integrity [3]. All these situations can be solved using traditional retrofitting methods and damping systems. The traditional retrofitting method is connected to stiffness enhancement. Resorting to the traditional method to mitigate structural problems causes the structure to shift to more unfavorable regions of the acceleration spectrum, thereby further amplifying the seismic inertia forces pulled by the system [4].

However, the integration of supplemental damping devices, specifically fluid viscous dampers (FVDs) in this study, substantially enhances the seismic performance of the bridge without introducing additional stiffness to the structural system [5]. Operating as velocity-

dependent devices, FVDs dissipate seismic energy by converting kinetic energy into thermal energy through fluid orifice flow. Consequently, they mitigate structural response without altering the fundamental dynamic characteristics, such as the natural periods and mode shapes, of the structure [6].

This study aims to evaluate the seismic performance of a 100-m-span steel truss railway bridge using Nonlinear Time-History Analyses in accordance with ASCE 41-13 [7] and TSC-2018 [8] specifications. The dynamic responses of the undamped baseline structure and the retrofitted model with longitudinal fluid viscous dampers (FVDs) are comparatively examined in terms of energy dissipation capacity, mid-span displacement demand, deck acceleration, base shear transfer to the substructure, and component-level plastic hinge formation.

2 Numerical Model

The structural system consists of a 100-m-long, simply supported steel truss bridge. To accurately replicate its geometry, a 3D numerical model was constructed in SAP2000 Finite Element Software [9], featuring custom-built-up cross-sections precisely defined via the integrated Section Designer module. Fig.1. illustrates the 3D model of the structure. The structural steel members were modelled assuming a structural steel grade of S235 with a nominal yield strength *(f_y)* of 235 MPa and an elastic modulus *(E)* of 210 GPa. To accurately capture the post-yield behavior during nonlinear time-history analyses, an isotropic strain-hardening material model with a hardening ratio of 0.02 was implemented. In terms of loading, superimposed dead loads were applied directly onto the longitudinal beams, while the railway traffic live loads were simulated using the standard load model 71 (LM71) governed by the DIN EN 1991-2 provisions [10] (Fig. 2). To capture the nonlinear dynamic response under seismic excitation, lumped plastic hinges were assigned to the structural members in strict accordance with ASCE 41-13 [7]. For the dynamic characterization, a modal analysis utilizing load-dependent Ritz vectors was conducted to ensure maximum modal mass participation.

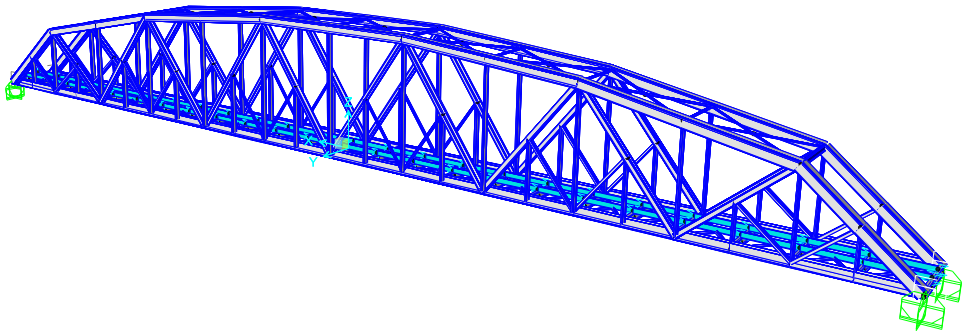

Fig. 1. The 3D 100-M-Span Steel Truss Railway Bridge Model.

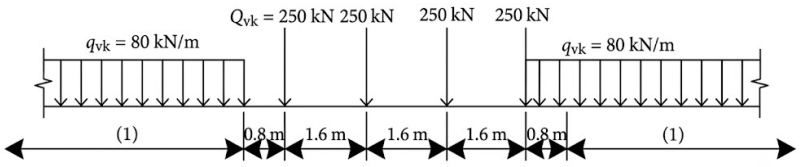

Fig. 2. Load Model 71 according to DIN EN 1991-2 [10].

3 Fluid Viscous Dampers

Nonlinear fluid viscous dampers (FVDs) were integrated into roller support regions of the bridge, while the other side is a pinned support region. In accordance with ASCE 41-13 [7], the damping force generated by the FVDs is governed by equation 1:

$$F = Cv^{\alpha} \quad (1)$$

Where C is the damping coefficient, υ is the piston velocity, and α is the velocity exponent.
Nonlinear fluid viscous dampers (FVDs) were joined to the bridge's roller support regions. To achieve a target viscous damping ratio *(ξ)* of 20% in accordance with ASCE 41-13 [7], the required total damping coefficient was analytically determined using the structural dynamic properties. Utilizing the fundamental period (T = 0.11 s) and the effective modal mass (m = 50.57 tons), the natural circular frequency (ω_n) and the theoretical critical damping coefficient (C_{cr}) were computed as 57.11 rad/s and 5777 kNs/m, respectively. Accounting for the symmetrical deployment of two FVDs at the support, the design damping coefficient per device equated to C= 578 kN(s/m)$^{0.4}$ with a non-linear velocity exponent of α = 0.4. To ensure practical feasibility, the dampers were configured based on the Taylor Devices catalogue model number 17130 [11], which features a peak force capacity of 500 kN and a stroke limit of ±100 mm. Figure 3 depicts the finite element model retrofitted with these longitudinal FVDs.

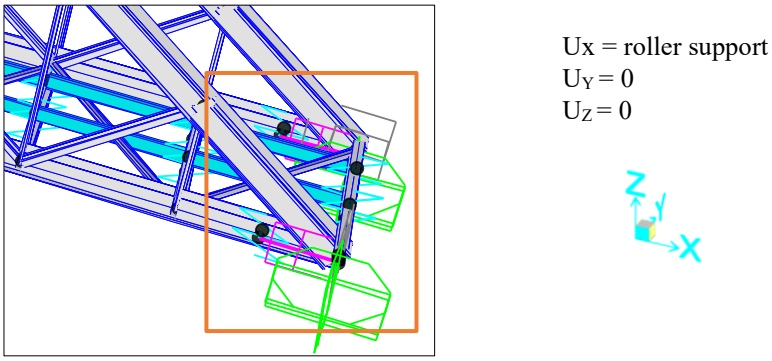

Fig. 3. Three-dimensional (3D) finite element model of the steel truss railway bridge retrofitted with longitudinally oriented FVDs which are purple colored.

4 Selection of the Ground Motion Records

Seismic inputs for the nonlinear time-history analyses were established based on local soil conditions and the Turkish Earthquake Hazard Map published by the Disaster and Emergency Management Authority (AFAD) [12]. Horizontal and vertical response spectra were defined for the DD1 (maximum considered earthquake) and DD2 (design earthquake) seismic hazard levels, which are compatible with the seismic regulations, namely the Guidelines for the Seismic Design of Highway and Railway Bridges [13] and the Turkish Building Code (TSC 2018) [8]. Moreover, seven real earthquake records have been selected from the PEER NGA-WEST2 global database [14] based on parameters such as fault mechanism, fault magnitude, fault distance to the bridge, and soil class, and scaled using the spectral matching method via the SeismoMatch [15] software. Ground motion records are shown in Table 1.

Table 1. Ground Motion Records

Ground Motion	Date	Magnitude (M_w)	Fault Type
RSN 286 (ITALY)	11/23/1980	6.9	Normal
RSN 736 (LOMAP)	10/18/1989	6.93	Reverse
RSN 746 (LOMAP)	10/18/1989	6.93	Reverse
RSN 1206 (CHICHI)	09/20/1999	7.62	Reverse
RSN 4101 (PARKFIELD)	09/28/2004	6.0	Strike Slip
RSN 3747 (CAPEMEND)	04/25/1992	7.01	Reverse
RSN 451 (MORGAN)	04/24/1984	6.19	Strike Slip

In accordance with Guidelines for the Seismic Design of Highway and Railway Bridges [13], spectral matching was confined to the $0.2T_1$ – $1.5T_1$ period interval across all directions

(corresponding to 0.022 s – 0.165 s for the longitudinal direction) to ensure that the natural frequency characteristics of the selected ground motions remained entirely unchanged. The high accelerations emerging beyond this band were intentionally retained to test the FVDs capacities under an extreme upper-bound period elongation scenario (Fig. 4).

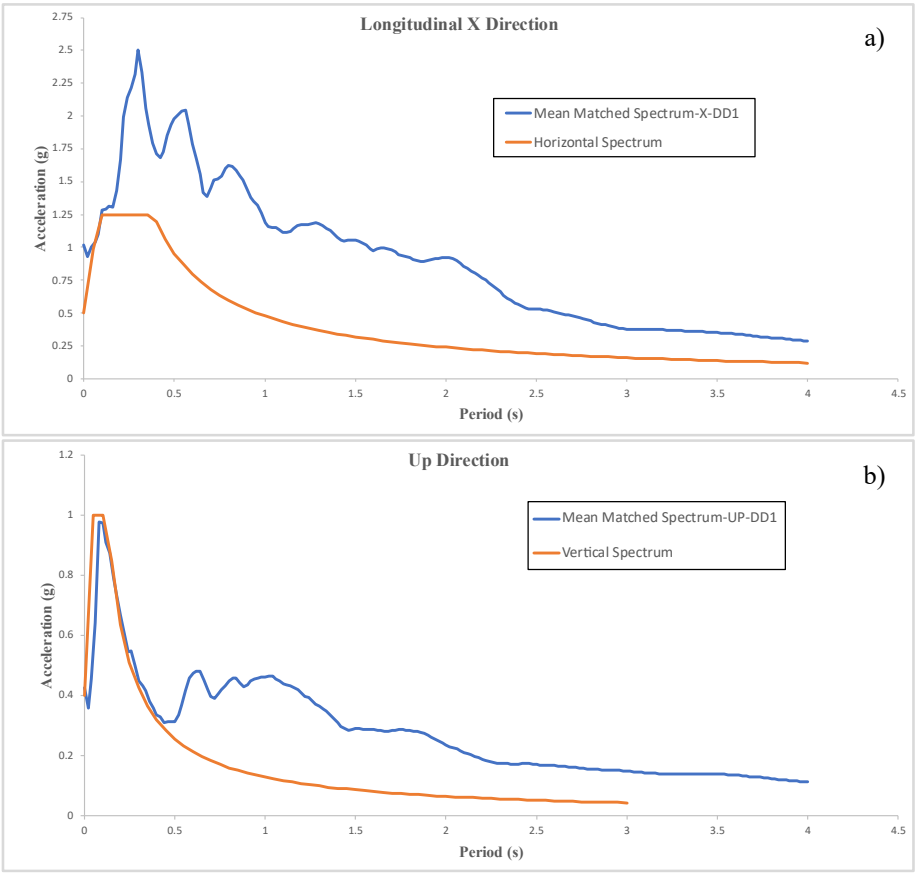

Fig. 4. Comparison of target and mean matched response spectra for DD1 seismic hazard level for (a) longitudinal and (b) vertical direction.

5 Results and Discussion

This section evaluates the seismic performance of the steel truss bridge retrofitted with fluid viscous dampers (FVDs) by analyzing energy dissipation behavior, displacement responses, base shear demands, deck accelerations, and plastic hinging mechanisms under the DD1 and DD2 seismic hazard levels. The comparative numerical results between the undamped and longitudinally damped models demonstrate that the integration of FVDs provides a continuous, stable energy dissipation mechanism that effectively mitigates dynamic responses and localized structural damage. While the extreme initial rigidity of the bridge inherently leads to a minor increase in total base shear due to superimposed velocity-dependent damping forces, the overall structural demand on primary members is substantially reduced, as evidenced by a controlled distribution of plastic hinges. While the analysis of the undamped baseline model revealed that fundamental periods of $T_1 = 0.11$ s in the longitudinal direction and $T_2 = 0.81$ s in the transverse direction, the damped model of the period revealed the same results which are $T_1 = 0.11$ s in the longitudinal direction and $T_2 = 0.81$ s in the transverse direction. This low longitudinal period indicates the extreme inherent rigidity of the structural system.

5.1 Energy Dissipation

The seismic energy-dissipation performance of FVDs is evaluated at the DD1 seismic hazard level. Fig. 5 illustrates the time-history energy components for the governing RSN 1206

earthquake. While the undamped model relies entirely on global structural damping, the retrofitted model with a longitudinal damper exhibits a continuous accumulation of nonlinear viscous damping energy, thereby reducing the demand on primary structural members. This performance is validated by the elliptical force-displacement hysteretic loops in Fig. 6, which indicate a stable energy-dissipation mechanism without stiffness degradation. Finally, Fig.7 shows the energy comparison across seven earthquakes. It appears that FVDs absorb energy prominently.

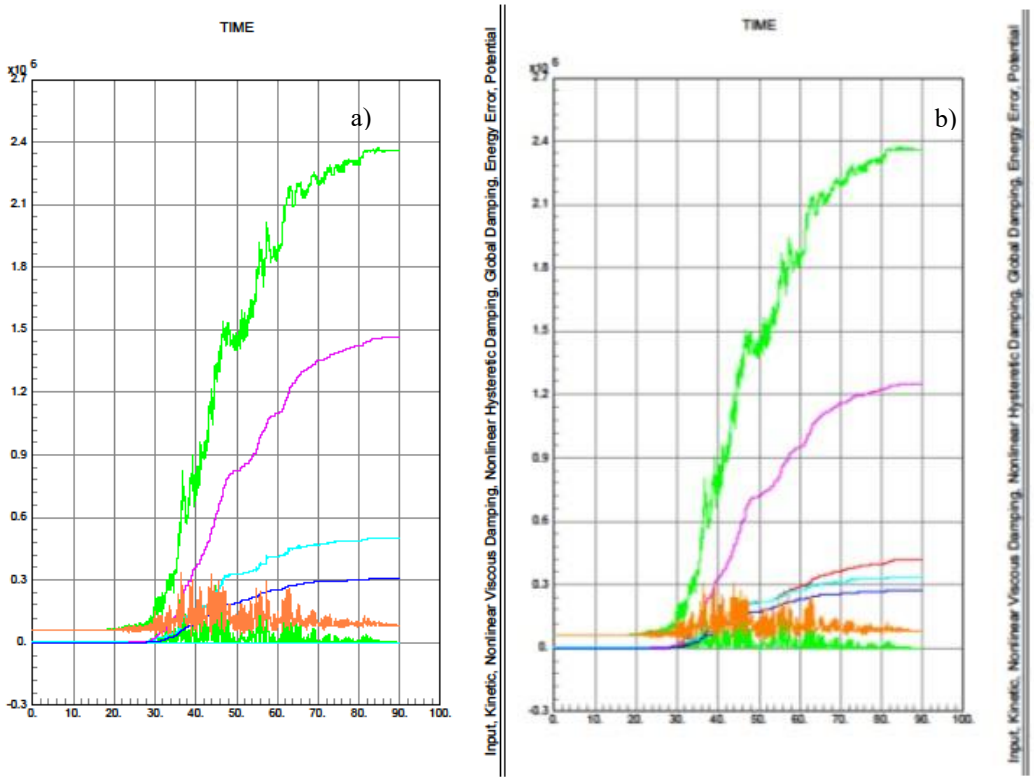

Fig. 5. Time history energy components for the RSN1206 earthquake under the DD1 seismic hazard level: (a) Undamped model and (b) longitudinal damping model.

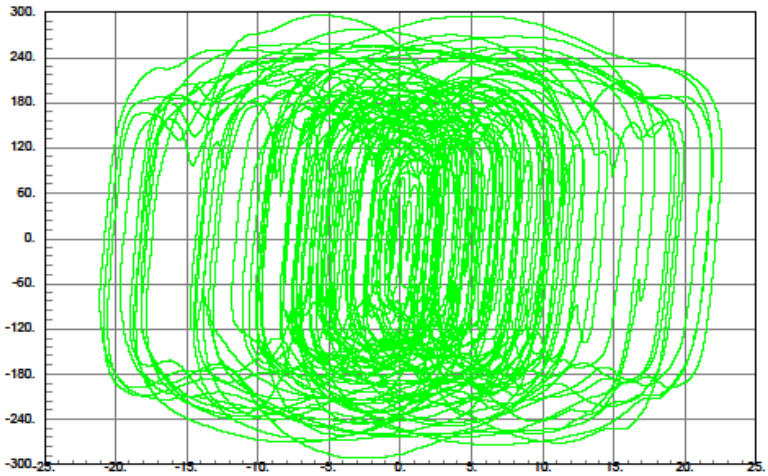

Fig. 6. Force-displacement nonlinear hysteretic behavior of the longitudinal FVDs under the RSN 1206 earthquake in DD1 seismic hazard level.

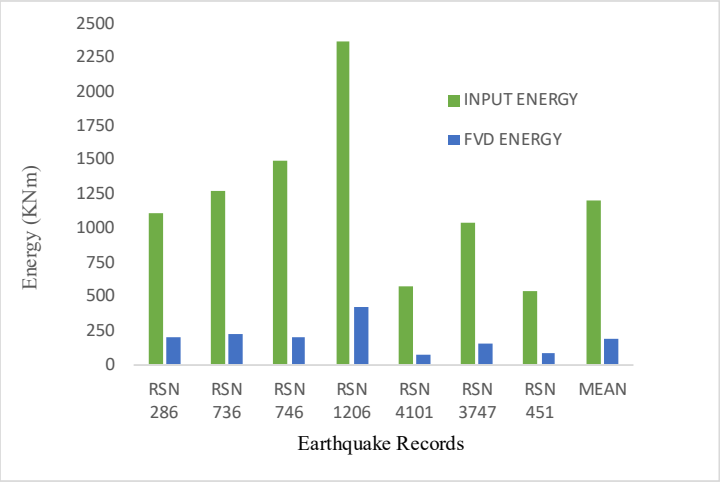

Fig. 7. Comparison of total seismic input energy and energy dissipated by fluid viscous dampers (FVDs) under the DD1 seismic hazard level across seven selected earthquake records.

5.2 Displacements

To evaluate the structural control efficacy of the longitudinal Fluid Viscous Dampers (FVDs), nonlinear time-history analyses were executed under the DD1 seismic hazard level utilizing seven distinct, spectrum-matched ground-motion records. The critical response quantities were monitored at the mid-span bottom-chord joint of the steel truss superstructure, which serves as a benchmark node due to its susceptibility to severe dynamic amplification. Table 2 comprehensively presents the comparative peak translational displacements for both the unretrofitted (undamped) and retrofitted (longitudinal damper) structural configurations. Intriguingly, although the supplemental damping system is physically oriented along the longitudinal axis of the bridge, the most substantial absolute and percentage reductions are manifested in the lateral direction *(U2)*.

Table 2. Peak joint displacements at the mid-span bottom chord node under the DD1 seismic hazard level.

	U1 (mm) (longitudinal direction)		**U2 (mm) (lateral direction)**		**U3 (mm) (vertical direction)**	
Earthquakes	Undamped	Longitudinal Damper	Undamped	Longitudinal Damper	Undamped	Longitudinal Damper
RSN 286	19.2	18.78	137.3	134.23	84.21	82.67
RSN 736	25.88	24.92	140.99	125.57	87.5	87.74
RSN 746	25.85	24.47	134.98	122.33	92.08	90.55
RSN 1206	22.27	21.19	157.86	148.48	91.91	88.89
RSN 4101	17.42	16.55	130.29	118.41	81.09	79.69
RSN 3747	17.03	16.04	127.47	116.1	67.84	65.66
RSN 451	17.17	16.03	106.64	99.54	74.28	71.25

5.3 Base Shear Force

Figure 8 illustrates a comparison of the peak longitudinal base reactions. Due to the high initial rigidity of the bridge structure (T=0.11 s), incorporating longitudinal FVDs inherently elevates the maximum base shear demand by approximately 10% under the DD1 seismic hazard level. According to structural dynamics principles and ASCE 41-13 [7], the total base shear ($Vtotal$) transferred to substructure is the simultaneous combination of the structure's restoring force and the supplemental damping force. This relationship is expressed in equation (2).

$$Vtotal = k_{eff}.D + Cv^{\alpha} \quad (2)$$

Where $keff$ is the effective structural stiffness, D is the displacement, C is the damping coefficient, and V^{α} represents the velocity-dependent term of the FVD.

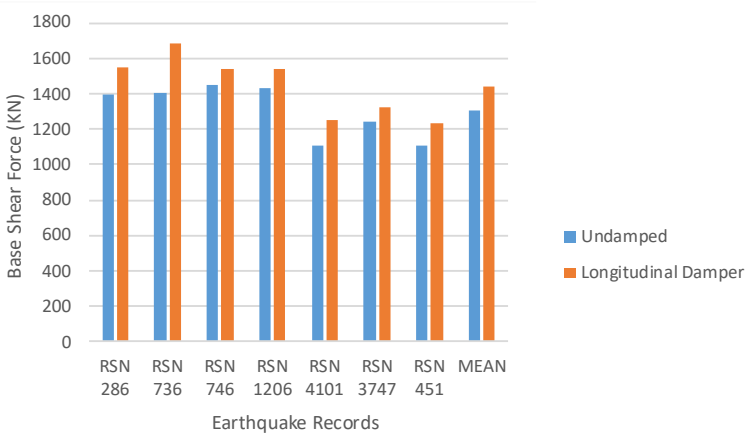

Fig. 8. Comparison of the peak longitudinal base shear forces transferred to the substructure under the DD1 seismic hazard level for seven earthquake records.

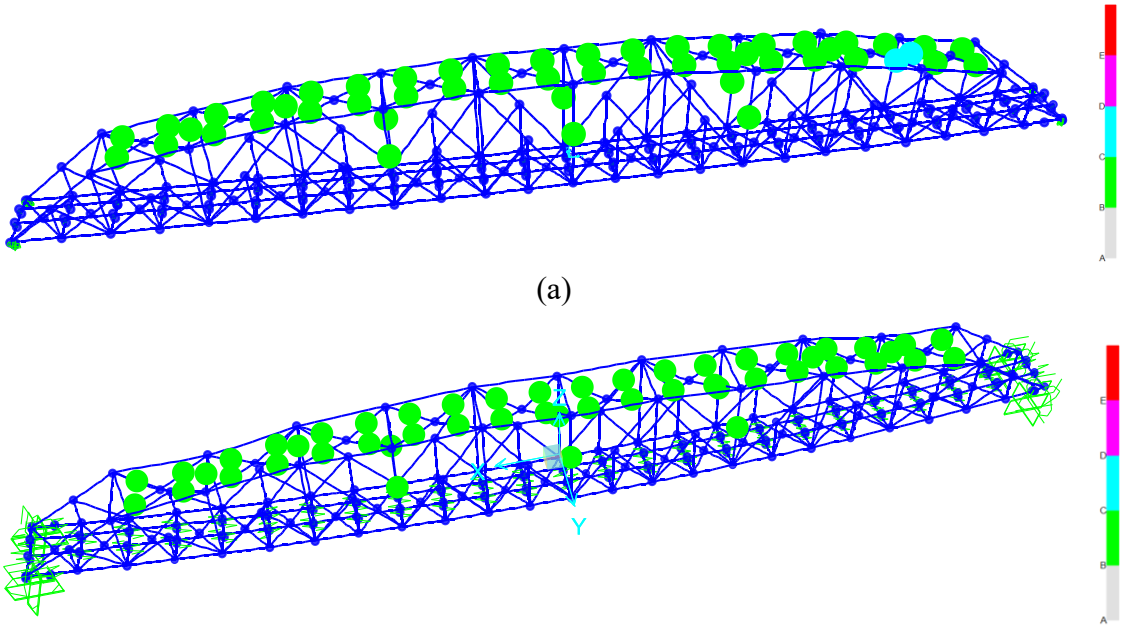
In this structural context, the extreme initial stiffness of the superstructure severely restricts longitudinal displacement responses to a scale of mere millimetres, thereby keeping the elastic restoring force vector ($k_{eff}.D$) virtually undiminished. Because the peak velocity-dependent damping forces ($C\upsilon^{\alpha}$) generated by the FVDs operate out of phase with the maximum elastic displacements, their non-linear vector superposition onto a stiff system inherently results in elevated peak concurrent reactions that are transferred directly to the substructure components.

5.4 Deck Accelerations



Peak longitudinal deck accelerations were investigated according to DD1 and DD2 seismic hazard levels for seven earthquakes from the middle bottom joint node of the steel bridge. Here is Table 3 showing the longitudinal acceleration values for all earthquakes at the bottom. Across all considered seismic records, the integration of FVDs provided a highly consistent reduction ratio, uniformly decreasing the peak accelerations by approximately 2% under the DD1 seismic hazard level and 3% under the DD2 seismic hazard level because of the high rigidity of the structure.

Table 3. Peak joint accelerations at the middle bottom node under the seismic hazard levels

Earthquakes		**U1 (m/s²) (longitudinal direction)**	
		Undamped	**Longitudinal Damper**
RSN 286	DD1	12.61	12.53
	DD2	5.47	5.43
RSN 736	DD1	10.72	10.23
	DD2	4.95	4.84

	DD2	5.27	5.21
RSN 4101	DD1	5.68	5.65
	DD2	3.44	3.49
RSN 3747	DD1	11.84	11.8
	DD2	5.64	5.65
RSN 451	DD1	8.94	8.75
	DD2	4.52	4.47

5.5 Element-Based Plastic Hinging Mechanism

The nonlinear material behavior and local damage states of the steel bridge members are evaluated based on the generalised component force deformation backbone curve (A-B-C-D-E) specified in ASCE 41-13 [7]. In this fundamental framework, point A represents the unloaded origin, B is the effective yield point (onset of plastic deformation), C denotes the ultimate strength, D indicates the residual strength, and E marks the total loss of load-carrying capacity. Fig.8. showed that the distribution of plastic hinges under the governing RSN 1206 earthquake under DD1 seismic hazard level. In the undamped model (Fig.8a), most members, especially on the top, exceed their elastic limit (B). Several local plastic hinges progress deeply into the inelastic region (between B and C), indicating the onset of permanent material deformations. Conversely, the integration of longitudinal FVDs (Fig.8b) visibly mitigates the formation and progression of these plastic hinges.

6 Conclusions

This study presented a comprehensive numerical investigation into the seismic retrofitting of a highly rigid, 100-meter-span steel-truss railway bridge utilizing longitudinal fluid viscous dampers (FVDs). The dynamic performance and structural efficacy of this strategy were rigorously evaluated through nonlinear time-history analyses executed under both the DD1 and DD2 seismic hazard levels. Based on the numerical findings, the following conclusions can be drawn:

- Energy Dissipation Efficacy: The integration of the longitudinal dampers successfully altered the global energy balance of the superstructure. Across the seven selected ground-motion records, the FVDs established a highly stable energy-dissipation mechanism, absorbing an average of 16% of the total seismic input energy. Crucially, this supplemental damping capacity was achieved without altering the fundamental natural periods or structural configuration of the bridge.
- Three-Dimensional Kinematic Behavior: Due to the inherently high baseline rigidity of the existing steel truss bridge in the longitudinal direction (T = 0.11 s), boundary

displacements along the operational axis were naturally constrained. Consequently, while the FVDs induced minor displacement reductions in the longitudinal and vertical directions, they yielded a substantial mitigation of approximately 10% in the lateral direction (T = 0.81 s). This cross-directional control highlights a strong multi-directional spatial coupling in the 3D kinematic behavior of the truss deck. Furthermore, the peak damper forces and stroke demands remained safely within the design limits across all seismic loading scenarios.

- Substructure Force Demands: Contrary to typical supplemental damping applications in flexible building structures, incorporating FVDs into this highly rigid system elevated the maximum base shear demand transferred to the foundations by approximately 10%. Because the extreme stiffness of the bridge limits displacement reductions, the primary elastic restoring forces remain fully active. The non-linear vector superposition of the velocity-dependent damping forces onto these undiminished restoring forces inevitably increases the concurrent global foundation demands.
- Acceleration Control and Railway Safety: Due to the low relative velocities associated with the stiff truss configuration, the FVDs provided marginal numerical reductions in the peak accelerations at the mid-span bottom chord node. However, the supplemental damping successfully suppressed transient dynamic amplifications under both the DD1 and DD2 seismic hazard levels. This attenuation provides a crucial upper-bound safety margin necessary to preserve track alignment and prevent train derailment risks.
- Localized Damage Mitigation: Although the high inherent rigidity of the superstructure bounded any drastic variations in the global plastic hinge distribution, the integration of FVDs provided a clear structural benefit. The supplemental energy dissipation effectively alleviated localized material strains, thereby maintaining critical structural members closer to their linear elastic thresholds and preventing severe hysteretic degradation.

Abstract. The durability of steel-reinforced deep beams can be significantly affected by aggressive environmental conditions, where reinforcement corrosion is a major concern. Fiber-reinforced polymer (FRP) reinforcement offers a corrosion-resistant alternative; however, its brittle behavior and the limited design guidance available for deep beams require further investigation. This study examines the shear behavior of high-strength concrete (HSC) deep beams reinforced with glass fiber-reinforced polymer (GFRP) bars. Three specimens were tested, including a reference beam without an opening and two beams with web openings at different locations, to evaluate the influence of opening presence and position on shear performance. The experimental program included load–deflection measurements, ultimate shear capacity assessment, and full-field strain monitoring using Digital Image Correlation (DIC). The results showed that web openings significantly reduced shear capacity, with strength losses of up to 49% compared to the solid reference beam. Locating the opening away from the primary diagonal load path toward the mid-span region recovered approximately 13% of the lost capacity relative to an opening located closer to the support. Strain measurements and DIC analyses confirmed the observed failure mechanisms and clearly identified the primary and alternative load-transfer paths in beams with openings.

Keywords: GFRP-RC Deep Beams, Web opening, DIC Camera.

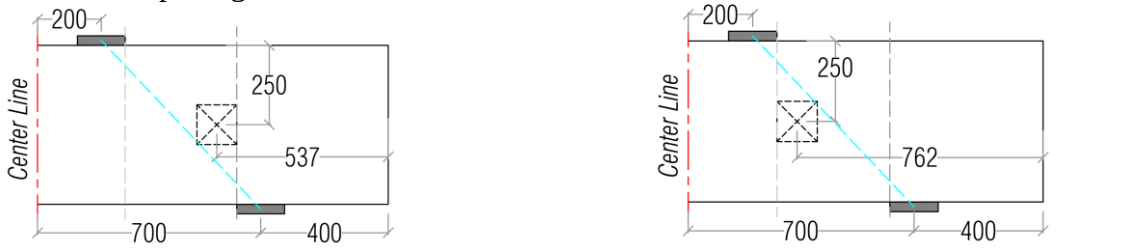
1 Introduction

Fiber-reinforced polymer (FRP) reinforcement has emerged as a durable, corrosion-resistant alternative to steel reinforcement, particularly for structures exposed to aggressive environments. However, its application in heavily loaded members such as deep beams remains challenging due to their nonlinear stress distribution and arch-action load-transfer mechanism, which render conventional beam theory inapplicable [1,2]. Despite increasing interest in FRP-reinforced concrete (FRP-RC) structures, the behavior of FRP-RC deep beams is not yet fully understood. Previous studies have shown that the shear capacity of FRP-RC deep beams is strongly influenced by the shear span-to-depth ratio (a/d), with lower values enhancing strength through improved arch action [1,4–6]. While FRP-RC deep beams can achieve shear capacities comparable to or exceeding those of steel-reinforced beams, they generally exhibit more brittle behavior and wider cracking. Shear resistance is governed primarily by concrete strut action, whereas aggregate interlock and dowel action contribute minimally [7]. Increasing FRP web reinforcement has been shown to improve strength and crack control; however, significant size effects remain [7,8].

Research on FRP-RC deep beams with openings, particularly those constructed with high-strength concrete (HSC), remains limited. Existing studies indicate that opening location relative to the primary load path is a key parameter affecting shear strength [9]. Moreover, current design provisions, such as ACI 440.11-22 [3], do not provide specific guidance for their design.

To address these gaps, this study investigates the shear behavior of HSC GFRP-RC deep beams with web openings at different locations. Three beams were tested, including a solid reference beam and two beams with openings positioned away from the primary shear load path. Digital Image Correlation (DIC) was employed alongside conventional instrumentation to monitor strain development and crack propagation, providing insight into the influence of opening location on shear load-transfer mechanisms.

2 Experimental Testing



2.1 Materials

The beam specimens were cast using high-strength concrete with a target 28-day compressive strength of 70 MPa. Cylinder tests conducted on the day of beam testing in accordance with ASTM C39/C39M-14 [10] indicated an average compressive strength of 74 MPa.. The GFRP reinforcement, supplied by Unique Fiberglass and Composites and manufactured in accordance with ASTM D8505-23 [11], included 20 mm diameter bottom flexural bars (Ultimate strength (f_u) = 804 MPa, Elastic modulus (E) = 50 GPa), 12 mm diameter top hanger bars (f_u = 860 MPa, E = 48 GPa), and 10 mm diameter bars for longitudinal skin reinforcement and shear stirrups (f_u = 945 MPa, E = 45 GPa).

2.2 Specimens' Details

The experimental program was conducted to investigate the shear behavior of GFRP-RC deep beams, with all specimens designed to promote shear-dominated failure. Flexural design followed ACI 440.1R-22 [3] using a conservative approach to prevent premature flexural failure, while shear capacity was evaluated using the strut-and-tie method in accordance with ACI 318-25 [12], given the absence of specific provisions for deep beams in ACI 440.1R-22 [3].

Three beams were tested: B1-OL1, B2-OL2, and B3-REF. The designation "B" denotes the beam series, "N" denotes the specimen number, "OL1/OL2" Denotes the location of the opening relative to the hypothetical compression strut (left or right), and "REF" the reference beam without openings. Beams B1-OL1 and B2-OL2 contained a 125 × 125 mm web opening at the bottom and top support edges, respectively (*Fig. 1*). Both specimens had identical reinforcement, consisting of six Ø20 mm bottom flexural bars, two Ø12 mm top hanger bars, and web reinforcement comprising 2 Ø10 mm horizontal bars at 86 mm spacing and 2-legged Ø10 mm vertical stirrups at 80 mm spacing. Beam B3-REF was identical to the other specimens but without a web opening.

(a) Opening at edge of bottom support, B1-OL1 (b) Opening at edge of top support, B2-OL2

Fig. 1. Detailed geometry and reinforcement schemes for test specimens.

2.3 Test Setup and Instrumentation

The beam specimens were tested under four-point bending using a Universal Testing Machine (UTM) with a constant shear span of 500 mm ($a/h = 1.0$) to ensure deep beam behavior. Two concentrated loads, spaced 400 mm apart, were applied under displacement control at a rate of 0.015 mm/s, while load, deflection, cracking, and failure data were continuously recorded. Strain development was monitored using electrical resistance strain gauges installed on the longitudinal reinforcement, web reinforcement, and selected concrete locations, while mid-span deflections were measured using an LVDT. In addition, a Digital Image Correlation (DIC) system was employed to capture full-field displacement, strain, and crack propagation using a calibrated high-resolution camera and a speckle-patterned beam surface under controlled lighting conditions.

3 Results and Discussion

3.1 Failure Mode and Cracking Patterns

All specimens exhibited shear-dominated failure governed by diagonal tension cracking. In beams with web openings, cracks initiated at the upper and lower corners of the openings and propagated toward the supports and loading points, forming a distinct diagonal failure plane. These cracks widened rapidly with increasing load until failure. In the reference beam, diagonal cracks formed near the loading and support regions and gradually merged into a main shear crack.

Although all beams failed in a similar diagonal shear mode (*Fig. 2*), the presence and location of openings significantly influenced crack development and shear capacity. Beam B2-OL2 (opening closer to the loading point) exhibited wider cracks at failure than B1-OL1, indicating higher shear resistance. This is attributed to the interaction between the opening and the principal compression strut: openings closer to the support more severely disrupt the load path, reducing shear capacity, while those nearer mid-spans have a lesser effect. Similar trends have been reported in previous studies [13,14].

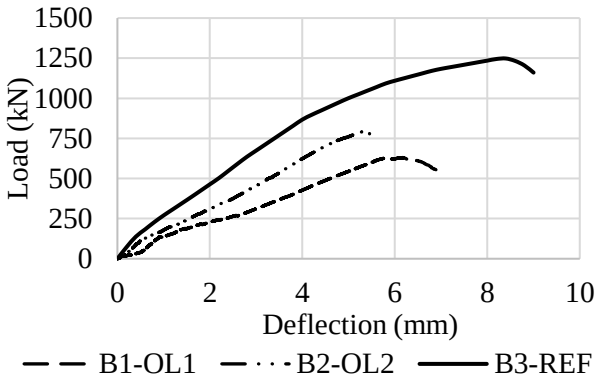
(a) (b)

Fig. 2. Cracking patterns at failure for the samples: (a) B1-OL1, (b) B2-OL2.

3.2 Load-Deflection Relationship

Fig. 3 shows the load–deflection response of the tested specimens, which exhibited a bilinear behavior consisting of an initial uncracked stiffness followed by a reduced post-cracking stiffness.

Beam B1-OL1 (opening toward the support) showed a 49% reduction in shear capacity and a 30% reduction in deformation capacity compared with the reference beam. Beam B2-OL2 (opening toward the loading point) exhibited lower reductions of 36% in both shear and deformation capacity. Although relocating the opening toward the loading zone reduces its adverse effect on shear resistance, it may increase vulnerability in the flexural region.



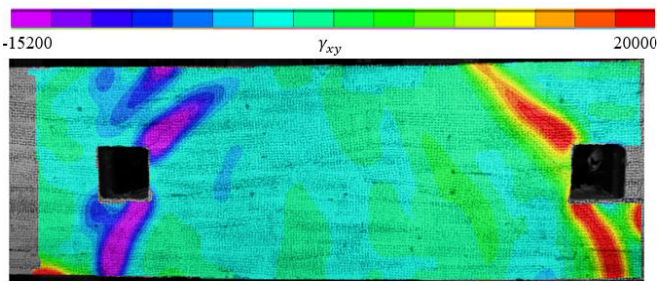


Fig. 3. Load-deflection curves for all tested beams.

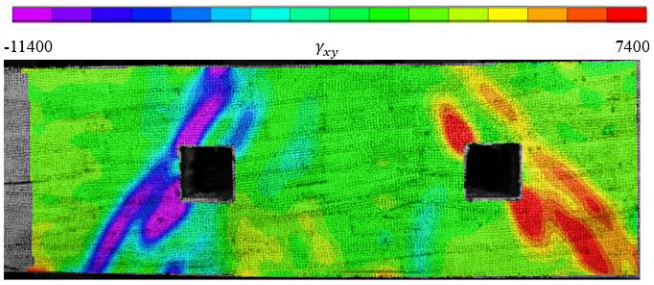
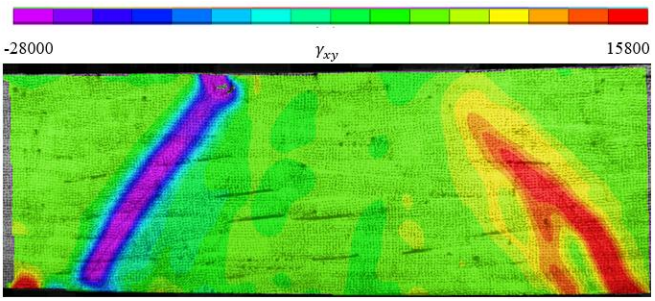


3.3 Strains Development

Strain gauges on the longitudinal bottom GFRP bars recorded high tensile strains, with mid-span values of 2000–3000 με (12–18% of ultimate strain). Similar high strains (up to ~3000 με) were measured near opening corners in longitudinal bars and stirrups due to diagonal crack proximity. In contrast, the top mid-span gauge recorded low to moderate compressive strains (<2000 με), indicating that concrete crushing did not govern failure.



The DIC-based surface strain measurements were calibrated and analyzed to obtain full-field strain contours at peak load. Figure 4 presents the in-plane shear strain (γ_{xy}) distribution, showing localized concentrations along diagonal crack paths, confirming the dominant role of shear action. The strain fields follow the expected diagonal compression strut between the load and support; however, openings significantly affect this load path. In beam B2-OL2 (*Fig. 4(b)*), partial stress redistribution around the opening indicates a less disturbed strut and the formation of alternative load paths. In contrast, beam B1-OL1 (*Fig. 4(a)*) shows a more pronounced interruption of the diagonal strut, resulting in higher strain localization and reduced shear efficiency.

4 Conclusions

- The presence of a web opening significantly reduced the shear capacity of the GFRP-RC deep beams, with strength reductions ranging from 36% to 49%, depending on the opening location.
- The influence of opening location was substantial. Relocating the opening away from the primary diagonal load path and toward the mid-span region reduced the loss in shear capacity by approximately 13% compared with an opening located closer to the support. However, this configuration resulted in approximately 6% greater deformation at failure.
- Strain measurements obtained from both conventional strain gauges and DIC were in good agreement and effectively captured the structural response of the tested beams.
- The DIC results provided clear visualization of the principal and alternative load-transfer paths, confirming the observed failure mechanisms in beams containing web openings.

Corner Radius Effect on Confined Strengths of FRP-Wrapped Rectangular Concrete Members

Onur Gedik[1]
[1] 0000-0002-3969-7824, İstanbul Okan University, Civil Engineering Department, İstanbul, Türkiye, onur.gedik@okan.edu.tr

Abstract. FRP strengthening of axial compressive strength in rectangular columns is more complex than in circular columns due to the non-uniform distribution of lateral confinement stresses along the perimeter. The rupture strain values of FRP obtained from coupon tests are significantly reduced in actual specimens, which is commonly attributed to microcracking, differences in loading conditions, and the presence of sharp corners. Failure of the wrapping material typically occurs at the corner regions near mid-height, highlighting the critical influence of corner geometry. To investigate the contribution of corner radius to confined strength, a comprehensive database of FRP-wrapped rectangular concrete specimens was compiled from experimental studies available in the literature. Although rounding the corners of rectangular cross-sections improves the overall structural behavior, the presence of existing longitudinal reinforcement and aspect ratio introduce physical boundary constraints. In this study, the effect of corner radius is evaluated in conjunction with aspect ratio, unconfined compressive strength, and confinement ratios. Furthermore, several existing analytical models and design-oriented expressions are reviewed and compared against experimental results, particularly in terms of minimum corner radius requirements and expected confinement efficiency. The findings aim to provide improved insight into the role of rounded corners in enhancing confinement performance and to support the development of more reliable and practical design recommendations for FRP-strengthened rectangular members.

Keywords: FRP, Compressive Strengthening, Concrete, Corner Radius

1 Introduction

FRP (Fiber Reinforced Polymer) confinement of concrete columns in order to enhance the axial compressive strength is in use for decades. Most of the studies carries out for such structural members were conducted over circular cross-sections, where the majority of the columns in need for retrofitting are rectangular cross-sections. Unlike circular cross-sections, the effectiveness of FRP confinement in rectangular cross-sections remains comparatively lower, mainly due to the non-uniform distribution of lateral confining stresses along the perimeter. These lateral stresses tend to concentrate at the corners, and, particularly in specimens with sharp corners, premature rupture occurs at stress levels significantly lower than those obtained from FRP coupon tests. As a result, the specimens fail before reaching their presumed maximum axial capacities. Since the corner radius represents the transition from a rectangular cross-section toward a circular geometry, it will be investigated as one of the most critical parameters governing the ultimate strength of FRP-confined specimens. After introducing the application of corner radius effect for the overall performance of the specimens defined by guidelines and prediction models, the contribution of the corner radius will also be evaluated with respect to the unconfined concrete strength, the aspect ratio of the section and the confinement ratios.

2 Database

A total of 455 FRP-confined specimens were collected from the literature [1]. All specimens consisted of rectangular concrete sections confined with carbon FRP (CFRP). Approximately 60% of the specimens were square sections. The unconfined concrete strength was categorized into three classes as low-, normal-, and high-strength concrete. Corner radii were divided into four groups with intervals of 10 mm. The confinement ratio ranges were determined based on the minimum threshold values associated with the observed strength enhancement reported in the study by Gedik [1], as well as the lower-bound limits defined by ACI 318 [2]. In addition, the confinement ratios for all specimens were calculated according to the TEC 2018 [3] equations. A summary of the database is presented in Table 1.

Table 1. Database Summary (Specimen Ratios)

		Geometry		f_{co} [MPa]			f_l/f_{co}			r_c [mm]

3 Corner Radius Effect in Guideline and Model Expressions

To investigate the contribution of corner radius to the strength enhancement of FRP-confined reinforced concrete members, selected design guidelines and predictive models will be examined. The considered codes and models were chosen based on their demonstrated accuracy in predicting the ultimate strength of FRP-confined rectangular sections [1]. Among the design guidelines, in addition to the Turkish Building Earthquake Code (TEC 2018) [3], which is used to define the strength classes adopted in this study, the provisions of ACI 440.2R-17 [2] and CNR-DT200 R1/2013 [4] will also be evaluated. As predictive models, the formulations proposed by İlki et al. [5], Wu and Wei [6], and Lim and Ozbakkaloglu [7] will be considered, as these models have been shown to provide the most reliable estimates of the maximum axial load capacities of FRP-confined rectangular sections.

3.1 Guidelines

TEC 2018 [3]. The Turkish code incorporates the effect of corner radius into the calculation of lateral confining pressure through a shape factor. The function given in Eq. (1) is a simplified form of the shape factor originally proposed by Restrepo and Vino [8]. However, the influence of varying aspect ratios can only be represented as a secondary effect, even when the maximum possible corner radius is applied. In this formulation, a shape factor equal to 1.0, corresponding to a circular section, is obtained when the corner radius is taken as one-half of the shorter side dimension.

$$\kappa_a = 1 - \frac{(b - 2r_c)^2 + (h - 2r_c)^2}{3bh} \tag{1}$$

For square specimens with no corner rounding, the shape factor is equal to 0.33, implying that approximately 67% of the confinement effectiveness expected for a circular section is lost. Although the Turkish code does not prescribe a minimum corner radius requirement, it specifies that sections with an aspect ratio greater than 2.5 are not considered suitable for this strengthening technique.

ACI 440.2R-17 [2]. ACI 440 imposes an aspect ratio limit of 2.0 and additionally requires that the largest cross-sectional dimension does not exceed 900 mm. Similar to TEC 2018 [3], the shape factor is defined based on the ratio of the effectively confined area, represented by the region enclosed by four parabolic curves, to the total cross-sectional area. However, unlike TEC 2018 [3], the effect of an aspect ratio different from unity is accounted for separately in both the calculation of the effectively confined area and the determination of the shape factor. Furthermore, this shape factor explicitly incorporates the area of the existing longitudinal reinforcement into the calculation. Shape factor can be found in Eq. (2).

$$\kappa_a = \frac{1 - \dfrac{\left[\left(\frac{b}{h}\right)(b - 2r_c)^2 + \left(\frac{h}{b}\right)(h - 2r_c)^2\right]}{3bh} - \rho_g}{1 - \rho_g}\left(\frac{b}{h}\right)^2 \tag{2}$$

Similar to the Turkish code, the American guideline considers the corner radius only as a parameter affecting the calculation of the effectively confined area. Likewise, for an unreinforced square section, the shape factor approaches 1.0 when the corner radius reaches its maximum possible value. Therefore, the main differences between the ACI 440 [2] approach and TEC 2018 [3] arise in the treatment of rectangular sections with aspect ratios other than unity and in cases where the contribution of existing longitudinal reinforcement is taken into account.

CNR-DT200 R1/2013 [4]. The Italian guideline employs a three-component effectiveness coefficient consisting of longitudinal, transverse, and inclined contributions. Among these, the transverse effectiveness coefficient is calculated directly as a function of the cross-sectional geometry. The shape factor adopted for this purpose is identical to that specified in the Turkish code. In addition, the same cross-sectional limitations defined by the American guideline are adopted. The corresponding shape factor formulation is presented in Eq. (3).

$$\kappa_a = 1 - \frac{(b-2r_c)^2 + (h-2r_c)^2}{3bh} \tag{3}$$

Overall, all three design guidelines employ similar shape factor formulations to account for the influence of cross-sectional geometry and corner rounding, and none of them prescribes a minimum corner radius requirement.

3.2 Prediction Models

İlki et al. [5]. In the model proposed by İlki et al., the calculation of the shape factor is refined by accounting for the reduction in cross-sectional area resulting from corner rounding. Apart from this modification, no additional treatment of the corner radius is introduced, and its influence is evaluated in a manner consistent with the approaches adopted in the design guidelines. The corresponding formulation is presented in Equation (4).

$$\kappa_a = 1 - \frac{(b-2r_c)^2 + (h-2r_c)^2}{3bh} - \frac{4r_c^2 - \pi r_c^2}{bh} \tag{4}$$

Wu and Wei [6]. Unlike the other approaches, the model proposed by Wu and Wei incorporates the effects of aspect ratio and corner radius through two separate terms within the lateral confining pressure formulation. The study in which this model was developed was specifically conducted to investigate the influence of aspect ratio on the behavior of FRP-confined rectangular members. The findings demonstrated that, after corner radius, the aspect ratio is the second most influential parameter governing the effectiveness of FRP confinement. The corresponding equation is presented below in Eq. (5).

$$\kappa_a = \left(\frac{2r_c}{b}\right)^{0.72} \left(\frac{h}{b}\right)^{-2.5} \tag{5}$$

According to the study, the confinement effectiveness progressively decreases as the aspect ratio approaches 2.0, eventually becoming negligible for highly elongated rectangular sections. As can be inferred from the form of the shape factor, this model is based on the premise that the effectiveness of FRP confinement is governed more by the geometric characteristics of the cross-section than by the concept of an effectively confined area. Accordingly, the influence of corner radius and aspect ratio is treated as a direct geometric effect on confinement efficiency rather than solely through the estimation of the effectively confined region.

Lim and Ozbakkaloglu [7]. Since the model proposed by Lim and Ozbakkaloglu was developed primarily using data from high-strength concrete specimens, consistent with the authors' earlier studies, its main focus was on the influence of unconfined concrete strength on the ultimate confined strength. Under such conditions, the lateral confining pressure becomes relatively small compared with the existing axial stress, and post-peak softening behavior becomes more pronounced. Consequently, unlike the model of Wu and Wei [6], the proposed formulation does not incorporate only the geometric characteristics of the section into the shape factor; it also accounts for the influence of the unconfined concrete strength. Equation (6) presents only the geometric contribution to the confinement effectiveness factor.

$$\kappa_a = \left(\frac{2r_c}{\sqrt{(h^2+b^2)/2}}\right)^{0.67}\left(\frac{h}{b}\right)^{0.5} \quad (6)$$

Furthermore, the study revealed that the attainable confinement-induced strength enhancement diminishes with increasing unconfined concrete strength, and this phenomenon was explicitly incorporated into the proposed model, unlike in most existing formulations.

4 Investigation of Corner Radius

To evaluate the influence of corner radius while accounting for the most significant size-related parameter, the ratio of corner radius to the cross-sectional perimeter was adopted. The analysis was conducted using the strength enhancement ratio, defined as $\boldsymbol{f_{cc}/f_{co}}$. The strength enhancement values presented in Figure 1 represent the mean values and corresponding standard deviations as shaded area, calculated from all specimens within each group.

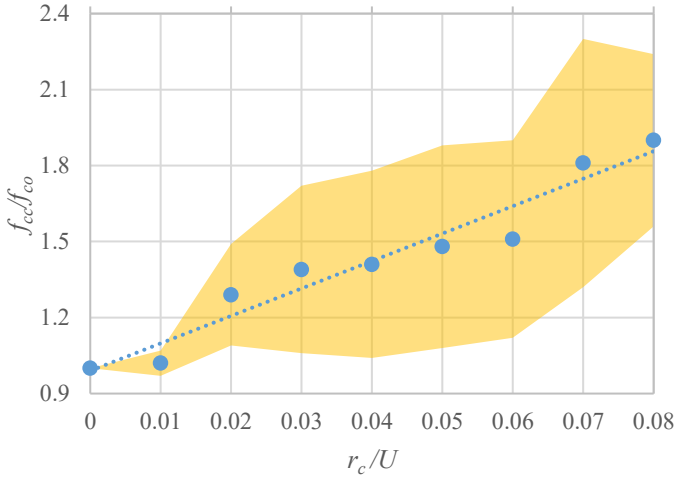

Fig. 1. Effect of corner radius over the enhancement ratio.

As can be observed from the figure, the strength enhancement ratio increases with increasing corner radius ratio. The irregular variation between these two parameters, together with the relatively high standard deviation values, can be attributed to the omission of other influential variables in the analysis. In addition to corner radius, parameters such as unconfined concrete strength, cross-sectional area, aspect ratio, and the ultimate strain capacity of the FRP material are expected to significantly influence the ultimate strength response.

In the following sections, the contribution of corner radius will be further examined with respect to unconfined concrete strength, aspect ratio, and confinement ratio.

4.1 Unconfined Concrete Strength

In order to evaluate the influence of unconfined concrete strength on the contribution of corner radius, a subset consisting of 150 × 150 mm square specimens was analyzed. Within the previously defined strength ranges, the variation of strength enhancement ratios with increasing corner radius is presented in Figure 2.

As seen in Figure 2, while the unconfined strength of specimens increases, the efficiency of the CFRP wraps reduces. Even though the efficiency reduces, with an increase in corner radius, the enhancement also increases. It is more prominent in low strength range while the contribution slows down with the increase in unconfined strength values as concluded in previous studies [9]. It should be kept in mind that the confinement ratios are varying and the given enhancement ratios are just average values.

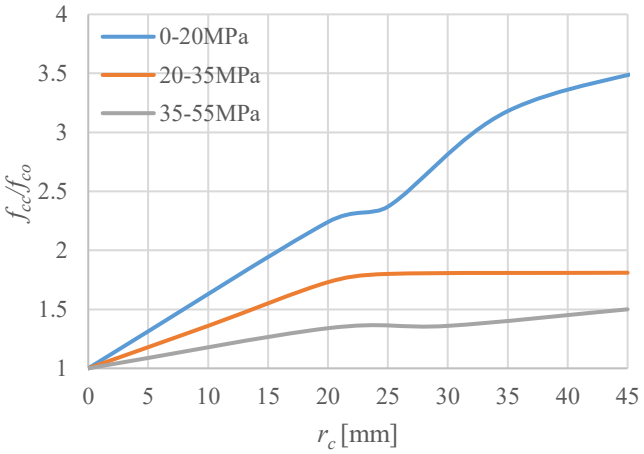

Fig. 2. Effect of corner radius over the enhancement ratio.

4.2 Aspect Ratio

The influence of corner radius was also investigated with respect to the aspect ratio using rectangular specimens with unconfined concrete strengths ranging from 20 to 43MPa. For this purpose, square specimens $(h/b = 1.0)$ and two types of rectangular sections $(h/b = 1.5)$ and $(h/b = 2.0)$ were considered. No restrictions were imposed on the confinement ratio or cross-sectional area, and the corresponding average values are presented in Figure 3.

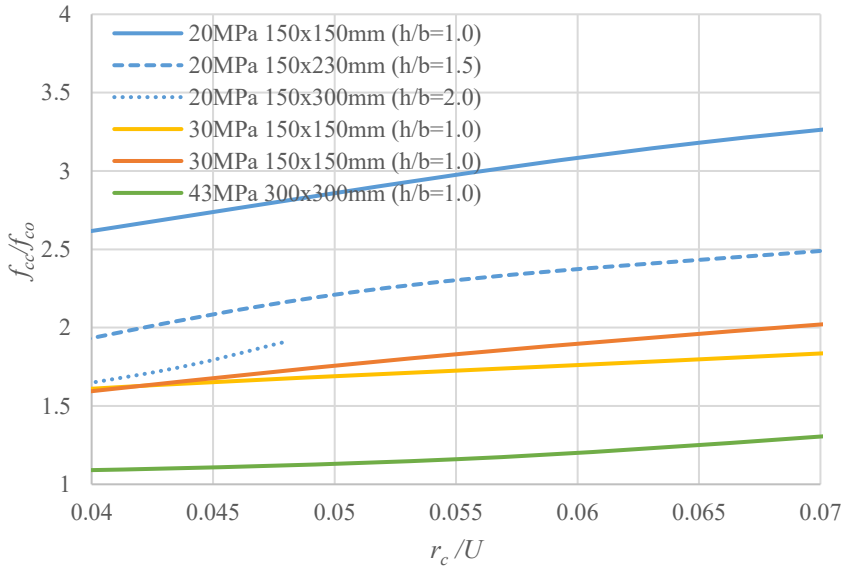

Fig. 3. Effect of aspect ratio over the enhancement ratio.

As shown in Figure 3, although the strength enhancement decreases with increasing aspect ratio for a given unconfined concrete strength, the influence of the corner radius-to-perimeter ratio remains evident. This observation suggests that neither the cross-sectional area nor the aspect ratio significantly affects the effectiveness of the corner radius ratio as a governing parameter for confinement-induced strength enhancement.

4.3 Confinement Ratio

The confinement ratio is defined as the ratio of the lateral confining pressure to the unconfined concrete strength, f_l/f_{co}. The lateral confining pressure was calculated using the expression given in Equation (7), which is based on the formulation adopted in TEC2018, excluding the

effect of the shape factor. This approach was selected as the reference measure of confinement intensity throughout the study.

$$f_l = \frac{E_{frp}\varepsilon_{frp}(b+h)tn}{bh} \tag{7}$$

Figure 4 illustrates the influence of corner radius on typical square specimens subjected to different confinement ratios. As can be observed from the figure, the contribution of corner radius to strength enhancement becomes more pronounced as the confinement ratio increases. In other words, the effect of corner rounding on the ultimate confined strength grows with increasing levels of FRP confinement.

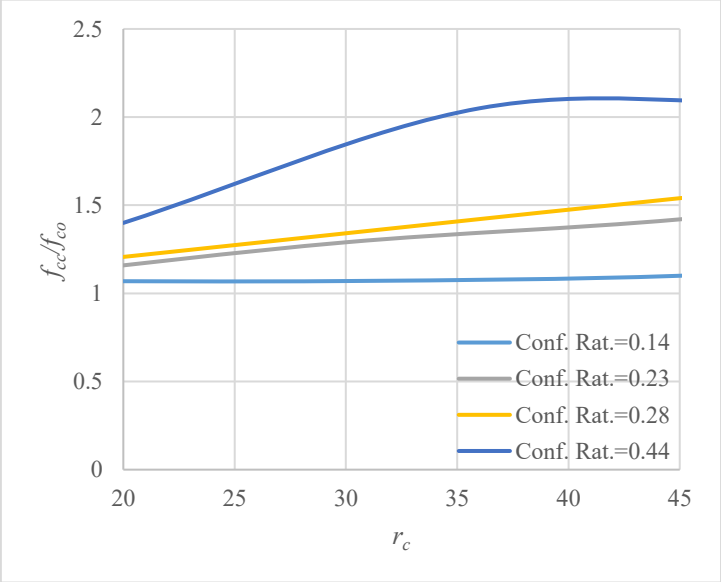

Fig. 4. Effect of corner radius over the enhancement ratio for several confinement ratios.

5 Comparison of Guideline and Model Expressions for Investigated Properties

The representation of corner radius within the shape factors adopted by the selected design guidelines and predictive models was discussed previously. The performance of these formulations in predicting the ultimate confined strength with respect to the investigated parameters was evaluated using the mean and standard deviation of the prediction results, and the findings are summarized in Table 2. In the table, the first value corresponds to the mean prediction ratio, while the second value represents the associated standard deviation. The predictive performance was assessed using the ratio of the predicted confined strength to the experimental confined strength, f_{cc}/f_{co}.

Table 2. Performance of the Expressions for Unconfined Concrete Strength Ranges

	f_{co} $[MPa]$								
	$f_{co} \leq 20$			$20 < f_{co} \leq 35$			$35 < f_{co}$		
r_c $[mm]$	$r_c \leq 15$	$15 < r_c \leq 30$	$30 < r_c$	$r_c \leq 15$	$15 < r_c \leq 30$	$30 < r_c$	$r_c \leq 15$	$15 < r_c \leq 30$	$30 < r_c$
TEC 2018 [3]	0.79/0.13	0.71/0.17	0.55/0.09	0.89/0.13	0.80/0.10	0.73/0.12	1.02/0.11	0.95/0.12	0.82/0.14
ACI 440.2R-17 [2]	0.85/0.17	0.80/0.10	0.66/0.07	0.97/0.14	0.86/0.12	0.84/0.11	1.11/0.11	1.00/0.12	0.94/0.14
CNR-DT200 R1/2013 [4]	0.99/0.16	0.89/0.20	0.70/0.12	1.08/0.15	1.00/0.11	0.93/0.14	1.21/0.13	1.14/0.14	1.02/0.16
İlki et al. [5]	0.93/0.14	0.91/0.19	0.72/0.10	0.99/0.12	0.95/0.09	0.89/0.13	1.10/0.12	1.04/0.13	0.91/0.14
Wu and Wei [6]	0.92/0.15	0.94/0.14	0.83/0.17	0.96/0.14	0.93/0.13	0.92/0.12	1.04/0.12	0.99/0.13	0.90/0.13
Lim and Ozbakkaloglu [7]	0.91/0.14	0.90/0.23	0.81/0.15	0.93/0.12	1.00/0.16	1.00/0.16	0.99/0.10	1.00/0.15	0.94/0.14

As can be seen from Table 2, almost none of the evaluated design equations adequately captures the influence of corner radius when the effect of unconfined concrete strength is considered. Among the examined formulations, only the model proposed by Wu and Wei can be regarded as providing relatively consistent predictions for the low-strength concrete group.

Table 3 summarizes the assessment of aspect ratio in relation to corner radius. The results indicate that the model proposed by İlki et al. [5] provides reliable predictions across all corner radius ranges for specimens with high aspect ratios. In contrast, for sections with $h/b \leq 1.5$, the provisions of the CNR guideline [4] appear to yield more accurate predictions.

Table 3. Performance of the Expressions for Aspect Ratio Ranges

Finally, the evaluation of the influence of corner radius with respect to different confinement ratio ranges is presented in Table 4. For low and medium confinement levels, the model proposed by İlki et al. [5] provides the most accurate predictions. For high confinement ratios, the model developed by Lim and Ozbakkaloglu [7] yields the most accurate estimates, although with slightly higher standard deviation values.

6 Conclusions

The influence of corner radius, one of the most critical parameters governing the strength enhancement of FRP-confined rectangular sections, was investigated with respect to the other characteristics of the specimens. By evaluating subsets of the database while keeping selected variables constant, it was found that increases in both unconfined concrete strength and confinement ratio enhance the contribution of corner radius to the ultimate strength gain. In contrast, variations in aspect ratio were observed to have little to no influence on the effectiveness of corner radius in improving the ultimate confined strength.

In addition, predictive models for estimating the strength of CFRP-confined concrete columns were evaluated with particular emphasis on the variation of corner radius. The interaction between unconfined concrete strength and corner radius was not consistently captured by any of the investigated models. With respect to aspect ratio, the Italian guideline [4] was found to provide more accurate predictions for square specimens, whereas the model

proposed by İlki et al. [5] yielded the most reliable results for rectangular specimens with an aspect ratio of 2.0.

Abstract. The structural modelling and analysis of unreinforced masonry (URM) buildings involves significant challenges due to their inherent complexities. Furthermore, the structural interactions and boundary conditions between different load-bearing components, such as continuous walls, vertical piers, horizontal spandrels and floor diaphragms, are often difficult to define, particularly in walls with irregular openings. To address these analytical difficulties, this study focuses on the Equivalent Frame (EF) method. This is a highly effective, simplified modelling approach that has recently been added to the current version of the Turkish Building Earthquake Code (TBEC-18). This study specifically investigates one of the most sensitive parameters in the EF method: the definition of rigid offsets, which determine the rigid nodes and the effective deformable length of the macro-elements, and evaluates its impact on the global seismic assessment. To achieve this, a comprehensive computational framework is developed using a MATLAB-based algorithm integrated with the SAP2000 Open Application Programming Interface (OAPI). By employing this computational tool, the study evaluates three URM structures impacted by the destructive 1995 Dinar earthquake. The aim is to establish the correlation between the actual physical damage and the analytical outcomes specified in the TBEC-18. Although post-earthquake field evaluations showed that these buildings sustained only limited damage during the 1995 Dinar earthquake, the TBEC-18 categorized them as 'Collapse Performance Level'. This discrepancy indicates that the structural safety limits defined in the code may underestimate the actual seismic capacity of existing URM buildings.

1 Introduction

The evaluation of the seismic vulnerability of existing masonry buildings continues to be an important issue worldwide. Many of these structures, including those of historical significance, are located in areas with varying levels of seismic risk and tend to show varying degrees of deterioration. Accurately assessing their earthquake risk is essential for identifying the most susceptible structures and determining the most appropriate strengthening procedures. This requires reliable and efficient modeling approaches that can realistically represent their seismic response (Pasticier et al., 2008).

Various modelling approaches for the structural analysis of masonry buildings have been proposed in the literature, each involving a different degree of idealization. As Lourenço (1996) explained, three main strategies can be adopted, depending on the desired accuracy of the model and the required computational efficiency (see Fig. 1). In the detailed micro-modelling approach, the masonry units and the mortar joints are represented separately using continuum elements and the interfaces between them are modelled using discontinuous elements. In the

simplified micro-modelling technique, the masonry units are expanded and the mechanical response of the mortar joints and interfaces is incorporated into the discontinuous elements. By contrast, the macro-modelling approach treats the masonry assemblage as a homogeneous continuum by averaging the properties of the units, the mortar and the interfaces.

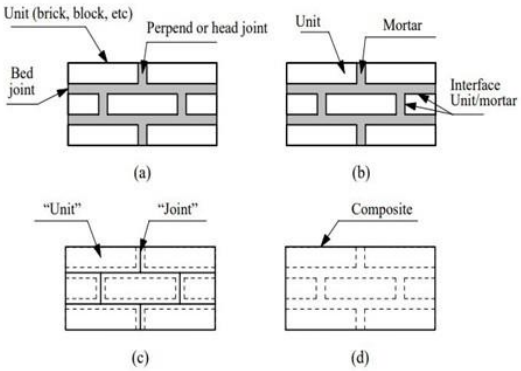

Fig. 1. Illustration of modeling strategies for masonry: a) sample of masonry; b) detailed micro-modeling; c) simplified micro-modeling; d) macro-modeling (Lourenço, 1996)

Among the various modelling approaches available in the literature, this study employs the EF method which is a well-known macro-modelling technique that is both practical and computationally efficient. In this approach, load-bearing masonry walls are represented by one-dimensional elements that simulate the behavior of individual wall segments. The EF model considers the axial, flexural and shear deformability of masonry panels, and rigid connections are employed to link these components (Siano et al., 2017). This method is based on the similarity between masonry buildings and two-dimensional frame systems, resulting in the structure being modelled as a combination of deformable macro-elements (piers and spandrels) and rigid nodes, as shown in Fig. 2.

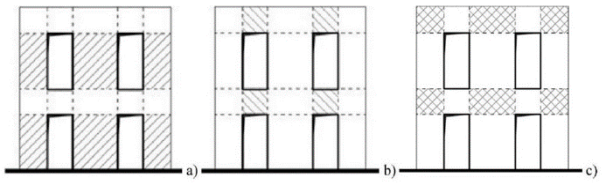

Fig. 2. URM wall idealization according to EF method: a) piers; b) spandrels; c) node panels (Siano et al., 2017)

The accuracy of the EF method is highly sensitive to the geometric definition of its components, specifically the definition of rigid offsets (RO), which dictate the rigid boundary zones and the effective deformable lengths of piers and spandrels. In the literature, various RO models for pier and spandrel members have been proposed (e.g., Dolce, 1991; Augenti, 2006; Moon et al., 2006; Cattari and Lagomarsino, 2009; Lagomarsino et al., 2013; Bracchi et al., 2015; Manzini et al., 2022). Different RO assumptions can drastically alter the lateral stiffness, period, and overall seismic performance evaluation of a masonry structure, leading to significant uncertainties in code-based assessments. Therefore, this study aims to investigate the seismic assessment of URM buildings and to evaluate the conservatism of code-based methodologies given in the TBEC-18 [11]. To achieve this, a comprehensive and fully automated computational framework is developed by integrating a MATLAB-based algorithm [12] with the SAP2000 OAPI [13]. This advanced tool enables the rapid generation of EF models and the automated execution of linear seismic assessments. Using this framework, a comparative analysis is performed on three URM buildings that survived the devastating 1995 Dinar earthquake. By comparing the analytical performance thresholds set out in the TBEC-18 with the actual post-earthquake damage states of these buildings, this study highlights the dramatic contrasts between code-based calculations and physical structural behavior.

2 Automated Methodology: MATLAB – SAP2000 Integration

Despite their conceptual efficiency, manually generating 3D EF models for complex, multi-story URM buildings is a highly challenging, time-consuming and error-prone process. The manual calculation of effective deformable lengths, the assignment of specific material properties, and particularly the precise geometric definition of RO for hundreds of structural members requires immense effort. To overcome these limitations and ensure analytical consistency, this study develops a novel, fully automated MATLAB-based algorithm. The algorithm begins with the preparation of a text-based input file (*.txt), which defines the coordinates of the exterior walls, interior walls, as well as door and window openings, as illustrated in Fig. 3.a. Once this dataset has been imported into the program, a sequential computational workflow is initiated. Firstly, the algorithm generates a three-dimensional visualization of the building's geometry for verification purposes (see Fig. 3.b). Subsequently, the program's integrated selection modules allow the user to dictate specific modelling assumptions by choosing the preferred effective height criterion for the piers and spandrel members (see Fig. 4). In this part, two distinct approaches are adopted for the EF model analysis: the “No RO” method and the “Dolce RO” method. The rationale for selecting these specific methods lies in their regulatory and academic relevance; the “No RO” approach is explicitly defined within the “Regulations Governing the Identification of Risky Buildings” (Riskli Yapıların Tespit Edilmesine İlişkin Esaslar-RYTEİE, 2019) [14], whereas the “Dolce RO” [4] method is one of the most widely cited and utilized approaches in the literature. Additionally, given the limited criteria available for their effective deformability, spandrels are modelled as fully rigid elements throughout this analysis. Finally, the algorithm automatically constructs the complete EF model of the building as shown in Fig. 5.

3 Case Studies and Results

In order to compare code-based analytical assessments with physical structural behavior, a linear seismic evaluation is conducted on three existing URM buildings affected by the 1995 Dinar earthquake (see Fig. 6) [15].

a) b) c)

Fig. 6. External views of the existing URM buildings investigated as case studies following the 1995 Dinar earthquake: (a) single-story (B1), (b) two-story(B2), and (c) three-story (B3) buildings

To accurately determine the seismic performance of the buildings under investigation, the first step is to generate representative mathematical models. In TBEC-2018, structural analysis can be performed using either the finite element or equivalent frame approaches. For this study, the computational models are constructed using the EF method (see Fig. 7).

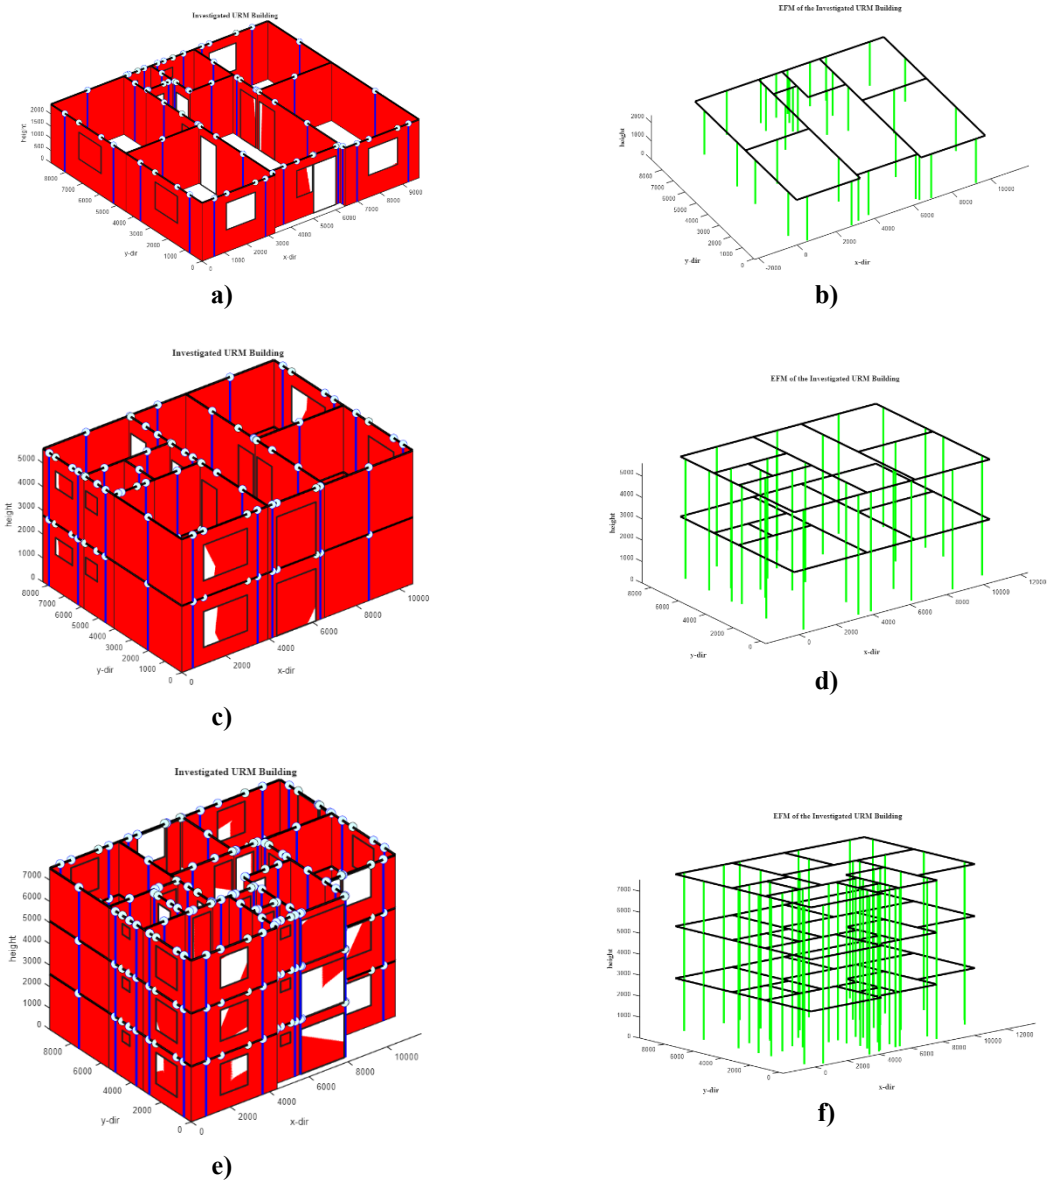

Fig. 7. 3D and EF views of the investigated URM buildings: a) B1; b) B2; c) B3, generated using the No RO criteria and fully rigid spandrels.

After defining the geometric dimensions and material properties, linear structural analyses are performed under the load combinations specified by TBEC-2018 (see Table 1). These analytical combinations are divided into two groups, COMB-A and COMB-B, based on varying gravity load magnitudes and multidirectional seismic actions. Specifically, combinations COMB1 to COMB8 fall within the COMB-A group [$G + Q + 0.2S + E_d^{(H)} + 0.3E_d^{(Z)}$], which considers the maximum vertical seismic effects by scaling the dead load factors to ($1 + 0.3*(2/3*S_{DS})$) and combining 100% of the horizontal seismic action in the principal direction with a 30% contribution from the orthogonal direction. Conversely, COMB9 to COMB16 fall within the COMB-B group [$0.9G + H + E_d^{(H)} – 0.3E_d^{(Z)}$], which employs a reduced gravity load of ($0.9 – 0.3*(2/3*S_{DS})$) to evaluate the structure under minimum vertical load.

The specific seismic demands acting on the structures are derived based on the local soil conditions and seismic hazard parameters obtained directly from the Türkiye Earthquake Hazard Map. For the specific location of the case study buildings (Konak, Dinar district (Latitude:38.078872; Longitude:30.169655)), the seismic parameters are determined corresponding to the seismic intensity level-2 (DD-2), which represents the standard design earthquake with a 10% probability of exceedance in 50 years (a return period of 475 years). Accordingly, the map spectral acceleration coefficients for the short period (S_S), the one-second period (S_1), the design spectral acceleration coefficients for the short period (S_{DS}) and the one-second period (S_{D1}) are obtained as 0.799, 0.188, 0.719, and 0.150 respectively. Furthermore, the peak ground acceleration (PGA) and peak ground velocity (PGV) for the investigated site are determined as 0.334 g and 18.630 cm/s, respectively.

Table 1. Load combinations according to TBEC-18

COMB – A	$G + Q + 0.2S + E_d^{(H)} + 0.3E_d^{(Z)}$
COMB – B	$0.9G + H + E_d^{(H)} - 0.3E_d^{(Z)}$

For the linear seismic assessment, the 'Equivalent Seismic Load Method (ESLM)' procedure specified in TBEC-18 is employed. According to this method, the total equivalent seismic load (i.e., base shear force), V_t, acting on the entire building in the considered earthquake direction is calculated using Eq. 1.

$$V_{tE}^{(X)} = m_t \times S_{aR}(T_p^{(x)}) \geq 0.04 \times m_t \times I \times S_{DS} \times g \quad (1)$$

The mechanical and physical properties of the masonry materials used in the structural models are defined in accordance with the reference values specified in TBEC-2018. Assuming solid clay brick construction, the unit weight of the load-bearing walls is 1.9 t/m³. In line with the code provisions, the characteristic compressive strength of the masonry (f_k) is assigned a value of 9 MPa. Consequently, the modulus of elasticity (E_m) is calculated as 6750 MPa using the specified correlation of $750*f_k$. Additionally, the initial shear strength (f_{v0}) of the walls is assumed to be 0.20 MPa.

In this study, the mathematical models of the investigated buildings are constructed utilizing the developed MATLAB-based algorithm. All geometric and topological parameters required for the EF model are computed in MATLAB and automatically transferred to SAP2000. Following this, the performance levels of the structures are evaluated using linear seismic assessments in the SAP2000 software. According to TBEC-18, the seismic performance of masonry buildings is evaluated based on three distinct criteria:

- the Limited Damage Performance Level (LDPL),
- the Controlled Damage Performance Level (CDPL), and
- the Collapse Performance Level (CPL).

A building is considered to satisfy the LDPL when the seismic shear demand can be resisted by all walls in both orthogonal directions. If, at any story, the walls with insufficient shear capacity account for less than 40% of the total story shear in the loading direction, the building is classified as meeting the CDPL. However, when this ratio exceeds 40%, the structure is classified as CPL (TBEC-18).

The detailed story- and direction-specific collapse ratios for different seismic load combinations are comprehensively presented in Fig. 8. As shown in the figure, the computed collapse ratios exceed the 0.40 limit defined by TBEC-18, regardless of the number of stories (B1, B2 or B3) or the orthogonal loading direction (x or y). While the 'Dolce RO' modelling approach changes the distribution of internal forces, often reducing the collapse ratios for certain combinations compared to the 'No RO' condition, these changes are insufficient to shift the global performance state. While some specific loading scenarios satisfy the CDPL

thresholds (e.g. COMB7 and COMB8 in the Y direction for the B3 building), the governing combinations generally push the structures into the collapse zone. Following the linear analysis procedure defined by TBEC-18, all three investigated buildings are classified under the CPL. The analytical results revealed the underlying critical structural behavior for this classification: while the load-bearing walls in these buildings safely withstood the applied axial compressive forces, they significantly failed to satisfy the required shear stress criteria. Consequently, this widespread inadequacy in shear capacity dictated their global seismic performance state.

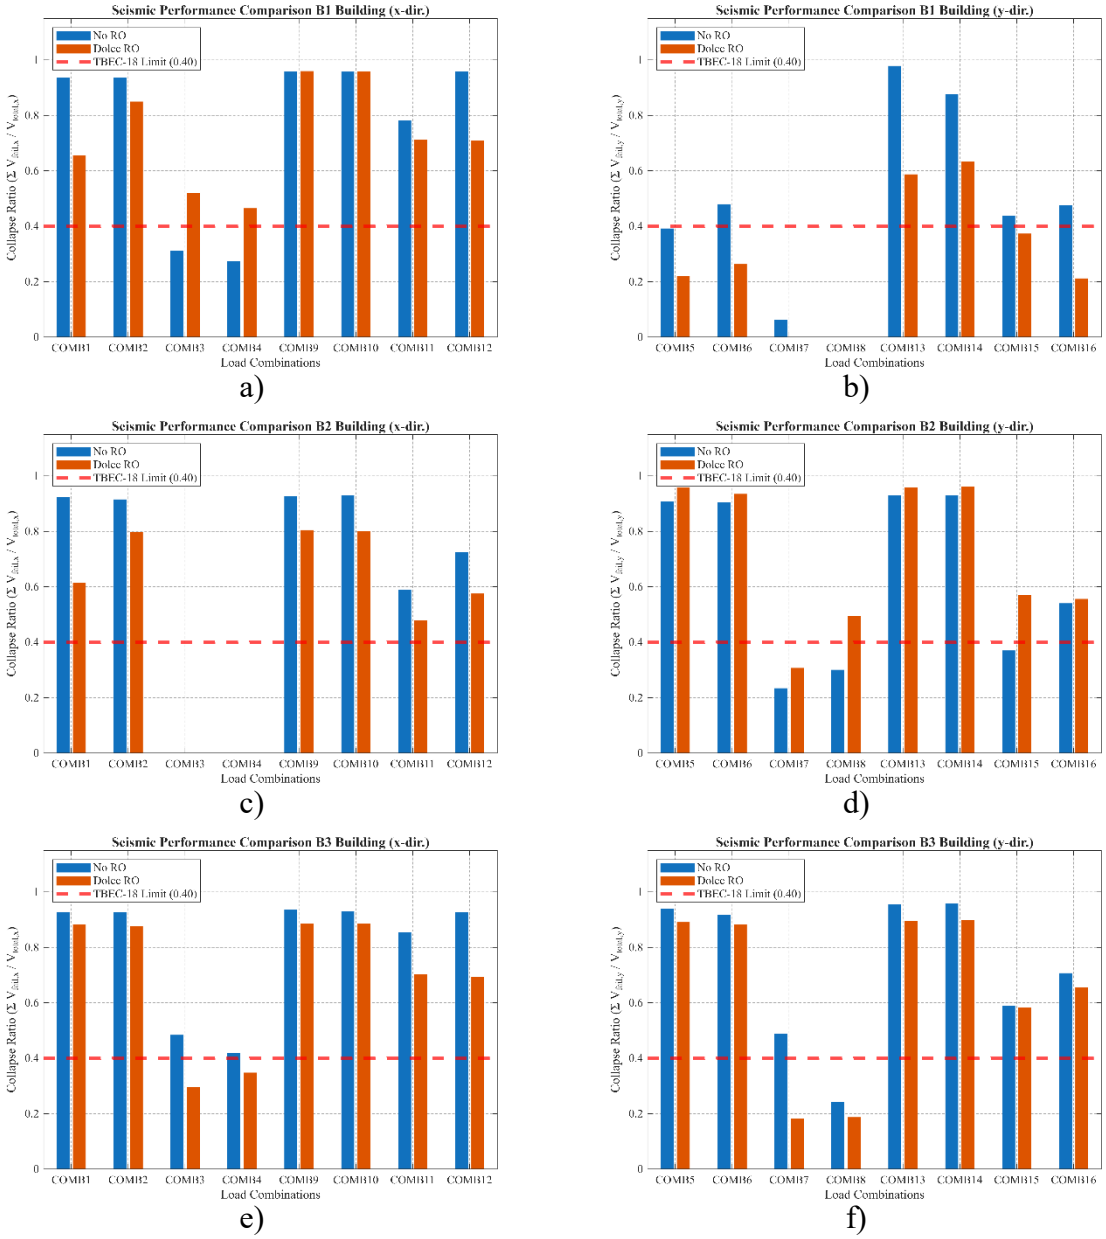

Fig. 8. Comparison of the seismic collapse ratios for different load combinations with "No RO" and "Dolce RO" modeling assumptions for the investigated URM buildings: (a, b) B1, (c, d) B2, and (e, f) B3 in the orthogonal x and y directions, respectively. The red dashed line denotes the critical threshold of 0.40 specified by TBEC-18 for the CPL.

4 Summary and Conclusion

This study investigates the provisions of TBEC-18 regarding the seismic performance assessment of URM buildings, comparing the code-based calculations with observed physical structural behavior. Despite the fact that post-earthquake inspections reported only minor to moderate damage in these buildings after the 1995 Dinar earthquake (Figure 6) (METU-EERC, 1996) [16], linear elastic evaluations performed according to TBEC-18 placed all of them in the CPL state. The clear discrepancy between the buildings' actual structural behavior and the results of the code-based assessment indicates that TBEC-18 may significantly underestimate the seismic capacity of existing URM buildings.

In summary, post-earthquake field observations show that the seismic response of URM buildings is strongly influenced by the intensity of earthquake demand as well as the interaction of major structural characteristics. Among these, building height, wall area ratio, and compliance with code-based plan layout requirements play a decisive role in improving structural performance. Therefore, a reassessment of the limit values specified in TBEC-18 for URM buildings would be appropriate.

Abstract. Cross-Laminated Timber (CLT) combined with folded plate systems offers highly efficient structural solutions, yet their overall performance is heavily dictated by the semi-rigid behavior of their angled joints. This study experimentally investigates the closing-mode bending performance of 90-degree L-type CLT joints to characterize their moment capacity, rotational stiffness, ductility, and progressive failure mechanisms. The experimental program was conducted using a 6-axis Load and Boundary Conditions Box (LBCB) at the FSMVU Structural Laboratory. Three distinct joint configurations were tested: pure structural adhesive (PUR), a mechanical cam-and-dowel system (Maxifix), and an internal steel angle bracket. Results revealed significant variations in load-displacement behavior. The pure adhesive joint exhibited the highest peak load capacity but failed catastrophically with a sudden rupture, characterized by severe wood fiber pull-out and cross-section splitting. The Maxifix system demonstrated moderate peak capacity; however, it provided substantial ductility. The steel pins embedded into the surrounding wood without shearing, allowing the joint to articulate safely like a hinge without total detachment. The steel angle bracket showed unexpected progressive failure, including premature screw shearing and internal wood wedge crushing due to geometric constraints. The findings conclude that while pure adhesives provide high initial stiffness, they lack essential ductility for extreme conditions. Conversely, mechanical systems offer high ductility but lower strength. Future studies will focus on hybrid systems combining structural adhesives with mechanical fasteners. This approach aims to achieve both high strength and post-peak ductility, providing a fail-safe mechanism for modular timber structures while optimizing manufacturing and assembly costs.

1 Introduction

Timber folded plate systems are innovative structures with high structural efficiency that, owing to their form-active nature, can span large openings with very slender cross-sections. These structures transform the material's own tectonics into an architectural expression while creating spatial boundaries (Fig. 1). However, the overall stability and performance of these load-bearing systems depend largely on the semi-rigid behavior at the intersection points of the plates.

In such composite systems, Cross-Laminated Timber (CLT) offers a revolutionary solution by acting as a continuous shear wall. In industrial structural applications, CLT panels are generally manufactured and used with a thickness greater than 6 cm and with at least three layers (laminae). However, recent analyses of the structural behavior of form-active timber folded plate systems relax this thickness requirement. Finite Element Analysis (FEA) and optimization studies conducted in a previous work (Akyürek and Köymen, 2026) showed that, thanks to the advantage provided by the form, spans of 10-12 meters can be safely covered with slender CLT plates 30-40 mm thick. Based on this scientific finding, the test specimens in the presented empirical study were standardized to a thickness of 40 mm.

Fig. 1. Architectural concept model of the "Barkat" project, featuring a cross-laminated timber folded plate structure.

In the literature, the potential of timber folded plates was demonstrated by Buri and Weinand (2008) specifically for plywood and CLT; however, particular attention was drawn to the mechanical constraints at acute-angled corner joints ranging between 10° and 80°. The stripping of wood fibers by traditional nailed or screwed connections reduces the structural capacity. Current industrial CLT design guides (KLH, 2012; Swedish Wood, 2019) generally provide solutions for standard right-angle connections, while data on the concealed (internal) use of metal reinforcements in variable-angle forms remain lacking. In studies conducted in Türkiye, Ceylan and Girgin (2019; 2020) investigated the withdrawal resistance of nails and metal angle brackets in CLT wall-floor connections. Ilgın et al. (2021), on the other hand, emphasized the potential of geometric interlocking methods such as dovetail and comb joints in solid timber, but noted that multi-axis CNC requirements limit industrial accessibility. Similarly, although Robeller et al. (2017) demonstrated the rotational stiffness of integrated mechanical joints in double-layered folded plates, the requirement for 5-axis CNC complicates practical application. On the other hand, the withdrawal strength of systems such as Maxifix (cam-and-dowel), a practical and demountable connection hardware in the timber industry, was investigated by Efe et al. (2012), pointing to the alternative potential of these fittings in structural joints.

In the digital design and static (FEA) modeling stages, timber joints are generally idealized mathematically as "fully rigid." In physical reality, however, joints inherently undergo deformation and exhibit a "semi-rigid" character. This critical interface between the rigid assumption in design and the actual mechanical capacity of the connection points makes it

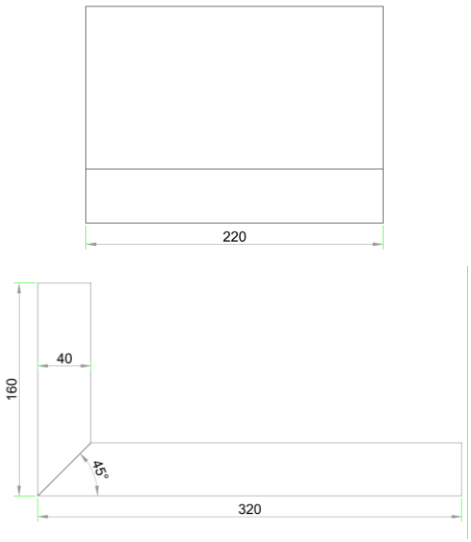
essential to perform empirical mechanical tests in order to verify the structural safety of the system.

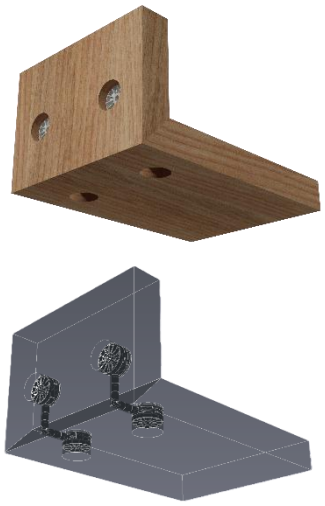
In line with this requirement, the 90-degree L-Type bending/closing test (Eckelman, 2003; Kasal et al., 2025), a universal standard in furniture and timber engineering, was applied in the experimental design of the presented study. The experiments were carried out using the 6-axis Load and Boundary Conditions Box (LBCB) at the Structural Laboratory of Fatih Sultan Mehmet Vakıf University (FSMVU). This laboratory's versatile testing capacity and infrastructure have proven their reliability in recent research investigating historic and modern timber joints (Doğramacı Aksoylar et al., 2026).

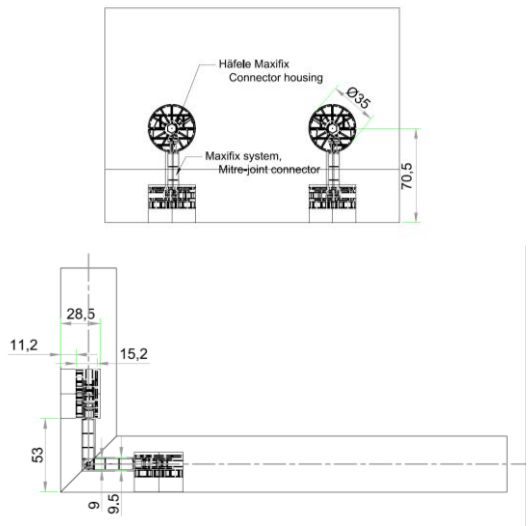
The main aim of this study is to comparatively investigate the mechanical behavior of concealed mechanical joint techniques (Maxifix, internal steel angle bracket) and integrated methods that are applicable to slender (40 mm) CLT folded plate systems without compromising aesthetics, against a reference specimen using pure structural adhesive (PUR). The original contribution of the study is that it reveals for the first time how these fittings—not previously tested empirically in the literature for acute-angled heavy timber plates—not only facilitate on-site work by aligning the panels during assembly, but also act as a ductile "mechanical fuse" that prevents sudden collapse in the event of brittle rupture of the adhesive under excessive load. It is intended that the resulting data on moment capacity, rotational stiffness, ductility, and progressive failure will provide a new reference set for the literature and pioneer the low-cost, safe construction of modular timber structures.

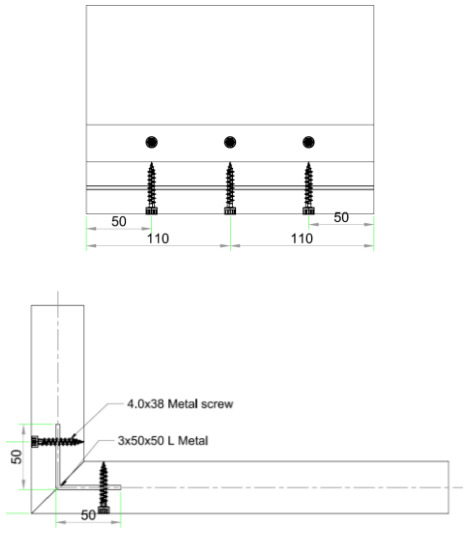
2 Materials and Methods

The specimen manufacturing processes in this study were carried out at the İZÜ Barkat Timber Construction Workshop, while the mechanical testing stages were conducted under the coordination of the FSMVU Structural Laboratory. Within the scope of the study, three different configurations were designed and tested in order to empirically compare the different joint details of folded plate systems.









2.1. Specimen Geometry and Joint Types

The specimens used in the experiments were produced from 40 mm thick Cross-Laminated Timber (CLT) panels, predicted by FEA analyses to be capable of spanning 10-12 meter openings in timber folded plate structures. In accordance with the L-type test configuration, the specimens were standardized with a fixed arm of 160 mm, a moving arm 320 mm high, and a width of 220 mm for both arms (Table 1). The cross-sectional faces were cut at a 45° miter angle to maximize moment transfer.

Three different joint types were addressed within the scope of the study:

1. **Adhesive (PUR) Joint:** This is the reference group, in which full surface-to-surface bonding is achieved using only structural polyurethane (PU) adhesive.
2. **Maxifix Connection (Mechanical Cam-and-Dowel):** This is a demountable mechanical system created using 35 mm diameter steel housings positioned 70.5 mm inward from the wood surface and 9 mm diameter articulated connecting dowels. No adhesive was used between the panels.
3. **Angle Bracket (Metal Angle Bracket) Joint:** This is a system in which a continuous steel L-profile measuring 3x50x50 mm placed at the inner corner is anchored with 5x40 mm countersunk-head sheet-metal screws driven in a staggered pattern from the inside outward into the solid part of the CLT. It was designed as a concealed detail in which the external architectural surface is not penetrated. However, due to manufacturing constraints, a 1.5x20x20 mm steel angle bracket and 5x50 mm chipboard screws were used in the experiments, and owing to geometric necessity the screws were oriented into the wood at an angle (diagonally).

Table 1. General views, connection details, and dimensions of the tested joint configurations.

Joint Type	3D Visualization	Technical Details & Dimensions
Pure Adhesive (PUR) Joint		
Mechanical Cam-and-Dowel (Maxifix) Joint		
Metal Angle Bracket Joint		

2.2. Test Setup

The experimental investigation of the L-Type timber joints was carried out using a six degree of freedom Load and Boundary Condition Box (LBCB) at the "Structural Mechanics and Earthquake Research Laboratory" of Fatih Sultan Mehmet Vakif University. To ensure a stable and rigid connection between the loading system and test specimen, a rigid steel reaction wall which is fabricated from steel sections and plates was bolted to the LBCB. The tests system capable of operating under both load-controlled or displacement-controlled loading protocols. A general view of the test setup used in this study is illustrated in *Fig. 2a*.

The test setup was designed based on a recently developed timber connection testing system reported in the literature (Dogramacı Aksoylar et al., 2026). The horizontal member (short arm) of the specimen was rigidly attached to the steel reaction wall using a fixing steel plate (10 x 50 x 320 mm) fastened with two M12 bolts. The displacement was applied to the free end of the vertical member (long arm) through a steel angle. The details of the test setup and applied boundary conditions are presented in *Fig. 2b*.

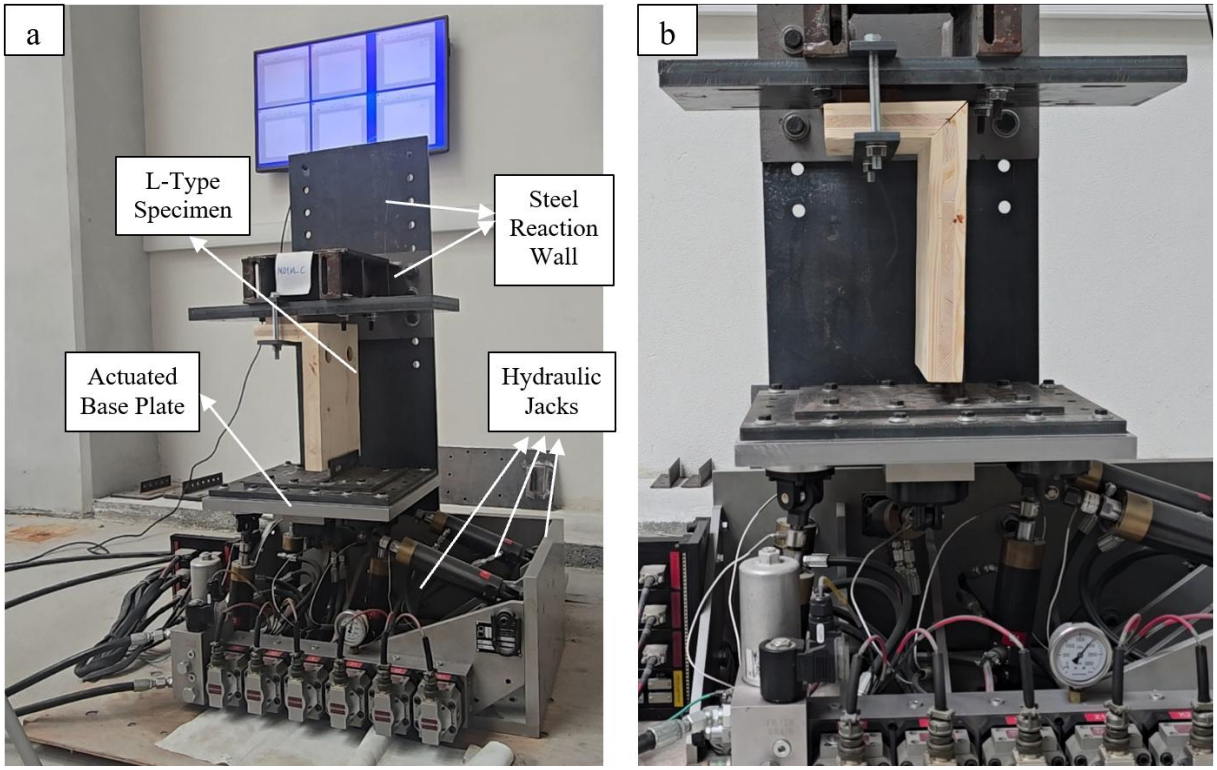


Fig. 2. Test setup a) general view b) applied boundary conditions.

2.3. Loading Protocol

The joint angles of folded plate systems may vary depending on the timber structural configuration. In this study, a standard joint geometry was adopted to enable a reliable and comparable evaluation of their behavior and load carrying capacities. For this purpose, a 90° L-type corner joint which is widely used in timber engineering and furniture studies (Eckelman, 2003; Kasal et al., 2025). was selected. The experiments were conducted in closing configuration in order to investigate the influence of using different fasteners on the mechanical performance of the joints.

The initial closing tests of L-type connections are carried out under monotonic loading to determine their maximum load carrying capacity and yield/ultimate displacements. In these tests, displacement-controlled loading is used and the free end of the vertical member is pushed upward in 1 mm incremental steps until a total displacement of 80 mm is reached. At each step,

the displacement was applied to specimen using moving plate and corresponding reaction force was recorded.

3 Experimental Results and Discussion

The load-carrying capacities and failure modes of corner joints with three different configurations were experimentally investigated. The configurations consisted of joints bonded only with structural polyurethane (PUR) adhesive, internal steel angle bracket, mechanical cam-and-dowel (Maxifix) connector. Their mechanical behavior was compared based on load-carrying capacity, stiffness and failure characteristics. The load – displacement relations obtained from the monotonic closing tests of joints are presented in *Fig. 3*. Table 1 summarizes the maximum lateral load, displacement at maximum load, stiffness evaluated at a displacement of 20 mm and corresponding failure modes of each specimen.

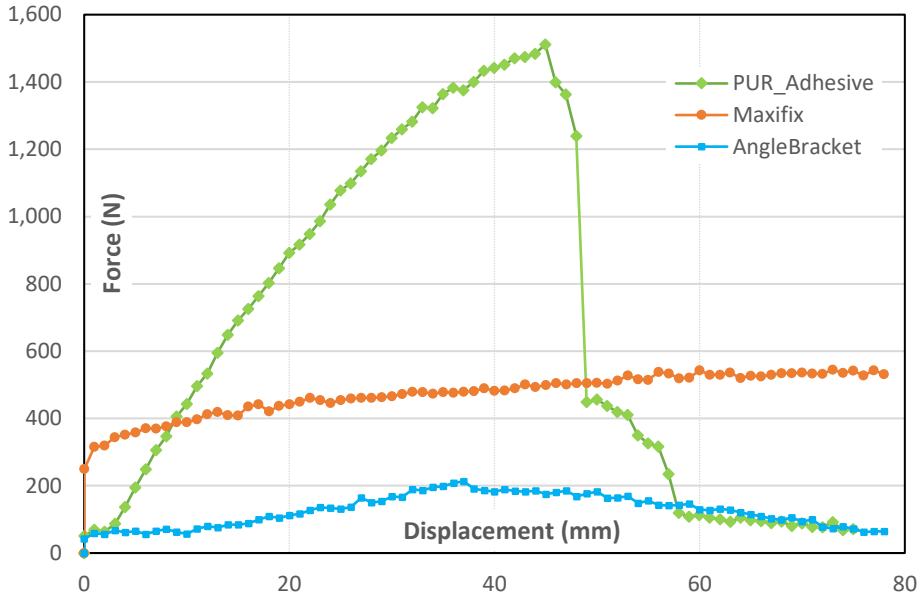

Fig. 3. Load-displacement relationships of L-type timber joints.

The experimental results showed that the type of fastener had a significant influence on the lateral behavior of the L-type joints. The specimen bonded with PUR adhesive exhibited highest lateral load capacity among all test specimens. The connection reached a maximum load of 1510 N at a displacement of 45mm. The load increased almost linearly during the initial loading stage, indicating high stiffness. The stiffness at a displacement of 20mm was 44.6 N/mm showed the high rigidity of bonding joint. After reaching the peak load, a sudden and substantial loss in load capacity occurred, with the resistance rapidly decreasing by approximately 450 N followed by a rapid reduction to nearly zero. This behavior indicates brittle failure mode caused by adhesive debonding at the wood-adhesive interface.

The specimen with the Maxifix connector exhibited a stable and consistent ductile response throughout the test despite its lower lateral load- capacity compared to the PUR adhesive. The load increased continuously without any significant loss, reaching its maximum capacity of 545 N at a displacement of 73 mm which was the largest displacement among all test specimens. At a displacement of 20 mm the stiffness was 22,1 N/mm approximately half of the PUR adhesive joint. At larger displacement levels, minor fluctuations were observed in the load-displacement curve. These fluctuations did not lead to a significant reduction in overall capacity. This indicates that joint with Maxifix connector possessed deformation capability. The connection exhibited stable and ductile response with failure characterized by wood embedment and deformation on the connector components (*Fig. 4*)

Table 2. Summary of experimental results.

Specimen Type	Maximum Load (N)	Disp. at max. load (mm)	Stiffness at 20mm (N/mm)	Failure Modes
Pure (PUR) Adhesive	1510	45	44,6	Brittle Failure Adhesive Debonding
Mechanical Cam and Dowel (Maxifix)	545	73	22,1	Ductile Behavior / Wood embedment
Inner Angle Bracket	213	37	55,9	Gradual Loss / Bending of angle bracket or pull out screws

Among all test specimens, the connection with inner angle bracket exhibited the lowest load-carrying capacity. The maximum lateral load was only 213 N at a displacement of 37 mm. Although this connection showed the highest initial stiffness (55,9 N/mm) its load-carrying capacity remained limited. The load increased almost linearly to the maximum load and then gradually decreased with increasing displacement. Unlike the PUR adhesive joint, no sudden loss was observed after the maximum load. The connection experienced a progressive reduction in load-carrying capacity due to bending of internal angle bracket and/or screw pull out. The observed failure mechanisms of each specimen examined and are presented in *Fig. 4*.

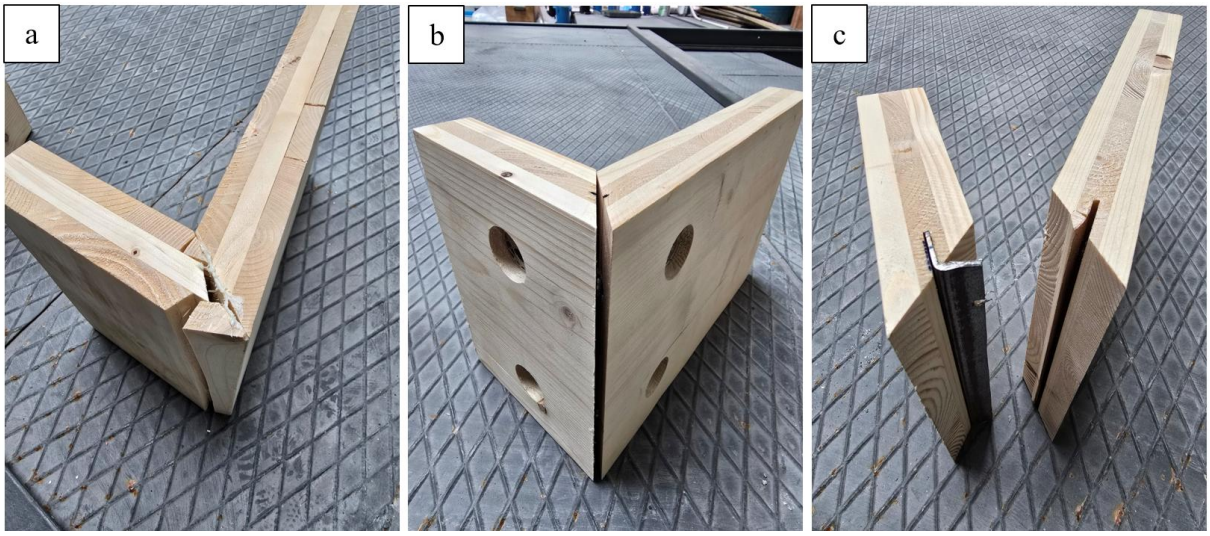

Fig. 4. Failure mechanisms of the three joint configurations at ultimate displacement: (a) Pure adhesive, (b) Maxifix system, (c) Angle bracket.

4 Conclusion

In this study, the bending/closing performance, moment capacity, and failure mechanisms of L-type corner joints configured with 40 mm thick CLT panels for use in timber folded plate systems were investigated empirically. The laboratory tests revealed that the joint types possess opposing but complementary potentials in their structural behavior.

The main conclusions obtained from the study can be summarized as follows:

- **PUR Adhesive Joint:** By offering the highest initial stiffness and moment-carrying capacity, it has the potential to initially meet the "fully rigid" expectation of theoretical

FEA analyses. However, at ultimate failure it exhibited a sudden and brittle fracture with tearing of the wood fibers, demonstrating a major weakness in terms of structural safety under excessive loading.

- **Maxifix Joint:** Although it lagged behind the adhesive systems in peak load capacity, it exhibited outstanding structural ductility thanks to its ability to crush the wood and continue rotating like a hinge.
- **Angle Bracket Joint:** The fitting-size constraints encountered in manufacturing and the resulting mandatory angled screwing caused the screws to tear the steel and strip out prematurely, preventing the system from displaying its full potential. This proved how critical geometry and fitting tolerances are in concealed detail solutions.

In light of these findings, it was concluded that, for the safe construction of large-span, slender modular timber folded plates, neither purely adhesive nor purely mechanical connections would be sufficient on their own. In this case, the ideal structural solution is considered to be "hybrid joint systems" in which the high stiffness of structural adhesive and the deformation capacity of concealed mechanical fittings are combined at the same interface.

In the subsequent stages of the study, different joint scenarios—adhesive, mechanical, and hybrid—will be tested with multiple repetitions in order to seek more comprehensive and definitive findings. In addition, the rotational stiffness and moment capacity data obtained from these studies will be used directly in the calibration of the Finite Element (FEA) model of the project's digital twin. Thus, the hypothesis that, in the event of debonding of the adhesive under extreme loading or environmental fatigue, the internal mechanical fitting will act as a ductile "structural fuse" that saves the structure from sudden collapse will be examined, contributing new findings to the timber engineering literature.

Acknowledgments

This research was partially supported by the Istanbul Sabahattin Zaim University Scientific Research Projects (BAP) Coordination Unit under grant number İZÜ BAP-2025-400-065. The authors gratefully acknowledge the Fatih Sultan Mehmet Vakıf University (FSMVU) Structural Laboratory and the İZÜ Barkat Timber Construction Workshop for providing the testing facilities and infrastructural support during the manufacturing and experimental phases of this study. Furthermore, special thanks are extended to Ali Özben for his valuable support in material procurement.

Abstract. This paper presents a scientometric analysis of research on the AI-enhanced mechanical behavior of laminated glass, based on 345 publications retrieved from the Scopus database between 2017 and 2026. Following relevance-based filtering, 74 studies were selected and analysed using keyword co-occurrence mapping and visualisation with VOSviewer. Five thematic clusters were identified: (1) fracture and mechanical behavior of glass materials, (2) mechanical behavior of laminated glass systems, (3) computational modelling of glass structures, (4) data-driven modelling of glass structural behavior, and (5) AI-enabled structural health monitoring. The findings reveal that foundational research on fracture mechanics and laminated glass behavior is well established. However, significant research gaps remain at the interfaces between the thematic clusters. One of the most important gaps is the limited integration of physics-informed neural networks with structural health monitoring frameworks. Another critical gap is the absence of data-driven models linking interlayer viscoelasticity to the structural response of laminated glass systems. These topics represent some of the most strategically significant and underexplored research directions in the field.

Keywords: Laminated Glass, Artificial Intelligence, Machine Learning, Structural Health Monitoring, Mechanical Behavior.

1 Introduction

Laminated glass has become an essential structural material in modern architecture due to its ability to simultaneously satisfy transparency, safety, and mechanical performance requirements. Unlike monolithic glass, laminated glass consists of two or more glass plies bonded by a polymeric interlayer, enabling the fractured glass fragments to remain attached after breakage [6] and thereby reducing the risk of catastrophic failure. This unique post-fracture behavior has promoted its widespread application in façades, roofs, skylights, pedestrian bridges, balustrades, and other load-bearing structural components where both structural integrity and occupant safety are critical.

Despite its increasing utilization, accurately predicting the mechanical behavior of laminated glass remains a challenging task. Its response is governed by highly nonlinear interactions among the glass layers, the viscoelastic interlayer, environmental conditions, loading rate, and fracture mechanisms [10]. The time- and temperature-dependent characteristics of polymer interlayers further complicate numerical modelling and structural analysis [4]. Consequently, conventional analytical formulations and finite element simulations often require substantial computational effort while remaining dependent on simplifying assumptions that may limit predictive accuracy for complex loading scenarios.

Recent advances in artificial intelligence (AI) have introduced new opportunities for addressing these challenges. Machine learning (ML), deep learning (DL), artificial neural networks (ANNs), convolutional neural networks (CNNs), support vector machines (SVMs) [5], and, more recently, physics-informed neural networks (PINNs) have demonstrated considerable potential for predicting structural responses, identifying damage, optimizing

design parameters, and supporting structural health monitoring (SHM). These data-driven approaches are capable of extracting complex nonlinear relationships from experimental and numerical datasets, thereby complementing conventional mechanics-based modelling techniques [8]. As a result, AI has emerged as an increasingly important research direction in the field of laminated glass engineering.

The rapid expansion of publications in this interdisciplinary domain has generated a diverse body of knowledge spanning fracture mechanics, computational modelling, optimization algorithms, structural monitoring, and intelligent prediction systems. However, despite the growing number of studies, current research remains fragmented across multiple disciplines. Existing review articles have primarily focused on either the mechanical behavior of laminated glass or the application of specific AI techniques, without providing a comprehensive overview of the intellectual structure and thematic evolution of this emerging research field. Consequently, researchers lack a systematic understanding of the dominant research themes, collaboration patterns, emerging topics, and future research opportunities.

Scientometric analysis provides a quantitative framework for exploring the development of scientific disciplines by combining bibliographic data with visualization techniques [1]. Unlike conventional narrative reviews, scientometric approaches reveal relationships among publications, keywords, authors, and research themes, enabling the identification of knowledge structures and emerging research frontiers [1]. Among the available visualization tools, VOSviewer has become one of the most widely adopted software packages [3] for constructing bibliometric networks and performing keyword co-occurrence analyses because of its effectiveness in revealing thematic clusters and research trends.

Motivated by these considerations, this study presents a comprehensive scientometric assessment of artificial intelligence applications in the mechanical behavior analysis of laminated glass. Publications indexed in the Scopus database between 2017 and 2026 were systematically screened using predefined inclusion and exclusion criteria, resulting in a final dataset of 74 publications extracted from an initial pool of 345 records. Bibliometric analyses were subsequently performed using VOSviewer to identify publication trends, research hotspots, thematic clusters, and emerging research directions. Particular emphasis is placed on examining how AI techniques have been integrated into laminated glass research and identifying existing knowledge gaps that may guide future investigations.

The findings reveal five major thematic research clusters that characterize the current landscape of AI-assisted laminated glass studies, encompassing fracture mechanics and mechanical performance, laminated glass behavior, computational modelling, data-driven predictive approaches, and AI-enabled structural health monitoring. Furthermore, the analysis highlights several underexplored research areas, including the integration of physics-informed neural networks with structural health monitoring systems, uncertainty-aware predictive modelling, hybrid AI–finite element frameworks, and digital twin technologies for intelligent glass structures. By providing a systematic overview of the existing literature and identifying future research priorities, this study contributes to establishing a clearer roadmap for the continued development of AI-assisted laminated glass engineering.

2 Research Methodology

This study employed a scientometric approach to systematically investigate the development of artificial intelligence (AI) applications in the mechanical behavior analysis of laminated glass. Scientometric analysis enables the quantitative evaluation of scientific literature by identifying publication trends, research hotspots, thematic relationships, and emerging research directions through bibliographic data and network visualization techniques.

Compared with traditional narrative reviews, this approach provides an objective and reproducible framework for revealing the intellectual structure of a research field [1].

2.1 Data Collection

The bibliographic data were collected from the Scopus database, which is one of the largest multidisciplinary citation databases and is widely used for bibliometric and scientometric research because of its comprehensive journal coverage and standardized indexing system [2]. Scopus was selected due to its high-quality metadata, extensive citation information, and compatibility with bibliometric visualization software such as VOSviewer.

The literature search covered publications published between 2017 and 2026, representing the period during which AI-based techniques experienced rapid development and increasing adoption in structural engineering applications [4]. To ensure comprehensive coverage of the relevant literature, a combination of keywords related to laminated glass, artificial intelligence, machine learning, deep learning, computational modelling, structural health monitoring, and mechanical behavior was employed. Boolean operators ("AND", "OR") were used to construct the search strategy and maximize retrieval accuracy.

The initial search identified 345 publications. Subsequently, duplicate records, conference announcements, editorials, notes, and publications unrelated to the mechanical behavior of laminated glass were excluded through a systematic screening process. After applying the predefined inclusion and exclusion criteria and performing a manual relevance assessment, the final dataset consisted of 74 publications, which formed the basis of the subsequent scientometric analyses.

Figure 1 illustrates the overall workflow adopted in this study, including database searching, screening, eligibility assessment, and bibliometric analysis.

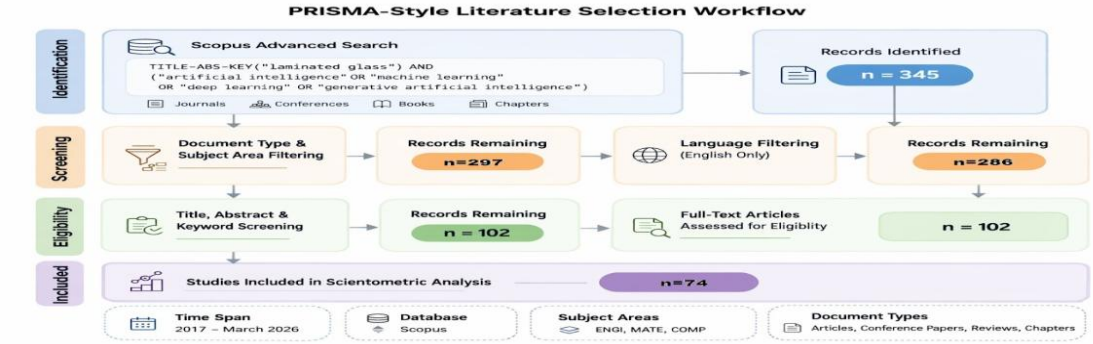

Fig. 1. Research workflow adopted for the scientometric analysis.

2.2 Bibliometric Analysis

The selected publications were analyzed using VOSviewer (version 1.6.x), one of the most widely used software packages for constructing and visualizing bibliometric networks [3]. VOSviewer provides powerful visualization capabilities for examining relationships among publications, keywords, authors, institutions, and countries through network-based mapping techniques.

In this study, keyword co-occurrence analysis was employed to identify the conceptual structure of the research field. Author keywords and index keywords were extracted from the selected publications, and a minimum occurrence threshold was defined to eliminate infrequently used terms that do not significantly contribute to thematic interpretation. Similar keywords with identical or closely related meanings were standardized to improve the consistency of the network structure.

The resulting keyword network was clustered automatically using the association-strength normalization algorithm implemented in VOSviewer [3]. In the generated maps, the size of each node represents the frequency of keyword occurrence, whereas the thickness of the connecting links reflects the strength of the relationships between keywords. Different colors indicate distinct thematic clusters representing major research topics within the field.

2.3 Research Framework

Following the construction of the keyword network, the identified clusters were interpreted qualitatively by examining the dominant keywords within each cluster together with the associated publications. This combined quantitative–qualitative approach enabled a comprehensive interpretation of the intellectual structure of AI-assisted laminated glass research.

The analysis focused on four principal aspects: publication characteristics and temporal research trends; conceptual relationships identified through keyword co-occurrence analysis; thematic research clusters describing the major scientific directions; and emerging research opportunities and knowledge gaps.

The identified research themes were subsequently interpreted in terms of their scientific significance and technological implications for future developments in laminated glass engineering. Particular attention was given to recent advances involving machine learning, deep learning, computational mechanics, structural health monitoring, and hybrid physics-based artificial intelligence approaches [4, 5].

By integrating bibliometric mapping with thematic interpretation, the adopted methodology provides a comprehensive overview of the current state of research while simultaneously identifying promising directions for future investigations. This framework also facilitates a better understanding of how AI techniques have evolved within laminated glass research and highlights emerging interdisciplinary connections between computational intelligence, structural engineering, and materials science.

3 Results and Discussion

3.1 Publication Characteristics and Research Trends

The bibliometric analysis reveals a remarkable increase in research activity concerning the application of artificial intelligence (AI) to the mechanical behavior analysis of laminated glass during the last decade. Following the screening procedure described in Section 2, a total of 74 publications were selected from an initial dataset of 345 records. The analyzed publications demonstrate that AI-assisted laminated glass research has evolved from a niche topic into an emerging interdisciplinary field that integrates structural engineering, materials science, computational mechanics, and data-driven modelling.

The annual publication trend indicates relatively limited research output before 2020, followed by a significant increase after 2021. This growth coincides with the rapid advancement of machine learning algorithms, increased computational capabilities, and broader adoption of intelligent modelling techniques within structural engineering [4]. Recent studies increasingly combine numerical simulations with artificial intelligence to improve prediction accuracy, reduce computational costs, and enhance structural safety assessments [8].

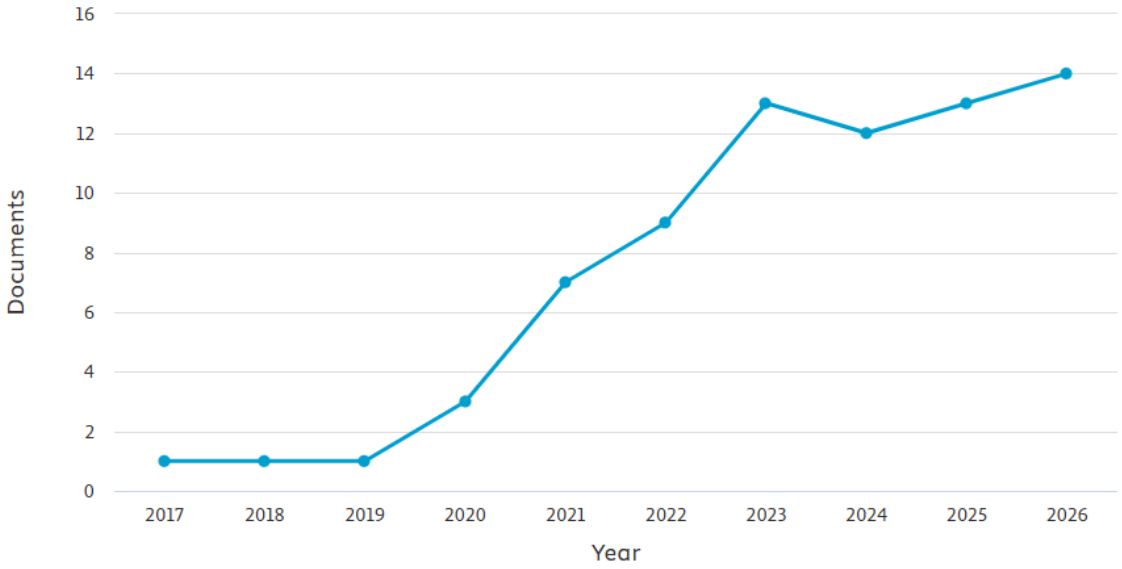

Fig. 2. Annual number of publications on AI-enhanced mechanical behavior of laminated glass, 2017–2026.

The geographical distribution of publications further demonstrates the global expansion of this research area. Significant contributions originate from countries with strong research activities in structural glass engineering and computational mechanics, particularly in Europe and Asia. International collaborations have also become increasingly common, reflecting the multidisciplinary nature of the field and the growing interest in integrating AI with advanced engineering applications.

Overall, the publication characteristics indicate that AI-assisted laminated glass research is currently transitioning from exploratory investigations toward more application-oriented studies involving intelligent structural design, performance prediction, and structural health monitoring.

3.2 Keyword Co-occurrence Network Analysis

To identify the conceptual structure of the research field, a keyword co-occurrence analysis was conducted using VOSviewer [3]. The generated bibliometric network reveals strong interconnections among engineering mechanics, artificial intelligence, computational modelling, and structural monitoring.

The keyword network is dominated by terms such as laminated glass, mechanical behavior, finite element analysis, machine learning, structural health monitoring, optimization, damage detection, and deep learning. The frequent occurrence of these keywords demonstrates that recent studies increasingly emphasize intelligent prediction methods rather than purely analytical or numerical approaches [5].

The visualization also highlights the existence of several densely connected research communities. High-frequency keywords occupy central positions within the network and exhibit strong link strengths, indicating their significant influence on the overall development of the research field. In contrast, recently emerging keywords appear on the periphery of the network, suggesting promising opportunities for future investigations.

The clustering algorithm implemented in VOSviewer identified five major thematic clusters, each representing a distinct yet interconnected research direction. Together, these clusters provide a comprehensive overview of the current scientific landscape of AI-assisted laminated glass engineering.

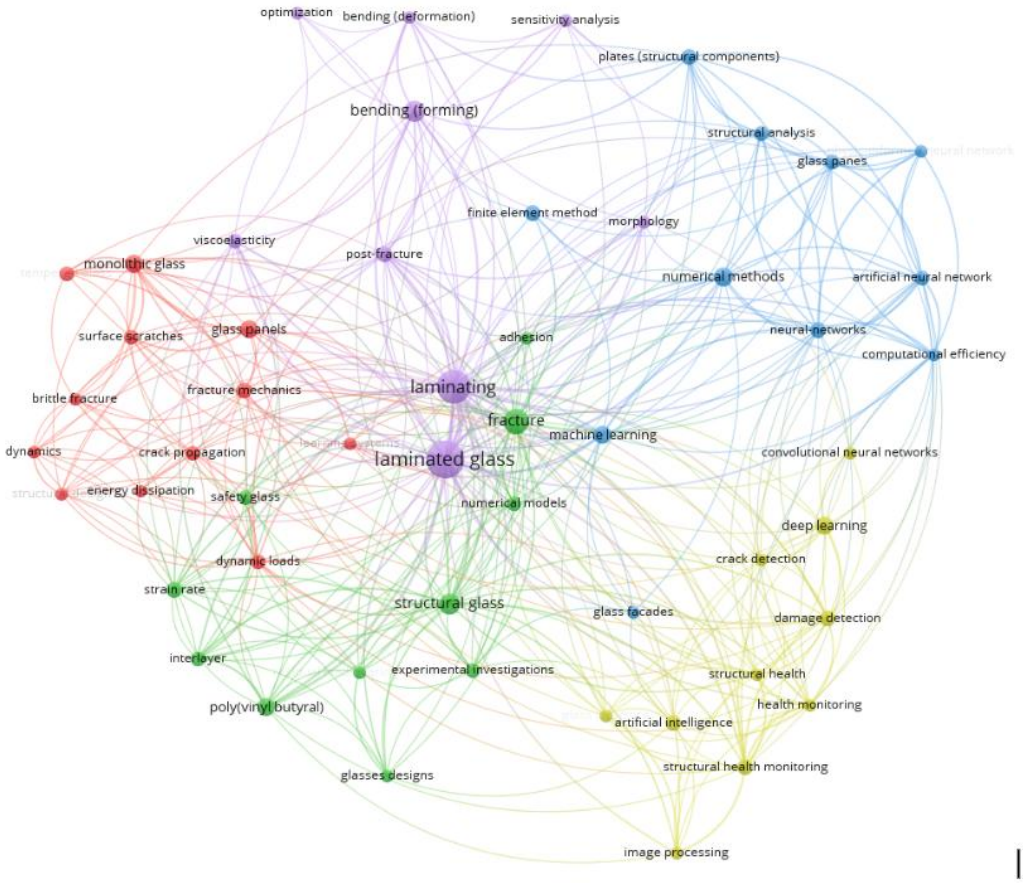

Fig. 3. Keyword co-occurrence network generated using VOSviewer.

3.3 Thematic Cluster Analysis

Figure 4 summarizes the functional role of each thematic cluster within the overall research ecosystem, illustrating how the field progresses from foundational mechanical knowledge toward applied, AI-enabled monitoring solutions.

Cluster	Role	Network position	Impact profile	Maturity
C1 Fracture & Mechanical Behaviour	Knowledge base	Low centrality, high citation impact	High individual paper quality	Established — foundational
C2 Laminated Glass Systems	Network backbone	Highest inter-cluster connectivity	Volume-driven, moderate NC	Mature — high output
C3 Computational Modelling	Method frontier	Newest avg. pub. year of all clusters	Low NC, rapidly growing	Emerging — pre-impact
C4 Data-Driven Modelling	Domain core	Dominant TLS; highest-NC niche (opt.)	Bimodal: dominant + isolated	Active — maturing
C5 AI-Enabled SHM	Applied frontier	High TLS, near-zero NC for newest kws	Citation lag — very recent	Nascent — pre-citation

Fig. 4. Functional roles of the five thematic clusters within the AI-enhanced laminated glass research ecosystem.

Cluster 1 – Fracture Mechanics and Mechanical Performance.
The first cluster primarily focuses on the mechanical response and fracture behavior of laminated glass subjected to various loading conditions. The associated studies investigate crack initiation, crack propagation, impact resistance, blast loading, and post-fracture structural performance [6, 10]. These investigations provide the mechanical foundation upon which intelligent prediction models are subsequently developed.

Although finite element analysis remains the dominant computational tool within this cluster, recent publications increasingly employ machine learning algorithms to predict fracture loads and residual load-carrying capacity [9]. AI models have demonstrated promising capabilities for learning complex nonlinear relationships that are difficult to represent using conventional constitutive formulations.

The evolution of this cluster illustrates the gradual transition from purely mechanics-based analyses toward hybrid computational approaches combining numerical simulations with data-driven prediction techniques.

Cluster 2 – Laminated Glass Behavior and Interlayer Mechanics.

The second thematic cluster concentrates on the influence of polymer interlayers on the structural performance of laminated glass. The viscoelastic characteristics of materials such as polyvinyl butyral (PVB) introduce significant nonlinearities that complicate structural analysis under varying environmental and loading conditions [4].

Numerous studies investigate temperature-dependent behavior, time-dependent deformation, and interlayer stiffness through experimental testing and numerical modeling [10]. More recently, artificial intelligence has been employed to estimate interlayer properties using limited experimental datasets, thereby reducing the need for extensive laboratory testing [7].

Despite these developments, accurately modelling interlayer viscoelasticity remains one of the most challenging problems in laminated glass engineering. This issue represents one of the major knowledge gaps identified through the scientometric analysis.

Cluster 3 – Artificial Intelligence and Computational Modelling.

The third cluster represents the core of AI-based laminated glass research. It encompasses machine learning, artificial neural networks, deep learning, surrogate modelling, and optimization techniques developed to predict mechanical behavior with reduced computational effort [4].

Traditional finite element simulations often require extensive computational resources, particularly for nonlinear dynamic analyses. AI algorithms offer an attractive alternative by rapidly approximating structural responses while maintaining acceptable prediction accuracy [8]. Consequently, recent studies increasingly employ neural networks as surrogate models for finite element analyses.

Emerging research within this cluster also investigates physics-informed neural networks (PINNs), which combine governing physical equations with machine learning algorithms [5]. Although only a limited number of studies currently apply PINNs to laminated glass structures, this approach appears highly promising for improving prediction accuracy while maintaining physical consistency.

Cluster 4 – Data-Driven Prediction and Structural Optimization.

The fourth thematic cluster focuses on intelligent prediction systems developed using data-driven methodologies. These studies primarily utilize machine learning algorithms for estimating structural capacity, optimizing material configurations, and improving engineering decision-making [7].

Optimization techniques supported by artificial intelligence enable engineers to identify efficient laminated glass configurations while satisfying mechanical and safety requirements. Various algorithms have been proposed to optimize glass thickness, interlayer properties, and structural configurations simultaneously [5].

Another emerging research direction involves uncertainty-aware prediction models capable of incorporating experimental variability into engineering design. Such approaches may significantly improve the reliability of AI-assisted structural assessment methods.

Cluster 5 – AI-Enabled Structural Health Monitoring.
The fifth cluster represents one of the fastest-growing research directions identified in the present study. Structural health monitoring (SHM) systems increasingly integrate artificial intelligence with sensor technologies to enable continuous condition assessment of laminated glass structures [5].

Deep learning algorithms, particularly convolutional neural networks, have demonstrated considerable success in automated damage detection, crack identification, and image-based inspection [8]. Combined with vibration monitoring and digital sensing technologies, methods enable early identification of structural deterioration before catastrophic failure occurs.

Nevertheless, the scientometric analysis indicates that relatively few studies have successfully integrated SHM systems with advanced AI frameworks capable of simultaneously considering mechanical behavior, environmental effects, and long-term structural performance. Consequently, this topic represents one of the most promising future research directions.

3.4 Emerging Research Opportunities

The thematic analysis demonstrates that artificial intelligence has become an increasingly important component of laminated glass engineering. However, several significant research gaps remain.

One of the most promising future directions is the integration of physics-informed neural networks with finite element modeling [5]. Such hybrid frameworks have the potential to combine the computational efficiency of machine learning with the physical reliability of mechanics-based simulations.

Another emerging opportunity involves the development of digital twins capable of continuously updating structural models using real-time sensor data. When integrated with AI-assisted structural health monitoring systems, digital twins may enable predictive maintenance strategies for glass structures operating under complex service conditions.

The analysis also highlights the need for explainable artificial intelligence (XAI) methods that improve the transparency and interpretability of machine learning predictions. Since engineering applications require reliable and physically meaningful predictions, improving model interpretability will become increasingly important for practical implementation.

Finally, future investigations should focus on developing unified AI frameworks capable of simultaneously considering fracture mechanics, viscoelastic interlayer behavior, environmental effects, and long-term structural performance. Such multidisciplinary approaches are expected to significantly advance the application of intelligent computational methods in laminated glass engineering.

4 Conclusions

This study presented a comprehensive scientometric analysis of artificial intelligence (AI) applications in the mechanical behavior analysis of laminated glass, providing a systematic overview of the current research landscape and identifying emerging directions for future investigations. Based on a carefully screened dataset of 74 publications retrieved from an initial pool of 345 records indexed in the Scopus database [2], bibliometric mapping and

keyword co-occurrence analyses were performed using VOSviewer [3] to reveal the intellectual structure of this rapidly evolving interdisciplinary research field.

The results demonstrate a clear increase in scientific interest in AI-assisted laminated glass research, particularly after 2021, reflecting the growing adoption of data-driven methods in structural engineering [4]. The bibliometric analysis identified five major thematic research clusters that collectively describe the current state of the field: (i) fracture mechanics and mechanical performance, (ii) laminated glass behavior and interlayer mechanics, (iii) artificial intelligence and computational modelling, (iv) data-driven prediction and structural optimization, and (v) AI-enabled structural health monitoring. These interconnected themes illustrate the transition from conventional mechanics-based analyses toward intelligent computational approaches that combine experimental observations, numerical simulations, and machine learning techniques [5, 6, 8].

The keyword network analysis further indicates that AI has evolved from a supporting computational tool into an integral component of laminated glass research [5]. Machine learning algorithms, artificial neural networks, deep learning techniques, and optimization methods are increasingly being employed to predict structural responses, reduce computational costs, improve design efficiency, and enhance damage assessment [7, 9]. At the same time, finite element modelling remains an essential analytical framework, suggesting that future developments are likely to rely on hybrid methodologies integrating physics-based simulations with data-driven intelligence.

Despite these significant advances, the scientometric analysis revealed several important research gaps. The integration of physics-informed neural networks with structural health monitoring systems remains limited [5], while uncertainty-aware predictive models and digital twin technologies have received comparatively little attention [4]. Furthermore, accurately representing the time-dependent viscoelastic behavior of polymer interlayers within AI-based predictive frameworks continues to be a major scientific challenge. Addressing these limitations will require stronger interdisciplinary collaboration among structural engineers, materials scientists, computational mechanics researchers, and artificial intelligence specialists [10].

Overall, this study provides a quantitative and visual representation of the evolution of AI-assisted laminated glass research while highlighting the principal scientific trends, thematic developments, and future research opportunities. The presented findings may serve as a useful reference for researchers seeking to identify promising research directions and develop more reliable, efficient, and intelligent computational approaches for laminated glass structures. As AI technologies continue to advance, their integration with computational mechanics, structural monitoring, and digital engineering is expected to play an increasingly important role in the design, analysis, and long-term performance assessment of laminated glass systems.

Abstract. In this study, the seismic behavior of a historic multi-span masonry arch bridge under bidirectional seismic effects was investigated comparatively using linear and non-linear dynamic analysis methods in the time domain. A three-dimensional finite element model of the bridge was created in the ANSYS environment using the SOLID65 element. To represent the non-linear plasticity behavior of the masonry material and the cracking/crushing damage mechanisms, the Drucker–Prager yield criterion and the Willam–Warnke failure criterion were used in combination. The Rayleigh damping approach was adopted for the damping matrix calculation, and acceleration records from the bridge site were scaled and applied simultaneously. The analysis results demonstrated that linear analysis was inadequate for representing the structure's post-elastic behavior and significantly underestimated the seismic demands. In the non-linear analyses, increases in displacements (magnification factors) ranging from 4.29 to 187.86 times, as well as permanent deformations, were observed due to cracking and stiffness loss. Stress distributions revealed that tensile and compressive stress increased markedly in conjunction with non-linear behavior, and that plastic stresses and cracking patterns were concentrated particularly in the arch vaults, arch-wall junction zones, and abutments. The findings demonstrate that non-linear material modeling is essential for the seismic performance assessment of historic masonry arch bridges and for the planning of conservation and reinforcement projects.

Keywords: Historical masonry arch bridges, Nonlinear time-history analysis, Seismic performance assessment, Damage mechanism.

1 Introduction

Historic masonry structures rank among the most valuable elements of humanity's cultural and architectural heritage, and the arch bridges found within these structures have formed critical components of transport networks for centuries. Masonry arch bridges are constructed from stone or brick materials, which, despite their high compressive strength, possess a very low tensile capacity and, by their very nature, exhibit quasi-brittle behavior [1,2]. The behavior of these structures under seismic loads is characterized by extreme complexity and non-linearity due to frictional sliding, micro-cracking, disintegration of the joint mortar, and axial/shear interactions [3].

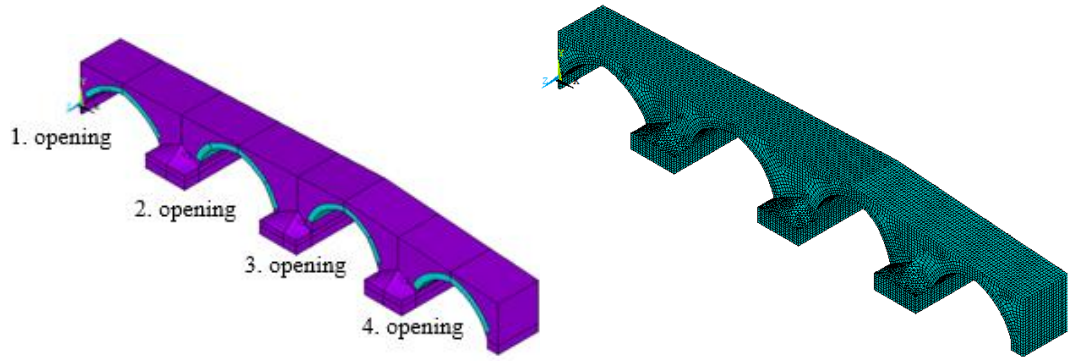
The safe preservation of historic masonry bridges in earthquake-prone regions for future generations depends on determining their seismic performance and potential damage mechanisms using realistic methods. Linear elastic analysis approaches, which were frequently favored in the past, are inadequate for representing the gradual loss of stiffness that the material undergoes under seismic loads, the redistribution of internal forces following cracking, and permanent deformations [4]. To overcome these limitations, recent research has widely

employed constitutive equations that combine pressure-dependent plasticity with macro-modeling-based fracture criteria.

Whilst the Drucker–Prager (DP) yield criterion is the leading approach for characterizing the yield behavior of earth under hydrostatic pressure [5], the Willam–Warnke (WW) failure criterion has been successfully applied to simulate tensile cracking and compressive crushing mechanisms in the material under three-dimensional stress conditions [6]. The combination of these two constitutive models has become a standard and reliable approach for modeling the non-linear behavior of granular and concrete-like quasi-brittle materials in specialized solid-element formats such as ANSYS SOLID65 [7,8].

In this study, the behavior of a historic masonry arch bridge with four spans under scaled simultaneous horizontal and vertical earthquake acceleration records was investigated using linear and non-linear (DP + WW) time-domain analysis methods. As part of the research, displacement time histories, displacement amplification factors, principal stress concentrations, equivalent plastic stress distributions, and cracking patterns were compared in detail, thereby revealing the decisive role of material non-linearity in the seismic response and damage mechanism of the historic bridge.

2 Nonlinear Constitutive Model



The nonlinear mechanical behavior of masonry is governed by frictional sliding, tensile cracking, and compressive crushing. Owing to its quasi-brittle nature, masonry exhibits high compressive strength but limited tensile capacity, rendering linear-elastic constitutive models inadequate for capturing stiffness degradation and irreversible damage under seismic loading. Therefore, pressure-dependent plasticity models, combined with fracture criteria, are widely employed in nonlinear finite element (FE) analysis of masonry structures [1].

The Drucker–Prager (DP) model is widely adopted because it accounts for the influence of hydrostatic pressure on yielding through material cohesion and internal friction angle, providing a realistic representation of masonry subjected to multiaxial stress states [5]. Since the DP criterion alone cannot simulate tensile cracking and compressive crushing, it is coupled with the five-parameter Willam–Warnke (WW) failure criterion, which predicts crack initiation, crack propagation, and compressive failure under complex loading conditions. Implemented in the ANSYS SOLID65 element, the combined DP–WW formulation has become a well-established approach for nonlinear analysis of historical masonry bridges, enabling realistic simulation of material degradation while maintaining computational efficiency through open- and closed-crack shear transfer coefficients [6–8].

3 Finite Element Model

A three-dimensional FE model of the historical multi-span masonry bridge was developed using ANSYS Mechanical APDL to investigate its seismic response under bidirectional earthquake excitation. As illustrated in Fig. 1, the bridge geometry was discretized using the eight-node SOLID65 element, which can represent both linear elastic behavior and nonlinear material response through tensile cracking and compressive crushing formulations. The arch barrels and side walls were modeled as separate material regions to account for their different mechanical properties, while the bridge foundations were assumed to be fully fixed at the base. The adopted FE discretization comprises 58,066 solid elements and 63,636 nodes, providing sufficient spatial resolution to accurately represent the bridge geometry and capture the structural response during both linear and nonlinear time-history analyses. The mesh density was selected to achieve a reasonable balance between geometric representation and computational efficiency for the transient dynamic analyses. The same FE model, mesh configuration, boundary conditions, and earthquake loading were employed in both the linear and nonlinear analyses to

ensure that any differences in structural response resulted solely from the constitutive material models adopted.

(a) (b)

Fig. 1. FE model of the historical masonry bridge, (a) three-dimensional geometric model and (b) discretized FE mesh.

3.1 Material Properties

The nonlinear constitutive model adopted in this study was defined using a macro-modeling approach, in which the masonry was represented as an equivalent homogeneous continuum. The linear elastic properties, including the elastic modulus, Poisson's ratio, and mass density, were assigned separately for the arch barrel and side walls to account for their different structural characteristics. To simulate the inelastic behavior of masonry under increasing loads, the DP yield criterion was used to model the onset of plasticity, while the WW failure criterion was used to simulate tensile cracking and compressive crushing. This combined constitutive formulation has been widely adopted for nonlinear FE analyses of historical masonry bridges because it realistically represents the frictional–cohesive nature of masonry while maintaining computational efficiency within the SOLID65 element available in ANSYS.

The nonlinear material parameters presented in Table 1 were selected based on published numerical investigations of historical masonry arch bridges. The adopted material properties represent a literature-based constitutive model that has previously been validated for historical masonry bridge analyses [9,10] and are therefore considered appropriate for the nonlinear time-history simulations performed in the present study.

3.2 Selection of Rayleigh Damping Parameters

The seismic response of historical masonry bridges is significantly influenced by energy dissipation mechanisms arising from frictional sliding, microcracking, mortar degradation, and contact interaction between structural components. Since these mechanisms are highly nonlinear and difficult to model explicitly, proportional (Rayleigh) damping is commonly used in both linear and nonlinear finite element (FE) analyses for its computational efficiency and numerical robustness [11,12].

In this study, the damping matrix was defined using the classical Rayleigh formulation, in which the viscous damping matrix is expressed as a linear combination of the global mass and stiffness matrices. A target damping ratio of 5% was adopted, consistent with values commonly reported for unreinforced historical masonry structures when experimental damping data are unavailable [13,14]. Prior to the time-history analyses, a modal analysis was performed to identify the bridge's dynamic characteristics. The first three natural frequencies were 12.781 Hz, 14.471 Hz, and 15.142 Hz, representing the dominant global vibration modes of the structure (Fig. 2).

Table 1. Mechanical properties and nonlinear constitutive parameters adopted for the historical masonry bridge.

Property	**Arch**	**Side Wall**
E (MPa)	3000	2500
ν	0.20	0.20
Density (kg/m³)	1900	1800
Cohesion c (MPa)	0.40	0.35
Friction angle φ	40°	40°
Dilatancy angle ψ	20°	20°
βopen	0.25	0.25
βclosed	0.75	0.75
fc	2.73 MPa	2.50 MPa
ft	0.27 MPa	0.25 MPa

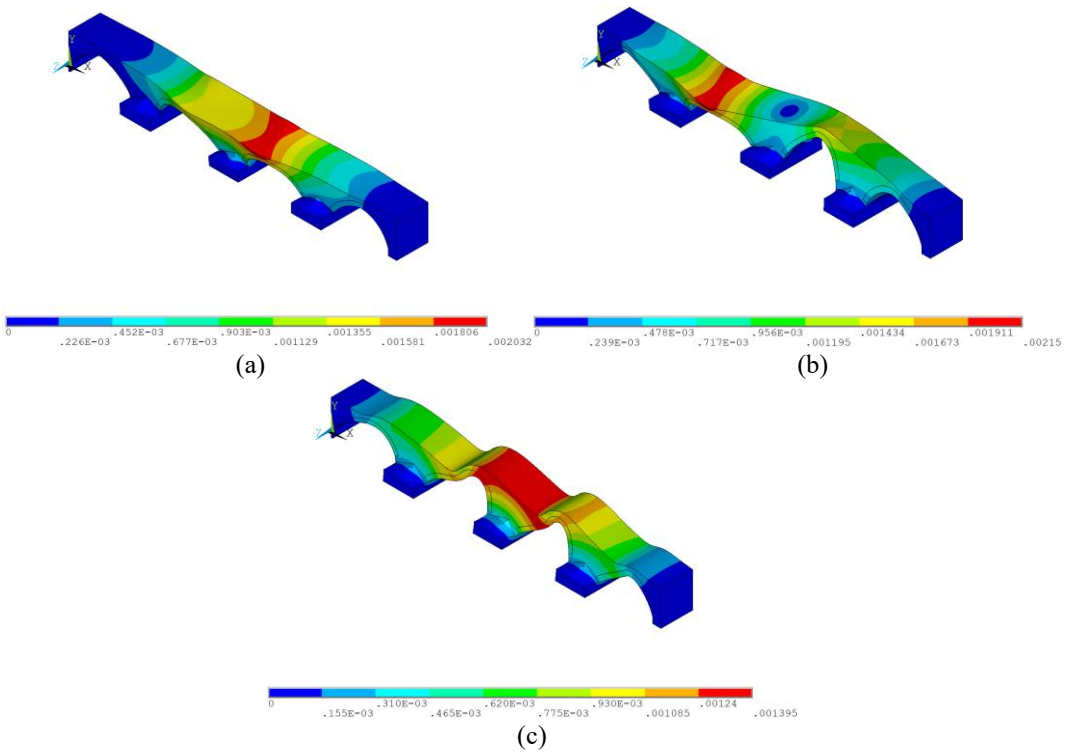


Fig. 2. First three mode shapes of the FE model of the historical masonry bridge: (a) first mode (12.781 Hz), (b) second mode (14.471 Hz), and (c) third mode (15.142 Hz).

The Rayleigh damping coefficients were calibrated using the first and twentieth natural frequencies. Unlike detailed three-dimensional solid models, which generate numerous localized high-frequency modes, the selected frequency range primarily reflects the global dynamic behavior that governs the seismic response. This approach provides a nearly uniform

damping ratio over the dominant vibration modes while avoiding excessive damping of localized deformation modes [15–17].

The same Rayleigh damping coefficients were employed in both the linear and nonlinear time-history analyses to ensure a consistent basis for comparison. In the nonlinear analyses, additional energy dissipation was captured through the Drucker–Prager and Willam–Warnke constitutive models, whereas the Rayleigh damping matrix represented only the viscous component of structural damping. This combined strategy provides a physically realistic and numerically stable representation of the seismic behavior of historical masonry bridges [15,17].

3.3 Selection and Scaling of the Earthquake Ground Motion

The seismic response of the historic masonry bridge was evaluated using the horizontal and vertical components of the Erzincan earthquake record, which were scaled according to the seismic demand specified by the current Turkish seismic design code for the bridge location (Fig. 3). The scaled ground motions were simultaneously applied in the longitudinal (X) and vertical (Z) directions to realistically represent the multidirectional seismic excitation and to capture the influence of vertical ground motion on the nonlinear response of the masonry bridge.

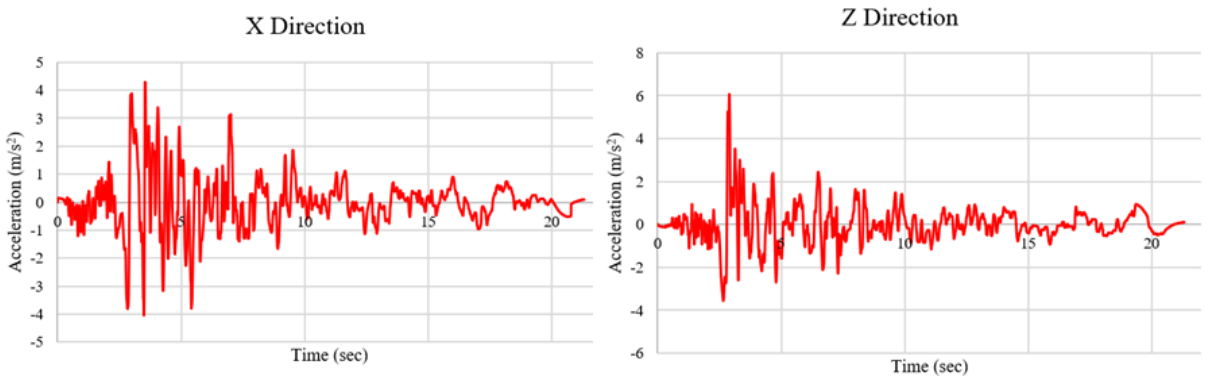

Fig. 3. Scaled horizontal (X) and vertical (Z) acceleration time histories of the Erzincan earthquake record adopted for the bridge site in accordance with the seismic demand specified by the Turkish seismic design code.

4 Results and Discussions

The seismic performance of the historic masonry bridge was evaluated through a comparative assessment of the linear and nonlinear dynamic analyses under the scaled Erzincan earthquake record. The discussion focuses on differences in displacement response, stress distribution, and damage evolution to elucidate the influence of material nonlinearity on the bridge's structural behavior. Together, these results provide a comprehensive understanding of the mechanisms governing the seismic response of historic masonry arch bridges.

4.1 Displacement response

The normalized displacement time histories presented in Fig. 4 highlight the differences between the linear and nonlinear dynamic responses of the historical masonry bridge. Since each displacement record was normalized by its own maximum absolute value, the comparison emphasizes the evolution of the response, oscillation characteristics, phase shifts, and stiffness degradation rather than the displacement magnitude.

The linear analysis exhibits oscillatory responses centered on the initial equilibrium position throughout the earthquake excitation, reflecting the constant-stiffness assumption of linear elasticity. In contrast, the nonlinear analysis follows the linear response during the early stage of the record but undergoes a distinct transition after approximately **5–6 s**, when cracking and

material degradation become significant. Following this transition, the displacement histories exhibit reduced vibration frequencies, noticeable phase shifts, and changes in equilibrium position, indicating progressive stiffness degradation and irreversible structural response.

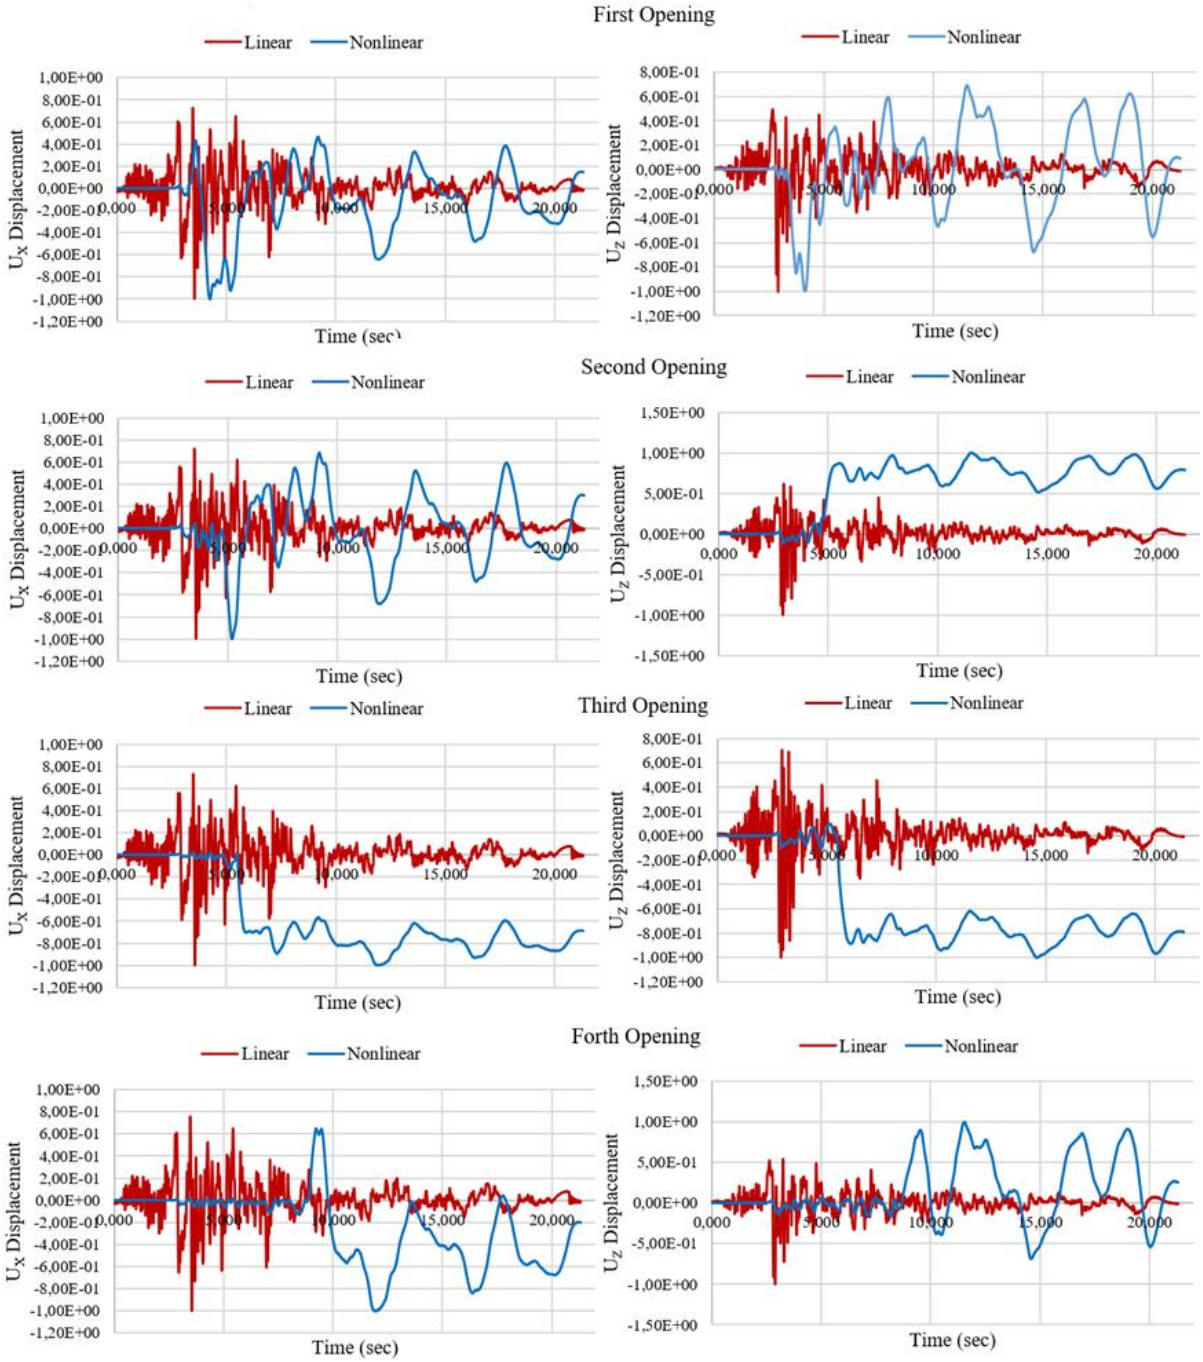

Fig. 4. Comparison of the normalized horizontal (UX) and vertical (UZ) displacement time histories at the first, second, third, and fourth bridge openings obtained from the linear and nonlinear dynamic analyses. Each displacement record was normalized by its maximum absolute displacement to facilitate comparison of temporal response characteristics, oscillation patterns, and nonlinear response evolution independent of displacement magnitude.

The nonlinear behavior varies among the four bridge openings. The first opening shows pronounced low-frequency oscillations after damage initiation, whereas the second opening, particularly in the vertical direction, develops a permanent positive equilibrium shift, indicating

irreversible deformation. In contrast, the third opening exhibits a persistent negative displacement bias, while the fourth opening experiences delayed nonlinear response accompanied by large-amplitude oscillations. These observations demonstrate that nonlinear material degradation and internal force redistribution are spatially non-uniform and strongly influenced by bridge geometry.

The normalized displacement histories should be interpreted together with the displacement amplification factors summarized in Table 2. While the normalized responses illustrate the temporal evolution of stiffness degradation and changes in vibration characteristics, the amplification factors quantify the increase in displacement due to material nonlinearity. The nonlinear analysis produced considerably larger maximum displacements than the linear analysis, with amplification factors ranging from 4.29 to 180.71 in the horizontal direction and 18.40 to 187.86 in the vertical direction. These findings demonstrate that linear dynamic analysis substantially underestimates both the magnitude and temporal evolution of the seismic response, highlighting the necessity of nonlinear dynamic analysis for the reliable seismic assessment of historical masonry arch bridges.

Table 2. Comparison of maximum displacements obtained from linear and nonlinear dynamic analyses.

Openings	Linear U_{xmax} (m)	Nonlinear U_{xmax} (m)	Amplification Factor	Linear U_{zmax} (m)	Nonlinear U_{zmax} (m)	Amplification Factor
1	2.62E-04	4.31E-02	164.51	2.64E-04	4.54E-02	172.28
2	6.92E-04	5.09E-02	73.57	9.86E-04	1.85E-01	187.86
3	7.18E-04	3.08E-03	4.29	1.27E-03	2.33E-02	18.4
4	3.27E-04	5.90E-02	180.71	3.40E-04	5.36E-02	157.856

4.2 Stress Distribution

Fig. 5 compares the distributions of the first (S1) and third (S3) principal stresses obtained from the linear and nonlinear dynamic analyses at the critical response time (t = 11.66 s). Compared with the linear analysis, the nonlinear model exhibits pronounced tensile and compressive stress redistribution, with localized stress concentrations around the arch barrels and pier–arch interfaces, reflecting stiffness degradation and internal force redistribution due to material nonlinearity.

Table 3 summarizes the corresponding principal stress and stress intensity values. The nonlinear analysis produced substantially higher tensile and compressive stress demands together with a significant increase in stress intensity, quantitatively confirming the stress redistribution observed in Fig. 5. These results demonstrate that linear dynamic analysis considerably underestimates the seismic stress demand of the historic masonry bridge.

4.3 Damage Mechanism

Fig. 6 presents the equivalent plastic stress distribution and the corresponding crack pattern at the critical response time (t = 11.66 s), which corresponds to the maximum resultant displacement of the third bridge opening. The equivalent plastic stress contours indicate that nonlinear material yielding is primarily concentrated around the arch barrels, arch–spandrel interfaces, and pier regions, reflecting localized inelastic deformation under seismic loading. The crack pattern exhibits a similar spatial distribution, confirming that damage initiates and propagates predominantly in the same critical zones where elevated plastic stresses develop.

The close agreement between the plastic stress concentration and crack distribution demonstrates that the nonlinear response of the bridge is governed by localized tensile cracking and progressive material degradation rather than uniform stress development. These observations are consistent with the previously discussed displacement response and highlight the importance of nonlinear material modeling for accurately capturing damage evolution in historic masonry arch bridges.

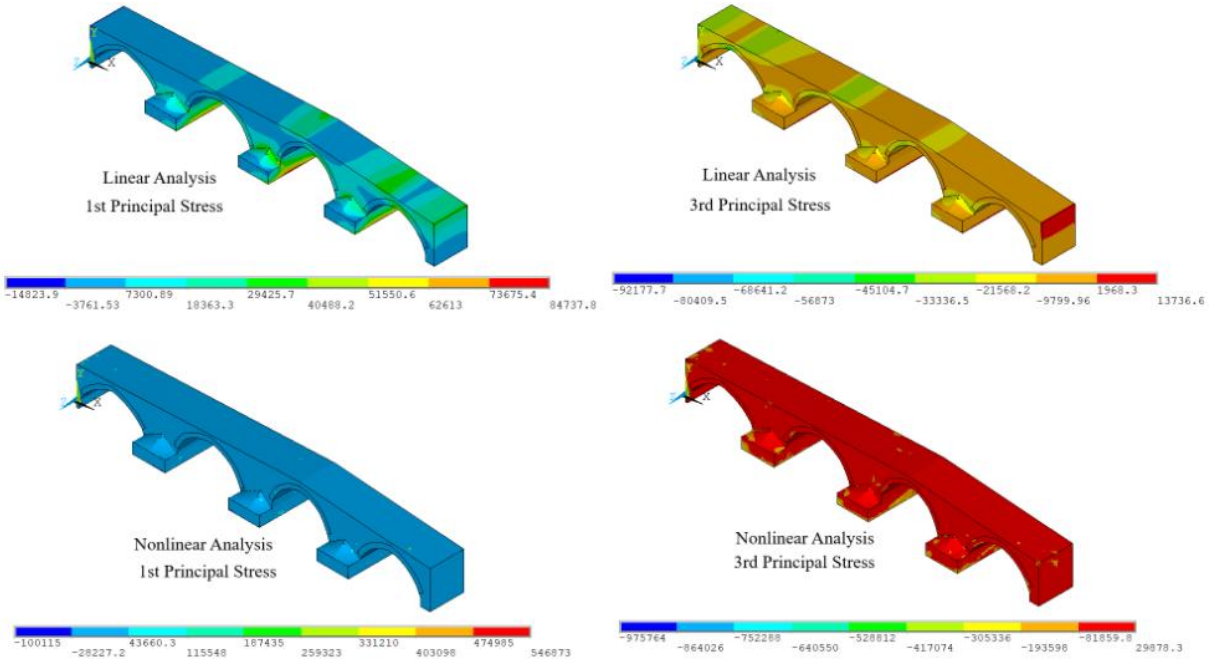

Fig. 5. Comparison of the first and third principal stress distributions obtained from the linear and nonlinear dynamic analyses at the critical response time corresponding to the maximum resultant displacement of the third bridge opening.

Table 3. Comparison of principal stress and stress intensity values at the critical response time.

Analysis	**Max. Principal Stress (MPa)**	**Min. Principal Stress (MPa)**	**Stress İntensity (MPa)**
Linear	0.085	-0.092	0.086
Nonlinear	0.547	-0.976	1.01

5 Conclusions

This study compared the seismic response of a historical four-span masonry arch bridge through linear and nonlinear time-history analyses using a three-dimensional FE model incorporating the Drucker–Prager plasticity model and the Willam–Warnke failure criterion. The results demonstrated that material nonlinearity significantly influences the bridge's dynamic response. Compared with the linear analysis, the nonlinear model predicted larger displacement amplitudes, stiffness degradation, phase shifts, changes in equilibrium, and permanent deformation after crack initiation. The wide range of displacement amplification factors further confirmed that linear analysis substantially underestimates the seismic response of historical masonry bridges.

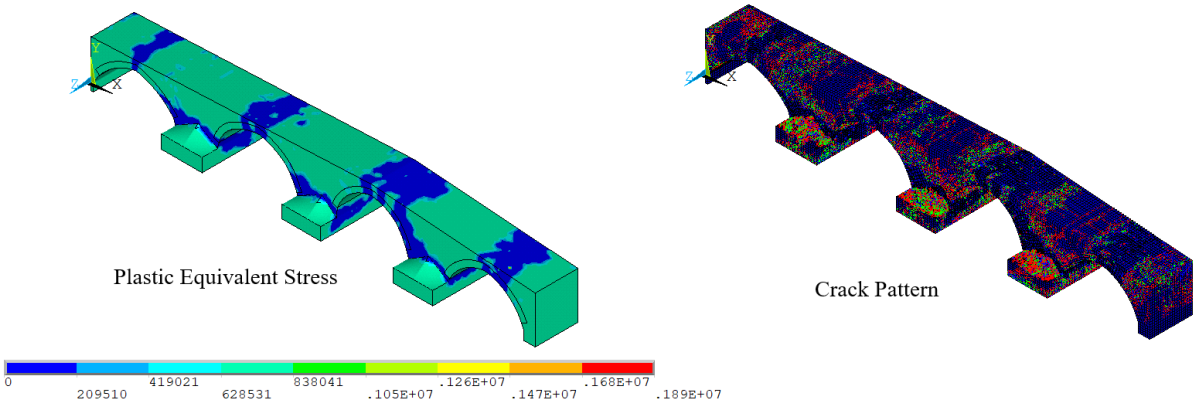

Fig. 6. Equivalent plastic stress and crack pattern obtained from the nonlinear dynamic analysis at the critical response time

The nonlinear analysis also produced considerably higher principal stress and stress intensity, revealing localized stress concentrations that the linear model could not capture. The agreement among the principal stress distributions, equivalent plastic stress, and crack patterns indicated that damage was concentrated primarily around the arch barrels, arch–spandrel interfaces, and pier regions, reflecting progressive material degradation and internal force redistribution under seismic loading.

Overall, the results confirm that nonlinear constitutive modeling is essential for realistic seismic assessment of historical masonry arch bridges. While linear dynamic analysis may be suitable for preliminary evaluation, it cannot adequately represent stiffness degradation, permanent deformation, stress redistribution, or damage evolution. Therefore, nonlinear dynamic analysis provides a more reliable basis for seismic vulnerability assessment and the development of effective conservation and strengthening strategies for historical masonry bridges.

Acknowledgments

The authors would like to express their sincere appreciation to the General Directorate of Highways (KGM), Türkiye, for providing the bridge geometry and the associated technical data, which formed the basis for the FE model developed in this study.

Abstract. In this study, random vibration analysis (RVA) of a nuclear power plant (NPP) structure under seismic loads was performed and its structural behavior was evaluated using the 1995 Kobe earthquake as a data point. A typical NPP structure, used in China, modeled as a three-dimensional system. In this study, RVA were conducted for firm, medium, and soft soil conditions to determine the effects of seismic motions on NPP systems. The study utilized a RVA theory based on the filtered white noise (FWN) ground motion model. The aim was to compare the obtained results for the fixed-base model and the soil-structure interaction (SSI) model. Thus, the effects of different soil types and SSI on the dynamic behavior of the structure are investigated using a RVA. The study concluded that soil type and SSI significantly affect the dynamic behavior of the studied NPP structure compared to the fixed-base assumption.

Keywords: Random vibration analysis (RVA), soil-structure interaction (SSI), filtered white noise (FWN) ground motion model, nuclear power plant (NPP)

1 Introduction

The dynamic behavior of NPP structures under seismic effects has long been assessed primarily using deterministic analysis methods. Deterministic approaches allow the structural response to be easily calculated under well-defined, uncertainty-free loads [1]. However, due to the inherently random nature of earthquake loads, these methods have limitations in accurately reflecting the real seismic behavior. In reality, dynamic effects such as earthquakes are often influenced by multiple vibration sources, and these effects exhibit a random character. Therefore, the use of RVA has become necessary to evaluate the behavior of NPP structures under seismic actions in a more realistic and reliable manner. This requirement becomes even more important, especially in cases where soil conditions play a decisive role in structural response. Particularly in NPP structures built on non-stiff soils, SSI is a critical parameter directly affecting the seismic performance of the structure, and considering the combined behavior of the soil and structure is of great importance for a safe design. In this context, numerous studies in the literature have examined the effects of SSI on the seismic behavior of NPP structures, and highlighting the decisive role of SSI in structural response.

Wang et al. [2] used a finite element model (FEM) with conductive boundaries to investigate the SSI of NPP buildings against vertical seismic effects and examined factors affecting computational accuracy, such as the dimension of the domain and the types of artificial boundaries. Firoj and Maheshwari [3] presented a detailed literature review of finite element method (FEM)-based approaches that consider SSI for NPP founded on alluvial soil. Nguyen et al. [4] investigated the effects of earthquake frequency content and SSI on the seismic behavior of nuclear reactor buildings by performing three-dimensional nonlinear analyses in the time domain. The study showed that both the earthquake frequency content and SSI highly influence how nuclear buildings behave under seismic load. Maheshwari and Firoj [5] presented the studies about SSI analysis in NPP and discussed the key issues. Bahuguna and Firoj [6] investigated the seismic performance of NPP structures constructed on layered sand soil by

considering the nonlinear behavior of both the structure and the soil using a FEM in ABAQUS. Li et al. [7] developed general SSI method based on the geographic information system, which can practically consider topographic irregularities and is suitable for efficient dynamic analyses in the time domain. Li et al. [8] investigated the seismic behavior of base-isolated NPP in layered sites using a nonlinear numerical analysis method and concluded that SSI, soil nonlinearity, and embedment effects have significant influences on the structural response. Wang et al. [9] investigated the effects of site conditions, seismic input, and artificial boundaries on structural response using a 3D FEM for buried NPP structures. Li et al. [10] developed a large-scale computational method for NPP structures using the scaled boundary FEM and conducted SSI analyses considering embedment effects, different foundation shapes and soil conditions.

Unlike previous studies in the literature, this study investigates the SSI behavior of a NPP structure under different ground conditions using RVA based on a FWN model. Within the scope of the analysis, a system modeled with both soil and structure was compared with a fixed-base structure model; SSI effects were evaluated based on stress and displacement results. Thus, the response of the structure under random dynamic loads such as earthquakes was revealed more realistically, and the effect of different ground conditions on the structural response was analyzed. It is predicted that the findings of this study will contribute to the more realistic determination of SSI in NPP structures.

2 Finite Element Model (FEM) of The NPP-Soil System

2.1 NPP Containment Building

A FEM of the NPP structure was created using the ABAQUS program, and numerical analyses were performed. In this study, two separate models of the NPP building were developed: a fixed-base model and a NPP model including the SSI**.** The FEM of the selected NPP containment building is given in Fig. 1.

The NPP containment structure model used in this study represents a typical NPP containment structure commonly used in China, and the geometric features, dimensions, and material parameters of the structure were created based on the data given in Lu X et al. [11] and Sadique MR et al. [12].

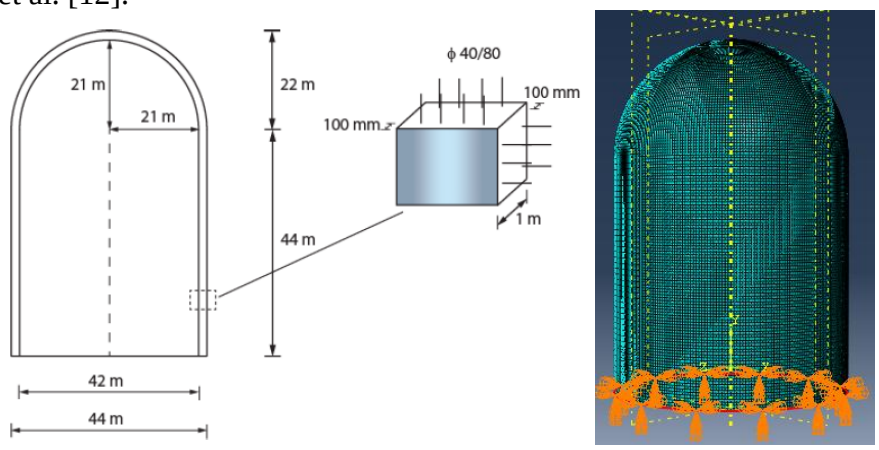

Fig. 1. Cross-sectional view and 3D FEM model of the NPP

For the NPP building B50 class concrete is used, and the concrete damaged plasticity model available in ABAQUS program is used for the concrete. The parameters used in the study were presented by Esfahani et al. [13].

The material properties for reinforcing steel are shown in the Table 1.

Table 1. Material properties for reinforcing steel [14].

Density (kg/m^3)	Young's Modulus (GPa)	Poisson's Ratio	Yield Stress (MPa)	Tensile Stress (MPa)
7850	210	0.3	503.06	603.43

2.2. Soil System

In order to determine the effect of the SSI on the considered NPP containment building, three homogeneous soil conditions are used, namely the firm, medium and soft soil conditions. For the selected soil conditions, standard soil properties obtained from the literature [4] are used (Table 2). In this study, the soil profile is assumed to be a single soil layer located on a rigid half-space. The thickness of the soil profile was assumed to be 30 m. To be able to take into account the nonlinear behavior of the soil medium in the analyses, the Mohr–Coulomb plasticity model included in ABAQUS is considered as the constitutive model.

Table 2. Soil properties [4]

Soil Type	Young`s modulus (MPa)	Poisson`s ratio	Unit weight (kN/m^3)	Damping (%)	Cohesion (MPa)	Friction angle (°)	Dilation angle (°)
Firm	2000	0.30	20	5	0.19	30	15
Medium	500	0.35	19	5	0.05	30	15
Soft	150	0.35	19	5	0.05	30	15

2.3. FE Modeling Of The NPP Containment Building-Soil System

ABAQUS/CAE 6.11 [14] software is used in this study to model the three-dimensional FEM of the NPP containment building-soil system. Considering a direct SSI approach, the NPP containment building, the foundation and the soil are modeled as a single interacting system. Fig. 2 shows the 3D FEM of the SSI.

The FEM of the structure was modeled in ABAQUS using layered shell elements, with a mesh size of 0.7 m x 0.5 m, and S4R type linear quadrilateral shell elements (30964 elements) were used. On the other hand, the soil and foundation are modeled using solid elements. Linear brick elements of type C3D8R (186984 elements) and quadratic brick elements of type C3D20R elements (58996 elements) are used in FE model of the underlying soil and foundation, respectively. The global mesh size of the soil below the foundation is considered as 0.7 m. While the mesh size increases gradually up to 4 m at the side boundaries, it increases from 2 m to 2.8 m along the depth of the soil medium.

As known, to avoid wave reflection from the boundaries, large soil domains can be used as a solution. But, considering the fact that enlarging the soil domain will require much computational work, in this study it is intended to use infinite elements (CIN3D8) at the lateral boundaries available in ABAQUS. Infinite elements provide quiet boundaries to the FEM in dynamic analyses [15]. On the other hand, the radius of the soil is considered as 140 m, more than three times the radius of the foundation. While the interaction between NPP and foundation is modeled with "Shell to Solid Coupling" contact, the interaction between foundation and soil is modeled with "Tie" contact. Fixed boundary conditions are adopted at the bedrock below the soil layer.

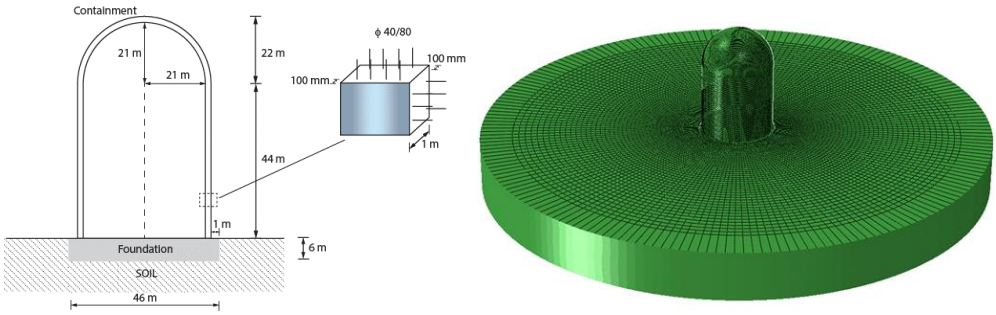

Fig. 2. Cross-sectional view and 3D FEM of the NPP building–soil system

2.4. Modal Characteristics

Eigenvalue analyses are performed to obtain its modal characteristics so that the Rayleigh damping coefficients α and β needed in ABQUS can be determined. The coefficients α and β can be determined as [16]:

$$\alpha = \xi \frac{2w_i w_j}{w_j + w_j} \quad , \quad \beta = \xi \frac{2}{w_j + w_j} \tag{1}$$

In this study, Rayleigh damping coefficients are determined from the dominant modes (w_i and w_j) of the combined soil-structure system and the damping ratios of the soil (ξ_{Soil}) and structure ($\xi_{Structure}$). A similar strategy was used by Bayraktar and Hökelekli [16]. While the dominant modes of the SSI system with firm soil are the 1st (f_1 = 3.1728 Hz) and 25th (f_{25} = 4.8195 Hz) modes, the dominant modes of the SSI system with soft soil are the 1st (f_1 = 0.9027 Hz) and 25th (f_{25} = 0.9509 Hz) modes. Similarly, for the SSI system with medium soil, the dominant modes are the 1st (f_1 = 2.1426 Hz) and 25th (f_{25} = 2.4302 Hz) modes. Thus, the calculated Rayleigh coefficients are given in Table 3.

Table 3. α and β parameters

Soil Type	Mass-proportional coefficient (α)	Stiffness-proportional coefficient (β)
Firm	1.202	0.00199
Medium	0.716	0.00348
Soft	0.291	0.00859

2.5. Earthquake Records

Table 4 contains information regarding the earthquake records used in the analysis. Only far-fault records were considered for this study. Additionally, the $(V_s)_{30}$ value, the most important parameter for determining soil class, was utilized. The $(V_s)_{30}$ value represents the average slip velocity in the first 30 meters, and in this study, soils were classified as soft (0-360 m/s), medium (360-700 m/s), and stiff (larger than 700 m/s).

Table 4. Kobe earthquake records

Earthquake	**Station Name**	**Earthquake Magnitude**	**Fault Distance (km)**	**Soil Class**	**$(V_s)_{30}$ (m/s)**	**PGA (g)**	**PGV (cm/s)**
Kobe	Rincon Hill	6.93	74.14	B	873.10	0.093	11.04

Earthquake	Station Name	Earthquake Magnitude	Fault Distance (km)	Soil Class	$(V_s)_{30}$ (m/s)	PGA (g)	PGV (cm/s)
Loma Prieta	B. Strawberry Canyon	6.93	78.41	C	512.27	0.075	9.68
Kobe	Kakogawa	6.90	22.50	D	312.00	0.324	26.86

3 Random Vibration Analysis

In order to investigate the effects of earthquakes in detail, analyses were carried out using random vibration theory, taking into account the FWN ground motion model. In this study, RVA were performed using the power spectral density (PSD) functions defined for the FWN model. RVA is an analysis method that takes into account uncertainties and random variables. This analysis can help to make design decisions to reduce risks by assessing the effects of random loads to which NPP structures may be subjected to over a period of time. The terms used in this study, such as PSD function, root mean square, etc., are expressed in the following formulations [15]. Abaqus obtains the root mean square (RMS) value by integrating a single-sided PSD across the frequency range.

$$\sigma(x) = \sqrt{R_x(0)} = \sqrt{\int_0^\infty S_x(f)df} \tag{2}$$

where $S_x(f)$ is the PSD function and $R_x(0)$ is the autocorrelation function of a variable.

3.1. Filtered White Noise (FWN) Ground Motion Model

This mathematical model is used to represent ground motions caused by earthquakes. The model filters out white noise in a specific frequency band to produce motions that represent real earthquake behavior. According to Clough and Penzien [18], the PSD function of ground acceleration is in the following form.

$$S_{\ddot{v}_g}(w) = S_0|H_g(w)|^2|H_f(w)|^2 \tag{3}$$

$$|H_g(w)|^2 = \frac{w_g^4+4\xi_g^2w_g^2w^2}{\left(w_g^2-w^2\right)^2+4\xi_g^2w_g^2w^2} \tag{4}$$

$$|H_f(w)|^2 = \frac{w^4}{(w_f^2-w^2)^2+4\xi_f^2w_f^2w^2} \tag{5}$$

Eqs. (4-5) are the frequency response functions of the first and second filters, respectively. These equations represent the dynamic properties of the soil system, the amplitude parameter of the white noise bedrock acceleration is defined as S0. Furthermore, the resonance frequency and damping ratio of the first filter are expressed by the parameters ωg and ξg, respectively, while the resonance frequency and damping ratio of the second filter are expressed by the parameters ωf and ξf. In this study, different homogeneous soil types were evaluated and for filter parameters, the values recommended by Der Kiureghian and Neuenhofer [19] were used as given in Table 5.

Table 5. Power spectral density (PSD) parameters for model soil types

Soil type	w_g (rad/s)	ξ_g	w_f (rad/s)	ξ_f

Firm	15.0	0.6	1.5	0.6
Medium	10.0	0.4	1.0	0.6
Soft	5.0	0.2	0.5	0.6

The S_0 coefficient was calculated for the stochastic analysis of the structures, for which the STOCAL [20] and STOCAL-II [21] computer programs were used. In the first stage, the PSD functions of the seismic motions evaluated in the study were obtained using STOCAL, and in the second stage, the PSD variances corresponding to the FWN ground motion models were calculated using the STOCAL-II program. S_0, is calculated as the ratio of the actual earthquake acceleration variance to the FWN model variance for each ground motion component as follows,

$$S_0=\frac{\sigma^2{}_{\ddot{u}g}}{\int_0^{\infty} H_g(w)^2 H_f(w)^2 dw}=\frac{\sigma^2{}_{\ddot{u}g}}{\Phi} \tag{6}$$

where $\sigma^2{}_{\ddot{u}_g}$ and Φ represent the variances of the actual ground motion acceleration and the FWN model, respectively. After generating the PSD values versus frequency by STOCAL, the variances of the ground motion components are determined by STOCAL-II. For the Kobe earthquake acceleration, the S_0 values were obtained as follows (Table 6).

Table 6. S_0 coefficient values for the Kobe earthquake

Soil Type	S_0 Coefficient Values for the Kobe Earthquake (m^2/s^3)
Firm	4.0843×10^{-5}
Medium	6.6067×10^{-5}
Soft	1.935×10^{-3}

The spectral density functions of FWN ground motion models were obtained for each soil type using the calculated S_0 coefficients.

Mean max values were calculated by considering the RMS of displacement (RU1) and the RMS of velocity (RV1) from the formulations given below [22]. The mean of maximum value can be expressed as follows, here p is the peak factor and σz is the RMS response.

$$\mu = p\sigma_z \tag{7}$$

$$p = \sqrt{(2lnv_eT)} + \frac{0.5772}{\sqrt{(2lnv_eT)}} \tag{8}$$

$$v_e = (1.9\xi^{0.15} - 0.73)v_0 \tag{9}$$

$$v_0 = \frac{1}{\pi}\frac{\sigma_{\dot{z}}}{\sigma_z}=\frac{1}{\pi}\left(\frac{\int_{-\infty}^{\infty} w^2 S_z(w)dw}{\int_{-\infty}^{\infty} S_z(w)dw}\right)^{1/2} \tag{10}$$

In the equation, the parameters ν_e and ν_0 represents reduced mean zero-crossing rate and mean zero-crossing rate respectively. T represents the duration of motion. In addition, ξ, σ_z and $\sigma_{\dot{z}}$ represents the modal damping ratio, standard deviation of the random process and its derivative, respectively. In the analyses, the duration of movement for each earthquake was determined from the recorded data, and a damping ratio of 5% was used as the basis.

4 Results and Discussion

This study investigates the RVA of a NPP structure under seismic loading and explores its effects on the SSI system. Analyses were conducted using random vibration theory, considering the FWN ground motion model. The FWN ground motion model was determined, and the seismic motion in the RVA is expressed as a spectral density function as shown in Fig. 3. A typical NPP structure was selected as an application. A FEM was obtained for the RVA of this structure system under the influence of seismic motion applied in the horizontal direction, and RVA was performed.

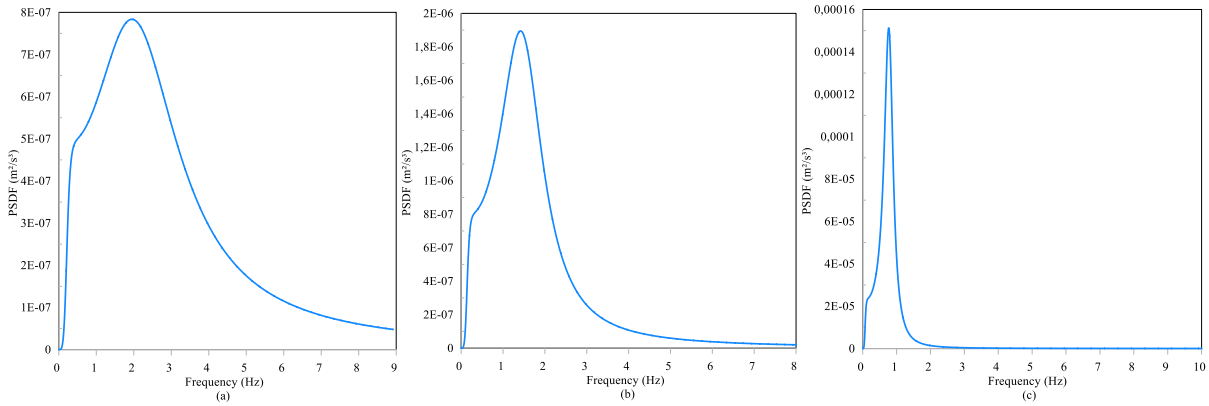

Fig. 3. PSD functions for (a) firm soil, (b) medium soil, (c) soft soil

The PSD functions given in Fig. 3 show that the dynamic behavior of the system changes significantly depending on the soil type. For firm soil, the energy is distributed over a wider frequency range, while as the soil softens, this distribution narrows and the dominant frequency shifts to lower frequency values. In the NPP-soil model, the dominant frequencies are obtained as 3.17 Hz, 2.17 Hz, and 0.90 Hz for firm, medium, and soft soils, respectively, while in the fixed-base model, this value is approximately 4.46 Hz. Especially in soft soil, the energy is concentrated in a narrow frequency band, forming a sharp peak. This variation causes a significant increase in the maximum displacement and stress values in soft soil condition and clearly demonstrates that SSI affects the structural response.

Since the maximum displacement occurs at the top of the structure, the mean maximum displacement value was calculated using Eq. (7) and presented in Table 7. In addition to the displacements, the maximum structural stresses (RMS of stress-RS11) were also compared as shown in Table 7.

Table 7. Mean of max displacement and max stresses in the NPP building

Kobe Eartquake								
	Soil+NPP				Fixed-base model			
Soil Type	**RU1 (m)**	**RV1 (m/s)**	**Mean Max Value (mm)**	**RS11 (N/m²)**	**RU1 (m)**	**RV1 (m/s)**	**Mean Max Value (mm)**	**RS11 (N/m²)**
Firm	4.00E-4	7.80E-3	1.22	5.64E+4	1.03E-4	2.76E-3	0.32	6.73E+3
Medium	1.70E-3	2.21E-2	4.98	1.25E+5	6.75E-5	1.66E-3	0.21	4.20E+3
Soft	1.92E-2	1.38E-1	52.14	5.63E+5	1.65E-4	2.22E-3	0.48	8.15E+3

Fig. 4 shows the displacement variation over the height of the NPP+soil and the fixed-base NPP model.

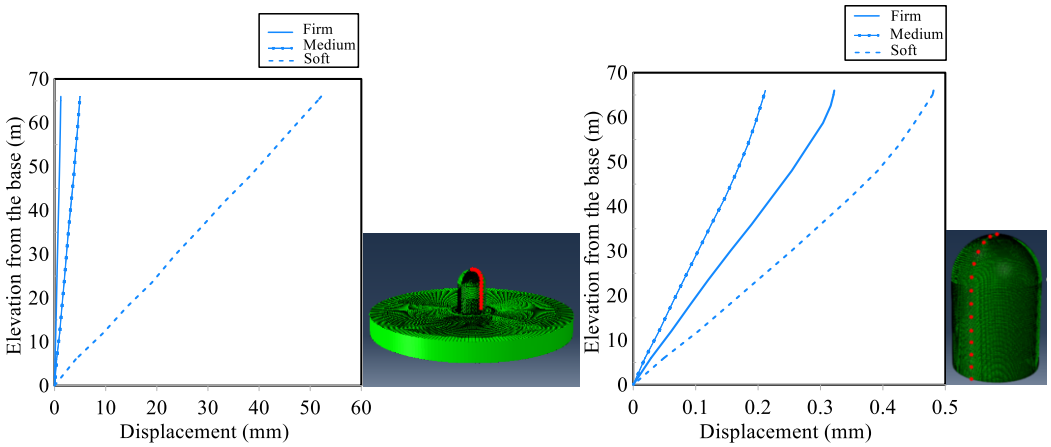

Fig. 4. Elevation–displacement graph for NPP+soil and fixed-base models.

Additionally, the variations of the maximum stresses RS11 in the NPP structure are presented in Fig. 5 and Fig.6.

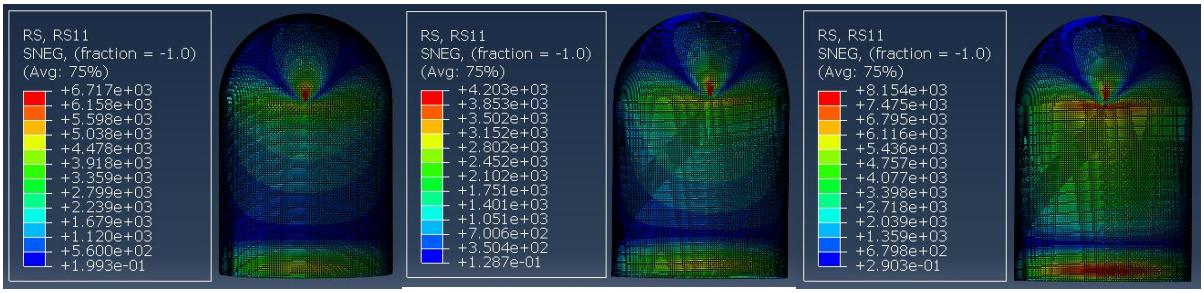

Fig. 5. RS11 stresses for firm, medium, and soft soils respectively (fixed-base model).

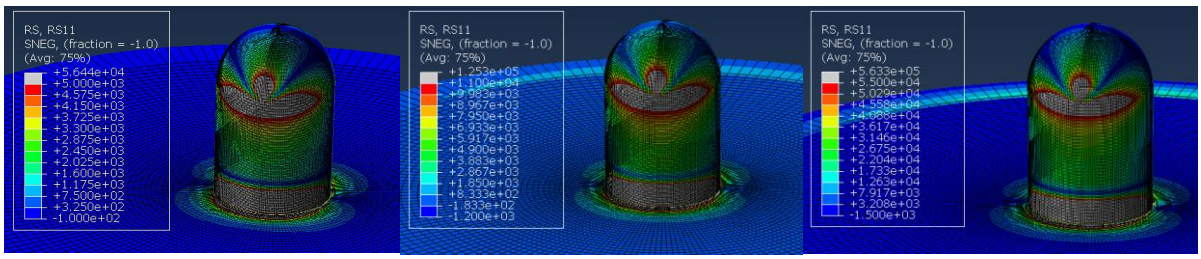

Fig. 6. RS11 stresses for firm, medium, and soft soils respectively (NPP-soil model)

The decisive influence of SSI effect on the seismic behavior can be clearly observed from the obtained results. As expected, the mean of max. displacement and RS11 stresses obtained for the NPP+soil model are larger for all soil types if compared with the fixed-base model. This difference is particularly pronounced in medium and soft soils. It can also be observed that the fixed-base model significantly underestimates displacements and stresses if soil deformation and wave propagation are neglected.

Considering the RVA based on the FWN model, it can be noticed that the soil medium causes an amplification effect in the frequency components, and this effect significantly increases the structural responses. In the NPP+soil model, due to the limited soil rigidity, the natural period of the system extends, and accordingly larger displacement and stress values take place under seismic loads. On the other hand, since the soil is assumed to be infinitely rigid in the fixed-base model, these amplification mechanisms are ignored, and the results are far from representing the actual behavior, especially for weak soil conditions.

5 Conclusions

Neglecting SSI, especially in medium and soft soil conditions, leads to underestimation of the results that may cause significant errors in engineering design. Therefore, using models that incorporate the SSI effect in conjunction with FWN-based RVA is of great importance in obtaining more reliable and realistic design results.

As future studies, it can be suggested that the results obtained using RVA be investigated comparatively with the fixed-base model, with the infinite element approach, and with the modeling by using spring-damper elements in external boundaries. It is believed that such comparisons will contribute to the identification of more realistic modeling approaches by revealing the effect of boundary conditions on the dynamic responses of NPP systems.

Abstract. The use of wind energy has increased rapidly in recent years, making the seismic performance of large wind turbines an important research topic. In this study, nonlinear time-history analyses were performed to investigate the earthquake response of an existing 2.5 MW onshore wind turbine. A detailed finite element model including the tower and blades was developed in OpenSees. The model was defined using appropriate element types, material models, structural idealizations, and boundary conditions for nonlinear dynamic analysis.

Three recorded ground motions were selected for the analyses. Two records had approximately the same peak ground acceleration (PGA) of 0.38g, while the third had a lower PGA of approximately 0.14g. The records with similar PGA values were selected to examine whether nearly identical peak accelerations can produce different structural demands. The lower-PGA record was included to evaluate whether a smaller PGA can still generate a comparable or greater structural response. In addition, all records were scaled by a factor of 15 to provide a common high scale-factor level and clearly expose nonlinear effects such as yielding and residual displacement. This scale factor was used for comparison purposes and does not represent a design earthquake. The structural response was evaluated in terms of tower-top displacement, base shear, base bending moment, and stress demand. The results were compared to assess the relationship between PGA and structural response and to determine the effect of scaling the ground motions by a factor of 15 on the nonlinear behavior of the wind turbine.

Keywords: Wind turbines; nonlinear time history analysis; finite element modeling; earthquake
ground motion

1 Introduction

Wind turbines are tall, flexible structures with a large mass concentration near the top of the tower. Their earthquake response is controlled by the distribution of mass and stiffness, the interaction among the tower, rotor-nacelle assembly, and blades, and the frequency, velocity, and duration characteristics of the input motion. Consequently, peak ground acceleration (PGA), although convenient, may not represent the interaction between a record and the turbine's dominant vibration modes.

The structure investigated in this study is a 2.5 MW onshore wind turbine located at the Wind Power Plant in Urla, İzmir, Türkiye. The turbine consists of a tapered tubular steel tower, a rotor-nacelle assembly, and three blades.

Previous studies have investigated wind-turbine response using time-domain analysis, nonlinear finite element models, and incremental dynamic procedures. Ishihara and Sarwar [1] highlighted higher-mode effects; Nuta et al. [2] and Patil et al. [3] evaluated nonlinear seismic

demand and damage states; and Katsanos et al. [4] emphasized the variability associated with ground-motion selection. This study therefore compares two records with nearly identical PGAs and one lower-PGA record at SF1 and SF15 to determine whether PGA-based ranking reproduces the ranking of tower-top displacement, base shear, base moment, and local material demand.

2 Numerical Modeling of the Wind Turbine

2.1 General Description of the Wind Turbine

The investigated system is a 2.5 MW onshore wind turbine consisting of a tapered tubular steel tower, a rotor-nacelle assembly, and three blades. The tower height is approximately 78 m, the hub height is approximately 90 m, and the rotor diameter is 90 m. The varying tower diameter and wall thickness were defined from the available technical data. At the same time, the rotor-nacelle mass and blade system were included to reproduce the dominant fore-aft and side-side response.

Table 1. Main properties of the investigated wind turbine.

Property	Value
Rated power	2.5 MW
Rotor diameter	90 m
Tower height	78 m
Hub height	90 m
Nacelle mass	91 tons
Rotor mass	55 tons

2.2 Model Generation and Material Properties

The model was generated in STKO, which served as the graphical pre- and post-processing environment for OpenSees [5]. Geometry, elements, materials, fiber sections, boundary conditions, and analysis stages were defined in STKO; the resulting Tcl files were fed into the OpenSees engine. This workflow also enabled verification of connectivity, local axes, section assignments, mode shapes, and nonlinear response quantities.

Blade geometry was reconstructed from technical drawings. Representative sections were assigned along a three-dimensional line-element idealization to retain the variation in blade stiffness and mass without incurring the computational cost of a detailed shell model. The tower and blades were modeled using three-dimensional nonlinear beam-column elements with fiber sections. The tubular steel sections of the tower were discretized into fibers, with all fibers assigned the same S355 steel. Although the tower sections consist of a single material, the fiber-section formulation enables the nonlinear stress-strain distribution across the section and the progressive spread of yielding under combined axial force and bending to be captured. Similar fiber-based modeling approaches have been adopted in previous nonlinear studies of wind-turbine towers [6]. This beam-based idealization is also consistent with wind-turbine models that use simplified rotor-nacelle masses to capture the global response efficiently [7, 8]. The tower fibers were assigned the OpenSees Steel02 material, based on the Giuffré-Menegotto-Pinto model with isotropic strain hardening. This material model was used to represent cyclic yielding, stiffness transition during load reversals, and the local stress-strain response of S355 steel. Representative GFRP properties were used for the blades to reproduce their global stiffness and mass contribution. Geometric nonlinearity was included using a P-Delta transformation.

(d) **(e)**

Fig. 1(d). Beam-column element idealization adopted for the wind turbine in the numerical model. (e). Fiber sections assigned to the beam-column elements in the numerical model.

S355 steel fibers represented the tower, whereas representative GFRP properties were assigned to the blades because their principal role was to reproduce global stiffness, mass distribution, and load transfer. The adopted material parameters are summarized in Tables 2 and 3.

Table 2. Mechanical properties of S355 structural steel.

Property	Value
Yield strength	355 MPa
Tensile strength	510-630 MPa
Modulus of elasticity	200 GPa
Shear modulus	81 GPa
Density	7850 kg/m³
Poisson's ratio	0.3

Table 3. Representative mechanical properties used for the GFRP blades.

Property	Value
Yield strength	450 MPa
Modulus of elasticity	38 GPa

The nacelle and the non-blade components of the rotor were represented by lumped masses at the hub-tower connection and linked to the tower and blade roots through rigid links. The mass and weight of the blades were assigned directly to the blade elements, avoiding double counting. This approach preserves the influence of the upper assembly on the natural frequencies and global response without explicitly modeling the drivetrain and hub mechanisms [3, 8]. The blades were assumed to remain stationary, and aero-servo-elastic effects were excluded.

Rayleigh damping was adopted in the nonlinear dynamic analyses. A critical damping ratio of 1% was used for the parked condition considered in all earthquake cases. This value is within the 0.5%-1% range reported for idle turbines and is consistent with the 1% Rayleigh damping used in parked-turbine seismic analysis [3, 7]. The Rayleigh coefficients were calculated from selected modes of the updated numerical model.

2.3 Modal Verification of the Numerical Model

Modal analysis was used to verify the global mass and stiffness distribution. The experimentally identified frequencies were approximately 0.36, 3.00, and 8.35 Hz. These values were obtained from field measurements on the same wind turbine examined in the present study, whose experimental modal characterization was reported in [9], where these frequencies were identified as its dominant global modes. The corresponding fore-aft and side-side frequencies from the OpenSees model are listed in Table 4. Close agreement in the first mode confirms that the model reproduces the dominant global bending response required for the subsequent nonlinear analyses.

Table 4. Updated numerical and experimental modal frequencies of the wind turbine.

Modal results	1st mode fre-	Effective modal mass (%)	2nd mode frequency (Hz)	Effective modal mass (%)	3rd mode frequency (Hz)	Effective modal mass (%)
Experimental	0.36	-	3	-	8.35	-
OpenSees - Fore-Aft	0.36	63.852	2.436	8.4	8.806	0.928
OpenSees - Side-Side	0.359	63.296	2.695	9.49	8.849	1.027

2.4 Boundary Conditions

Foundation flexibility was represented by a three-dimensional zero-length spring element placed between the tower-base node and the ground-side support node. Linear-elastic uniaxial materials were assigned to the six translational and rotational degrees of freedom of the zero-length element. The horizontal translational stiffness was defined as 2.76×10^7 kN/m in both the x and y directions, while the vertical translational stiffness in the z direction was taken as 4.25×10^7 kN/m. The rotational stiffness was defined as 9.60×10^8 kN·m/rad about each of the three global axes. The upper node of the zero-length element was connected to the tower base, whereas the lower node represented the ground-side support. This configuration allowed the flexibility of the foundation-soil system to be incorporated through equivalent translational and rotational springs without explicitly modeling the complete foundation and surrounding soil domain. All spring components were assumed to remain linear elastic throughout the analyses.

The earthquake records were applied using the OpenSees MultipleSupport excitation pattern. For each analysis, the acceleration time history was imposed on the ground-side support node in the selected horizontal direction. Zero acceleration values were added before and after each recorded ground motion. The values added at the beginning allowed the analysis to start from a stationary condition. In contrast, those added at the end allowed the structural response to be evaluated after the ground-motion excitation had ended. The original time increment of each record was retained.

3 Ground-Motion Selection and Analysis Procedure

3.1 Targeted Ground-Motion Selection

The study adopts a focused comparative nonlinear time-history framework rather than a code-based statistical assessment or formal fragility analysis. The selected records are treated as representative case studies because statistically calibrated fragility or incremental dynamic analysis requires a larger record set and multiple intensity levels [10].

The ground-motion records were selected considering the regional seismotectonic characteristics and local soil conditions of the wind turbine site at the Wind Power Plant in Urla, İzmir. The geotechnical investigation conducted at the site reported shear-wave velocities ranging from 600 to 1000 m/s. From the records satisfying these site-related criteria, three ground motions, denoted EQ1, EQ2, and EQ3, were adopted for the focused comparative analyses. EQ1 and EQ2 have nearly identical PGA values of 0.382 g and 0.381 g, respectively, whereas EQ3 has a lower PGA of 0.142 g. This selection directly tests whether PGA alone can rank earthquake severity for a slender, dynamically sensitive wind turbine.

Table 5. Selected ground motions and analysis intensity levels.

Record	Earthquake	Year	Station	Magnitude (Mw)	Rjb (km)	Vs30 (m/s)	PGA at SF1 (g)	PGA at SF15 (g)
EQ1	San Fernando	1971	Lake Hughes #12	6.61	13.99	602.1	0.382	5.73
EQ2	Northridge-01	1994	LA 00	6.69	9.87	706.22	0.381	5.715
EQ3	Taiwan SMART1(45)	1986	SMART1 E02	7.3	51.35	671.52	0.142	2.13

3.2 Analysis Cases and Response Measures

Each ground motion was applied in its original form (SF1) and after amplitude scaling by a factor of 15 (SF15). SF1 characterizes record-to-record variability at the original intensity, whereas SF15 drives the model toward the nonlinear range, allowing response amplification and local yielding to be compared.

The engineering demand parameters were the maximum relative tower-top displacement, base shear and base bending moment, together with the stress-strain response at a common reference fiber located at the tower base. For all three records, this response was extracted from Element 117, Gauss point 0, Fiber 190. Additional tower-wide post-processing was used to identify localized yielding associated with residual deformation.

3.3 Fourier Analysis Procedure

To support the PGA-based comparison, Fourier amplitude spectra were calculated for the three acceleration records. The first fore-aft and side-side modal frequencies obtained from the numerical model were 0.360 Hz (T = 2.778 s) and 0.359 Hz (T = 2.786 s), respectively. The corresponding second-mode frequencies were 2.436 Hz in the fore-aft direction and 2.695 Hz in the side-side direction. These four modal frequencies were superimposed on the Fourier

spectra to compare the frequency content of each record with the fundamental dynamic characteristics of the turbine. Because the two first-mode frequencies are nearly identical, their markers appear very close together on the spectra and together represent the fundamental-frequency range of the structure. Fourier amplitude spectra do not explicitly account for damping, phase characteristics, excitation duration, modal participation, or frequency shifts associated with nonlinear stiffness changes. Therefore, they were used as a qualitative and complementary frequency-domain measure rather than as a standalone predictor of structural demand. Therefore, a high Fourier amplitude near a modal frequency does not necessarily mean that the structure will experience a large nonlinear response. This is especially important at SF15, where nonlinear behavior can change the stiffness and vibration characteristics of the turbine during the earthquake. These changes cannot be captured by the Fourier spectrum of the input ground motion alone.

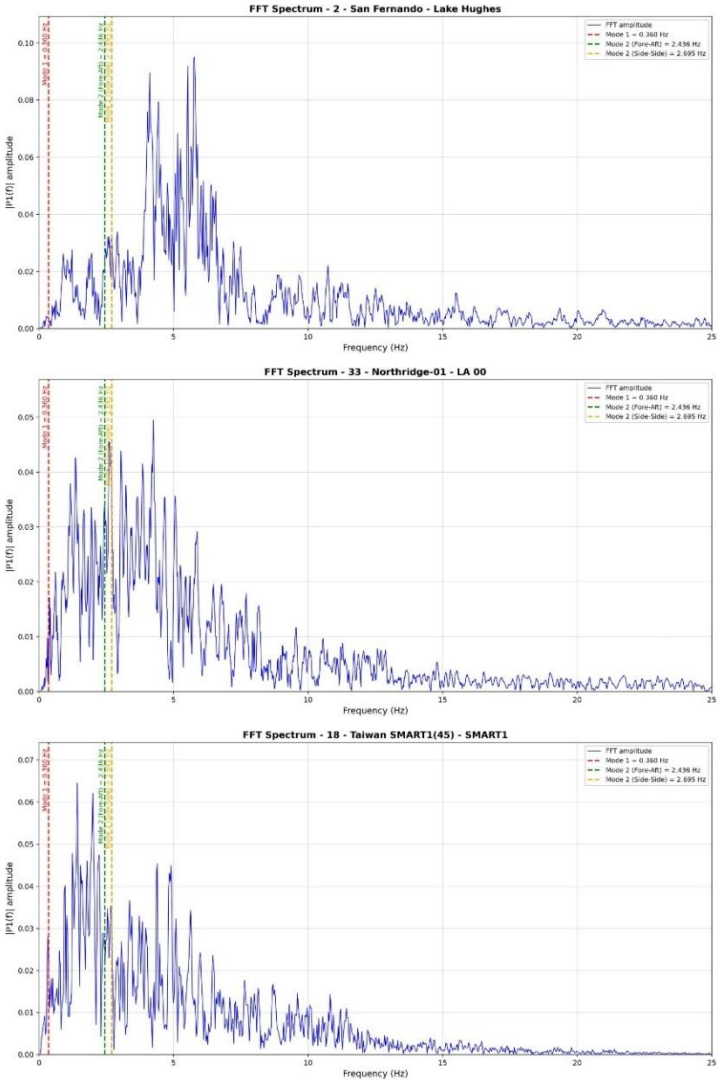

Fig. 2. Fourier amplitude spectra with the first and second structural frequencies superimposed: (a) EQ1-San Fernando, Lake Hughes; (b) EQ2-Northridge-01, LA 00; and (c) EQ3-Taiwan SMART1(45), SMART1.

4 Results and Discussion

4.1 Peak Structural Response

Table 6 summarizes the peak responses from the six nonlinear analyses. At SF1, EQ1 and EQ2 have virtually identical PGA, yet EQ2 produces approximately 57% greater tower-top displacement, 81% greater base shear, and 73% greater base moment than EQ1. The

pronounced differences cannot be explained by PGA amplitude alone and instead reflect record-specific characteristics such as frequency content, duration, and modal participation, consistent with the ground-motion variability documented for wind-turbine seismic assessment [4, 8].

The lower-PGA EQ3 provides a clearer example: despite a PGA of only 0.142g, it produces the largest SF1 tower-top displacement (0.199 m), a larger base moment than EQ1 and a stress demand comparable with EQ2. Thus, ranking the records by PGA does not reproduce the ranking of structural demand, in agreement with earlier observations that nonlinear time-history analysis is needed to capture record-specific amplification of wind-turbine seismic demand that PGA alone cannot predict [2, 3].

Table 6. Peak global response under SF1 and SF15.

Record/scale	PGA (g)	Maximum Relative Displacement (m)	Maximum Base Shear (kN)	Maximum Base Moment (kN.m)
EQ1 / SF1	0.382	0.067	412.542	9,688.715
EQ1 / SF15	5.730	0.530	6,160.000	124,516.442
EQ2 / SF1	0.381	0.105	745.170	16,809.054
EQ2 / SF15	5.715	1.441	8,614.011	182,059.341
EQ3 / SF1	0.142	0.199	341.695	15,937.173
EQ3 / SF15	2.130	2.494	5,129.924	193,178.325

At SF15, EQ2 and EQ1 retain nearly identical scaled PGA values, but EQ2 produces 2.72 times the displacement, 1.40 times the base shear, and 1.46 times the base moment of EQ1. EQ3, although having the lowest scaled PGA, governs tower-top displacement (2.494 m) and base moment (193,178 kN m), whereas EQ2 governs base shear (8,614 kN).

The results indicate that PGA compatibility alone may not be sufficient for selecting ground motions for wind-turbine analysis. Records with similar PGA values produced different structural responses, while records with lower PGA values produced greater demands. Therefore, ground-motion selection should consider spectral characteristics in relation to the dominant structural periods, and multiple response measures should be evaluated concurrently.

4.2 Frequency Content and Response-History Interpretation

Figure 2 shows that EQ1 has relatively low ground motion energy near the first fore-aft and side-side modal frequencies of 0.360 Hz and 0.359 Hz, respectively, whereas EQ2 and EQ3 contain more pronounced energy content in this range. This closer correspondence with the first structural modes is consistent with the larger displacement and base-moment demands produced by EQ2 and EQ3 compared with EQ1. The spectra were also examined near the second fore-aft and side-side modal frequencies of 2.436 Hz and 2.695 Hz, respectively, to assess the possible contribution of higher-mode excitation. In contrast, the dominant frequency content of EQ1 is concentrated mainly around 4-6 Hz, above the first- and second-mode frequencies considered in the comparison, which helps explain its lower displacement response.

The response histories in Fig. 3 are consistent with the peak values reported in Table 6. At SF1, EQ3 produces the largest tower-top displacement, whereas EQ2 produces the largest base shear and base bending moment. This response ordering is also consistent with the FFT comparison, since EQ2 and EQ3 have greater Fourier amplitudes near the first structural frequency than EQ1.

At SF15, EQ3 produces the largest tower-top displacement and base bending moment, whereas EQ2 exhibits a different response characteristic. Following the Northridge-01 excitation, the EQ2-SF15 tower-top displacement continues to oscillate about a shifted equilibrium position,

indicating a persistent residual response. The fiber-level mechanism associated with this displacement offset is examined in Section 4.3.

This contrast shows that peak global demand and residual response need not be governed by the same record. Accordingly, PGA, peak response, and post-earthquake residual deformation should be evaluated as complementary indicators rather than as interchangeable measures [2-4].

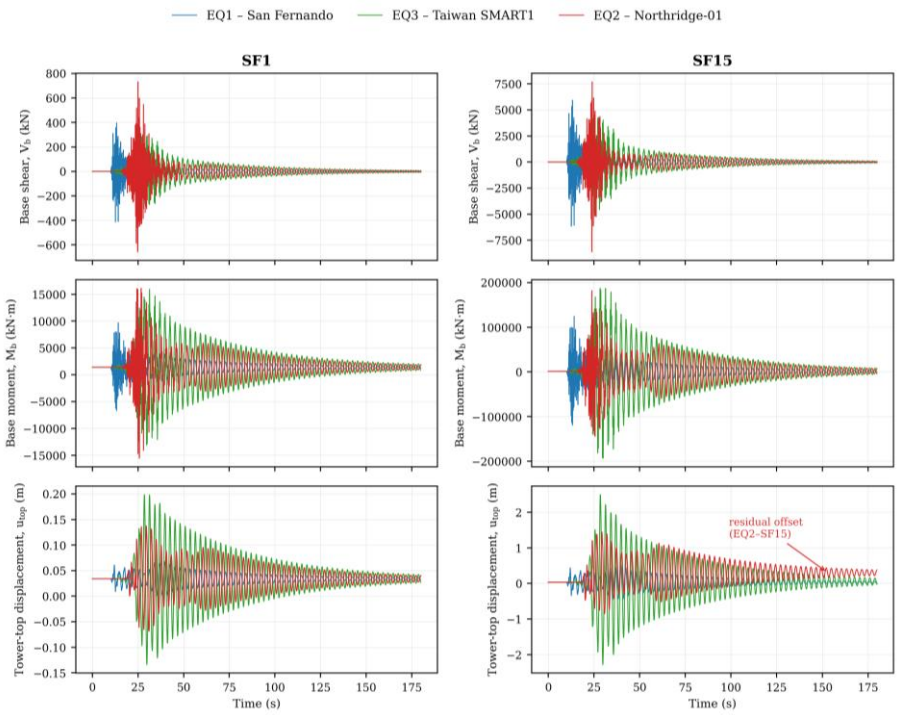

Fig. 3. Comparative SF1 and SF15 time histories of base shear, base bending moment, and tower-top relative displacement for EQ1-San Fernando, EQ2-Northridge-01, and EQ3-Taiwan SMART1. The EQ2-SF15 displacement history exhibits a persistent post-earthquake offset.

4.3 Fiber-Level Response and Residual Deformation at SF15

Table 7 and Figure 4 compare the stress-strain responses obtained from the same tower-base reference fiber (Fiber 190), located within Gauss point 0 of Element 117, for all three SF15 analyses. This common location was selected to provide a consistent basis for comparing the local material demands generated by the three records; it was not assumed to represent the maximum material response over the entire tower. For S355 steel with E = 200 GPa and a nominal yield stress of 355 MPa, the corresponding nominal elastic yield strain is approximately 0.00178.

Table 7. Peak response at the common tower-base fiber under SF15.

Record	Max. stress (MPa)	Max. strain	Response interpretation
EQ1	248.5	0.0012460	Essentially elastic
EQ2	341.0	0.0018807	Limited hysteretic response at base fiber
EQ3	354.7	0.0019245	Most pronounced base-fiber response

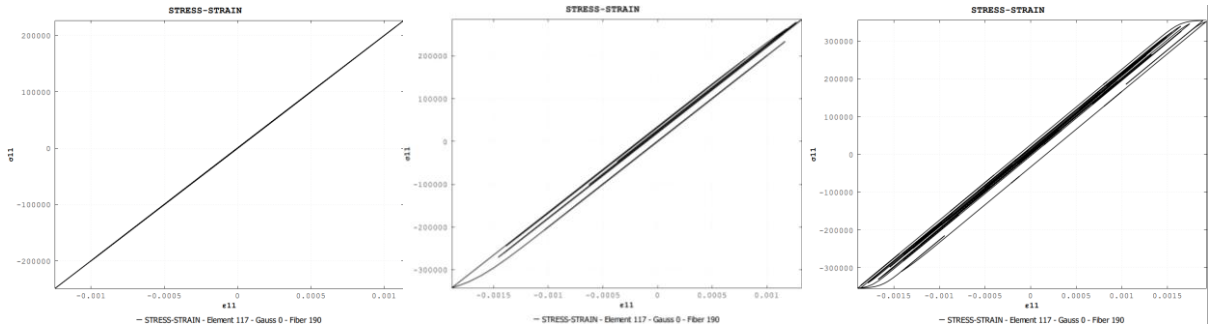

Fig. 4. Stress-strain response at the common tower-base fiber (Fiber 190) located within Gauss point 0 of Element 117, under SF15: (a) EQ1, (b) EQ2 and (c) EQ3.

At the selected tower-base fiber, EQ1 remains elastic, reaching a maximum stress of 248.5 MPa and a strain of 0.001246. EQ2 shows only minor hysteretic behavior. Although EQ3 has a lower PGA, it produces the largest response at this fiber, with a peak stress of 354.7 MPa, a maximum strain of 0.0019245, and the widest hysteresis loop.

However, the base-fiber results do not capture the most critical response along the tower. For EQ2 at SF15, more significant yielding occurs at an upper-tower section corresponding to Element 108, Gauss point 1, Fiber 163. The stress-strain loops at this location indicate repeated yielding and plastic-strain accumulation, as shown in Fig. 5.

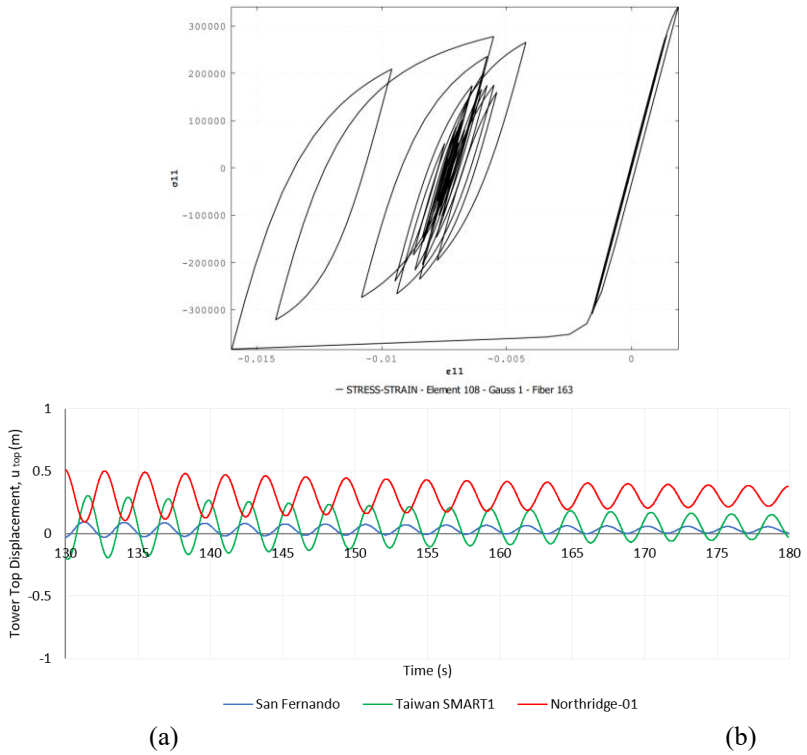

Fig. 5. Localized upper-tower yielding under EQ2-Northridge-01 at SF15 and the corresponding residual tower-top displacement: (a) upper-tower hysteretic response and (b) shifted free-vibration response.

The upper-tower yielding observed in the EQ2-SF15 analysis is consistent with the residual offset in the tower-top displacement response. The two fiber locations represent different aspects of the structural behavior. The base fiber compares the three earthquake records at a common location, while the upper-tower fiber captures the local yielding associated with the residual deformation in EQ2-SF15.

These results describe local fiber-level behavior and should not be interpreted as yielding of the entire tower. Identifying nonlinear response at two different elevations also demonstrates the ability of the fiber-section beam-column model to capture distributed plasticity along the tower, consistent with previous studies on offshore wind-turbine structures [6]. Previous studies have investigated nonlinear seismic response in wind turbines and the effects of ground-motion characteristics and record-to-record variability [2-4]. Other studies have also used fragility analysis to evaluate wind-turbine seismic performance [7,8]. This study adds to the literature by directly comparing two records with nearly identical PGA values and one record with a lower PGA for the same 2.5 MW onshore wind turbine. The results show that similar PGA values do not necessarily produce similar structural demands, and that a record with lower PGA can govern some response measures. They also show that peak displacement, base shear, base moment, and local nonlinear response may be governed by different records. Therefore, wind-turbine seismic assessment should consider both ground-motion characteristics and multiple structural response measures, rather than PGA alone.

5 Conclusions

This study investigated the nonlinear seismic response of an existing 2.5 MW onshore wind turbine using three ground-motion records at SF1 and SF15. The results showed that PGA alone did not consistently represent the relative severity of the structural response. Records with nearly identical PGA values produced different displacement and force demands, while the lower-PGA record governed some response quantities.

The analyses also showed that different response measures may be governed by different records. In particular, the record producing the largest tower-top displacement did not necessarily produce the most pronounced local nonlinear response or residual deformation. These findings indicate that wind-turbine seismic assessment should consider ground-motion characteristics together with multiple global and local response measures rather than relying on PGA alone.

The study was intentionally limited to three records and two intensity levels for a focused comparison. Therefore, the results should be regarded as illustrative rather than statistically generalizable. The analyses were also limited to a single turbine under parked, single-horizontal-direction excitation, and SF15 was used to expose nonlinear behavior rather than to represent a site-specific design earthquake.

Future studies should consider larger ground-motion sets and multiple intensity levels. Incremental dynamic analysis and fragility-based assessment could be used to quantify record-to-record variability and to investigate structure-related intensity measures such as spectral acceleration near the dominant vibration periods.

Abstract

Accurate prediction of the shear capacity of reinforced concrete (RC) exterior beam-column joints is important for seismic assessment and design. This study investigates the use of CatBoost for predicting exterior joint shear capacity using a database of 270 experimental specimens described by 14 geometric, material, reinforcement, and loading variables. Feature-importance analysis identified column height (h_c), column width (b_c), and beam width (b_b) as the most influential variables, while SHAP analysis showed that h_c, b_b, and b_c had the widest contribution ranges. The results indicate that CatBoost can represent the nonlinear relationships governing exterior joint shear capacity while providing interpretable information on the contribution of key variables. The proposed approach can be considered a complementary data-driven tool for structural engineering assessment and future model-development studies.

Keywords: Exterior Beam-Column Joint, CatBoost, Gradient Boosting, Machine Learning, Shear Capacity, SHAP

1 Introduction

In reinforced concrete (RC) frame systems, the beam-column joints represent critical regions that facilitate force transfer between members under seismic action. In particular, exterior joints are susceptible to high shear stresses and brittle failure mechanisms due to the more limited confinement effect they experience compared to interior joints *(Figure 1)*. Therefore, it is imperative to reliably estimate the shear strength of the joint region to ensure the ductile behavior of the structural system [1-3].

A variety of analytical models and code-based empirical equations have been developed to determine joint shear strength. However, it should be noted that joint behavior is influenced by numerous variables, including column and beam geometry, concrete strength, longitudinal and transverse reinforcement detailing, and axial load. The inherent multivariate and nonlinear characteristics of this phenomenon have led to a significant increase in the utilization of machine learning methodologies in recent years for the purpose of predicting the strength and damage behavior of beam-column joints [4,5].

Research on machine learning is also rapidly increasing in the literature. Karabini et al. [6] and Karampinis et al. [7] employed ensemble learning and SHapley Additive exPlanations (SHAP)-based interpretability approaches to predict damage modes in beam-column joints. Mehta et al. [8] addressed the shear strength and damage modes of exterior joints using machine learning on an extensive experimental database. Kamal and Abd El Ghany [9] evaluated 203 experiments on RC exterior beam-column joints using Random Forest, XGBoost, and neural network-based models, while utilizing SHAP and permutation importance analyses. Shah et al. [10] examined various models using data from 194 experimental joints, employing ten-fold cross-validation and SHAP/PDP analyses. Recent studies have demonstrated that, in addition

to prediction accuracy, the interpretability of model decisions from an engineering perspective is becoming increasingly significant.

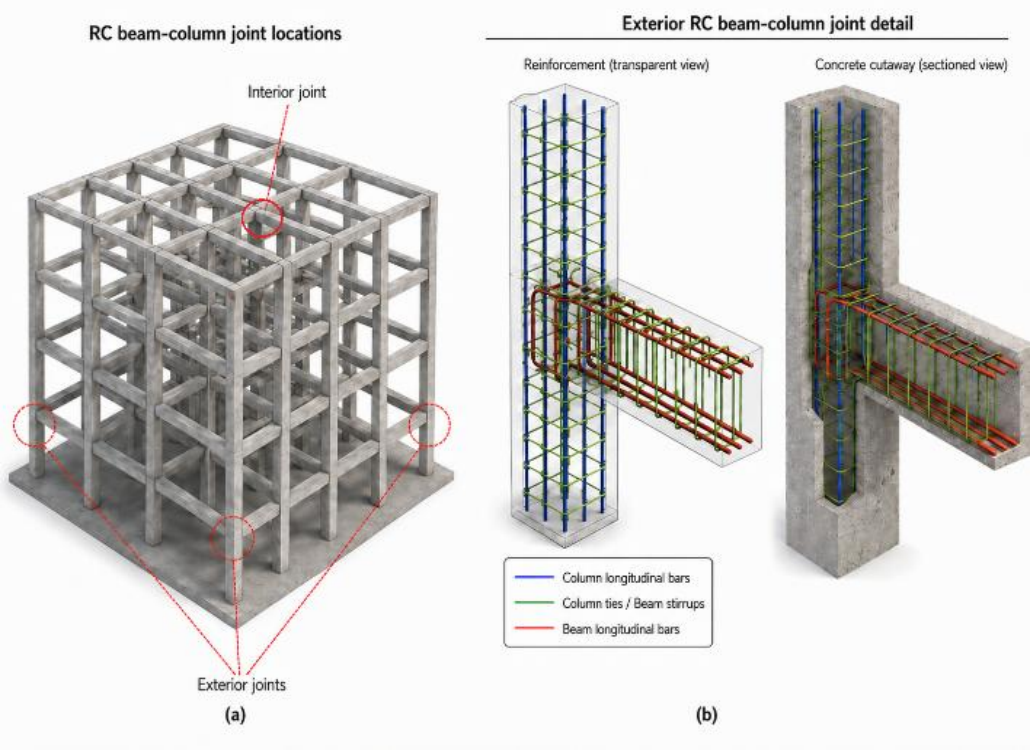

Figure 1. (a) Locations of beam-column joints in an RC frame, (b) 3D reinforcement detailing of an exterior RC beam-column joint.

Contrary to extant literature, this study utilizes the CatBoost regression algorithm, developed as an optimal model for limited datasets, to calculate the shear capacities of beam-column joints. In this context, a database comprising 270 experimental specimens [11] was analyzed using the CatBoost regression model. The performance of the model was evaluated based on success metrics, and the relative influence of parameters affecting shear capacity was examined through feature importance scores and SHAP analysis [13]. The objective of this study is to integrate CatBoost-based prediction with model interpretability within a unified evaluation framework.

2 Methodology and Data Framework

2.1 Data Compilation

The present study employs a database of exterior RC beam-column joints, which was compiled from experimental studies specifically, those utilized by Doğan [11] and published by Parate and Kumar [12]. The database under consideration contains parameters for a total of 270 exterior joint specimens obtained from experimental studies conducted between 1967 and 2016. For each specimen, the joint geometry, material properties, reinforcement layout, and axial load data are presented alongside the experimental shear strength.

The analyses were conducted using a total of 14 input variables and a single target variable. The input variables encompass concrete compressive strength, column and beam cross-sectional dimensions, reinforcement ratios, reinforcement yield strengths, joint region reinforcement areas, and axial load. The target variable is the experimental joint shear strength ($V_{ij,exp}$). Prior to analysis, the data file was examined for numerical validity and the presence

of missing observations; no missing observations were identified. The parameter names, units, and basic statistical values are presented in *Table 1.*

Table 1. Statistical values for Input and output parameters

Parameter		Details	Unit	Min	Max	Median
Input	f_c	Concrete Compressive Strength	MPa	18.00	109.60	37.00
	P_{axial}	Axial Load	kN	-100.00	2156.00	200.00

Output	$V_{ij,exp}$	Shear Strength	kN	62.29	1771.80	331.60

2.2 CatBoost Model

CatBoost is a gradient boosting algorithm based on decision trees [13]. In the gradient boosting approach, multiple trees constructed sequentially are used in conjunction rather than a single decision tree. The incorporation of each new tree into the learning process serves to minimize the prediction errors committed by the preceding model. This structural design enables the model to represent non-linear relationships and interactions among input variables.

In this study, the CatBoost regression algorithm architecture, a gradient boosting tree model, was selected to predict the shear strength of exterior beam-column joints in RC buildings. During the implementation process, the experimental dataset was initially loaded into the

system, and data preprocessing steps were initiated. The model was implemented using the Python programming language via the Spyder interface. A total of 14 parameters, as identified in the extant literature, were designated as independent variables (inputs) within the model. These parameters are believed to directly influence joint shear strength. The defined inputs and the target variable, experimental shear strength (Vij,exp), were formatted numerically. The dataset was examined for missing or erroneous observations (NaN), and data consistency was verified. The prepared dataset was divided into two main groups to impartially evaluate the model's generalization capability. The dataset, constituting 80% of the total was designated as the training set to optimize the model's decision tree structures and weights, while the remaining 20% was set aside as the test set to measure performance on data the model had not previously encountered.

In regard to the hyperparameters utilized for the CatBoost regression model, the values of 1,000 for the number of iterations, 0.03 for the learning rate, and 6 for the depth were employed. The RMSE was designated as the loss function, and the model was trained using these parameters. The hyperparameter configuration was set to yield the most optimal prediction. During the training process, the CatBoost model generated predictions by establishing a correlation between the target shear strength and the independent input parameters found in the test set.

The algorithm's prediction accuracy and model performance were evaluated using the Coefficient of Determination (R^2), Root Mean Squared Error (RMSE), and Mean Absolute Error (MAE) metrics. Furthermore, CatBoost feature importance scores were calculated to ascertain which variables the model relied on most during the prediction process and the weight assigned to each variable within the model's decision-making mechanism. Finally, SHapley Additive exPlanations (SHAP) analysis was employed to assess the contribution of the variables, whether increasing or decreasing, to the model's predictions [14]. The algorithm's code flow is presented in *Table 2.*

Table 2. CatBoost model analysis flow.

Algorithm: CatBoost model for RC exterior joints
Require: Experimental dataset D containing 270 specimens, 14 input variables X, and target variable $y = V_{ij,exp}$
Ensure: Predicted shear strengths, performance metrics, feature importance scores, and SHAP values
1: Check numerical consistency of the dataset
2: Remove observations containing missing values
3: Split the dataset into training and test subsets:
Training set: 80% (n = 216) Test set: 20% (n = 54) random_state = 42
4: Initialize CatBoost regression model:
iterations = 1000,
learning_rate = 0.03,
depth = 6,
loss_function = RMSE,
random_seed = 42
5: Train the CatBoost model using the training dataset
6: Predict shear strength values for the test dataset
7: Evaluate model performance using R^2, *RMSE*, and *MAE*
8: Calculate CatBoost feature importance scores
9: Compute SHAP values using the training dataset
10: Generate prediction and interpretation plots
11: Return Predicted values, performance metrics, feature importance scores, and SHAP results

3 Results

3.1 Model Performance

The CatBoost model's prediction performance on the test set was found to be $R^2 = 0.913$, with error metrics RMSE = 107.07 and MAE = 51.35. The R^2 value indicates a strong agreement between experimental results and model predictions. The higher value of the root mean square error (RMSE) relative to the mean absolute error (MAE) indicates the presence of larger discrepancies between the ground truth (i.e., the experimental results) and the predicted values in certain samples.

Figure 2 compares the experimental and predicted shear strength values of RC column-beam joint regions. A considerable proportion of the data points align with the ideal fit line, represented by the equation y = x. The model demonstrates a general adherence to the prevailing trend, particularly at low and medium strength levels. However, a notable concern emerges when examining samples from the high-strength region, where substantial underestimations or overestimations are observed. These deviations are hypothesized to be associated with the limited number of high-shear-strength samples in the test set and the fact that the database was compiled from disparate experimental programs.

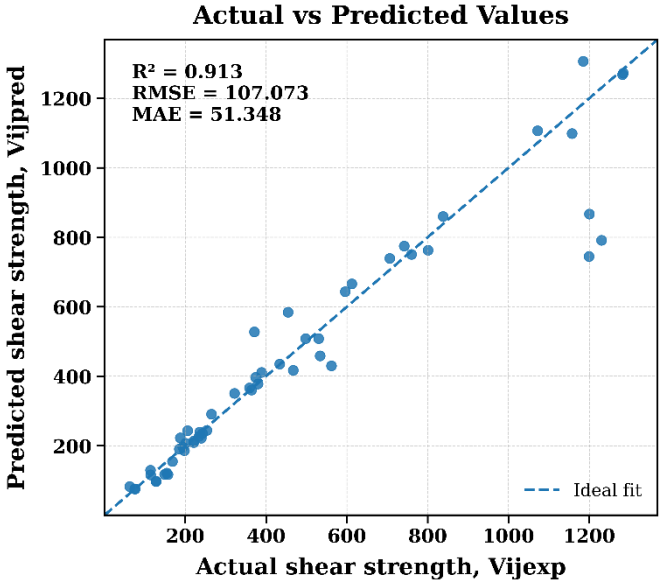

Figure 2. Comparison of experimental and predicted shear strength values.

3.2 Feature Importance and SHAP Analysis

The CatBoost feature importance results are presented in *Figure 3*. The highest importance scores were obtained for the column height (h_c), column width (b_c), and beam width (b_b) variables. These variables are followed by the top beam reinforcement ratio (ρt) and beam height (h_b). The findings suggest that the model places significant reliance on variables delineating the joint geometry when generating predictions. However, it is imperative to acknowledge that feature importance scores are not a direct measure of physical causality. Instead, they reflect the model's predictive behavior based on the existing dataset.

The SHAP summary plot in *Figure 4* illustrates the direction and magnitude of the contributions of the variables in the training set to the predictions. The variables h_c, b_b, and b_c demonstrate wider SHAP distributions in comparison to the remaining parameters. This result aligns with the key geometric parameters that were identified as significant in the feature importance analysis. It has been demonstrated that elevated values of h_c, b_b, and b_c are

predominantly associated with positive SHAP contributions, whereas diminished values are associated with negative contributions. Consequently, the trained CatBoost model has demonstrated a consistent correlation between increased geometric dimensions and enhanced shear strength predictions.

While the axial load variable acting on the column element at the connection zone is considered low in terms of overall importance, it yields high positive SHAP contributions in certain instances. This finding indicates that the effect of axial load does not manifest at the same level across all samples. While SHAP results can facilitate the comprehension of the relationships within the model, they should not be regarded as direct evidence of causality.

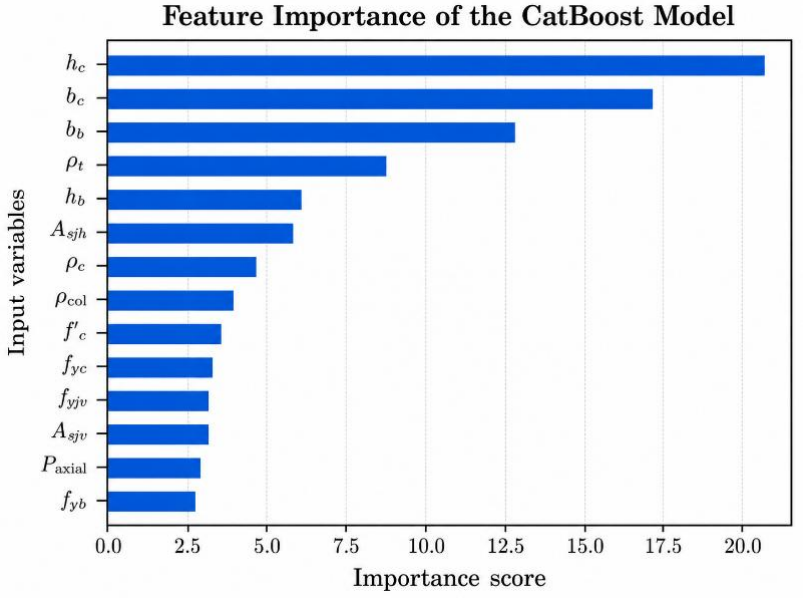

Figure 3. CatBoost model feature importance scores.

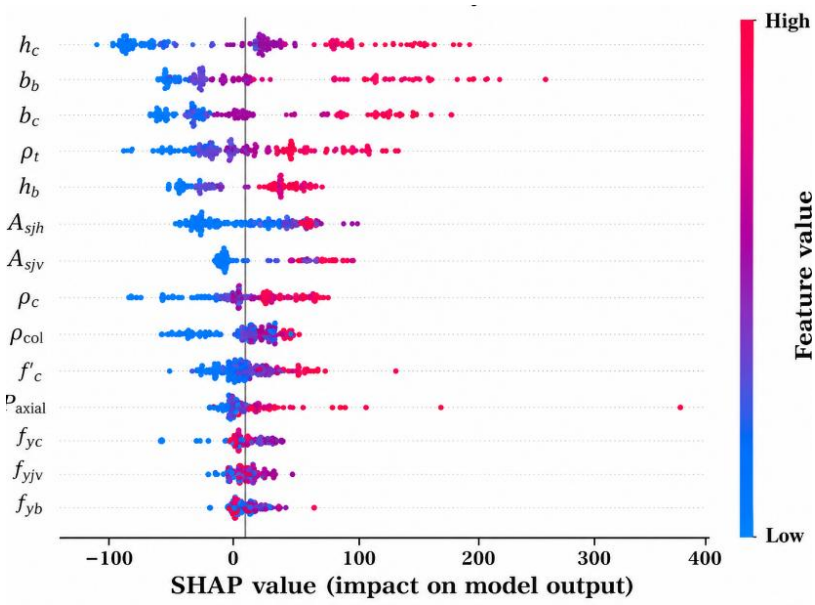

Figure 4. CatBoost model SHAP graph.

4 Conclusion and Discussion

In this study, the shear strength of RC external beam-column joints, which play an essential role in structural systems, was estimated using the CatBoost algorithm. The findings indicate

that the CatBoost algorithm constitutes a viable data-driven approach, capable of representing nonlinear relationships in external joint shear strength.

Feature significance and SHAP analyses have demonstrated that geometric variables such as column height (h_c), column width (b_c), and beam width (b_b) are particularly salient in model predictions. The SHAP analysis indicated that elevated values of these parameters are predominantly correlated with favorable prediction contributions. Consequently, the model can be utilized not only to generate predictions but also to examine the relative effects of variables on model behavior.

In scenarios where ground truth data is scarce, the CatBoost algorithm has demonstrated its efficacy, particularly for small and medium-sized datasets. This is due to its capacity to discern intricate nonlinear relationships and its incorporation of mechanisms that curtail overlearning. The study's findings indicate that CatBoost is a highly suitable and superior option when compared to other machine learning regression algorithms, particularly Boosting models.

Machine learning methods have seen increased utilization in a variety of structural engineering problems, including strength estimation, damage classification, structural performance evaluation, and rapid preliminary assessment. The findings of this study demonstrate that the CatBoost algorithm and explainable artificial intelligence approaches can be used as effective and complementary tools in data-driven evaluation of RC joint behavior. However, in order to more comprehensively demonstrate the generalization capacity of the model, further studies are necessary to consider larger and more balanced databases, different joint geometries, and loading conditions. Furthermore, comparisons with independent experimental validation datasets will contribute to the evaluation of the reliability of the developed approach and its usability in practical engineering applications.

Abstract. This study presents a micromechanical explicit finite element model to investigate fracture evolution in structures subjected to crack parallel stress (CPS) conditions. Conventional fracture mechanics approaches primarily focus on crack opening mechanisms driven by tensile stresses normal to the crack surface, recent studies have demonstrated that stresses acting parallel to the crack propagation direction may significantly influence fracture energy dissipation and damage evolution in materials. In this context, the present study aims to analyze the effects of crack parallel stresses by modelling the Bažant's Gap Test, which has recently attracted considerable attention in the literature. Achieving this objective as realistically as possible is essential to ensure that the developed framework can serve as a reliable computational reference for future research. In order for the model to be presented in a way that includes micro effects, the developed M7 concrete micromaterial model is used in the ABAQUS software via a subroutine file. The proposed three-dimensional modelling approach incorporates a micromechanical representation of damage initiation and propagation under dynamic loading conditions. The results demonstrate that crack parallel stresses substantially alter the evolution of the fracture process. The findings of this study contribute to the understanding of multiaxial fracture behavior and provide a computational basis for improving predictive fracture models in concrete like materials.

Keywords: Computational modelling; Fracture mechanics; Gap test; Micro-plane model.

1 Introduction

Recent advances in fracture mechanics have focused on understanding the CPS effect, a phenomenon that significantly influences fracture energy, crack propagation, and damage mechanisms across a wide range of materials. The gap test, first formalized by Nguyen et al. [1], has become the benchmark experimental approach for isolating and quantifying CPS effects in quasi-brittle fracture. Subsequent studies by Bažant, Dönmez, and co-workers [2, 3] refined theoretical interpretations through phase-field, peridynamic, and crack-band models, emphasizing the need to revise classical fracture mechanics assumptions. Zhang et al. [4] explored hydraulic and shale fracture behavior under CPS conditions. Brockmann and Salviato [5] demonstrated the broad applicability of CPS based analyses. Collectively, these works establish the CPS effect as a micromechanical mechanism governing energy dissipation, localization, and fracture scaling, highlighting its crucial role in advancing predictive modeling of materials.

In this study, an explicit finite element model of the gap test is developed to investigate the influence of CPS effect on microcrack initiation, propagation, and stress redistribution. An

explicit finite element model of the gap test is developed with the primary objective of systematically investigating the influence of CPS on the fracture behavior of materials. The model explicitly captures microcrack initiation and subsequent propagation, allowing for a detailed examination of how these stresses affect both the growth of microcracks within the fracture process zone. By integrating these features, the proposed approach provides a comprehensive tool for understanding the micromechanical mechanisms governing fracture under multiaxial stress states, offering insights that can inform improved predictive models and design strategies for concrete, composites, and other heterogeneous materials.

2 Gap Test and Microplane Modelling

Bažant, proposed the gap test to address the limitations of traditional methods, providing a theoretical framework and preliminary experimental results that highlight the importance of CPS effect. Schematically representation of Bazant's gap test set-up is shown in Fig. 1 [1]. In this set-up, *a* is crack length, *D* is panel width, *L* is roller span length and *s* is top span length. The scope of this research encompasses developing and validating a numerical model for the gap test, with a critical evaluation of the literature to identify gaps in current understanding. The importance lies in providing a more accurate representation of material behavior under stress, which has significant implications for engineering design and safety. This approach offers several innovative contributions such as scientific quality, innovation potential, methodological contribution and theoretical contribution. The research will refine the theoretical understanding of CPS effects and provide robust numerical data to support Bazant's gap test methodology. The development of a sophisticated finite element model represents a methodological advancement, enabling more precise simulations of material behavior under complex stress conditions.

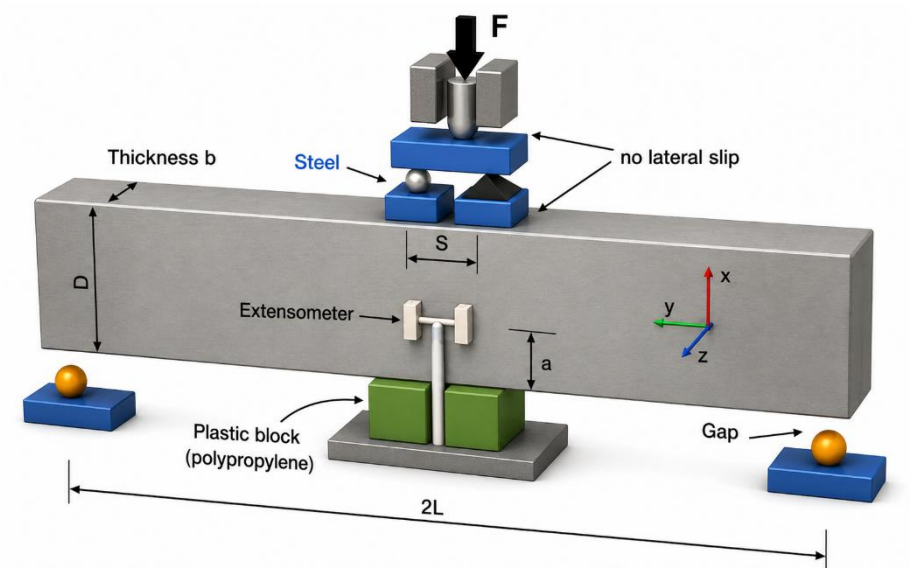

Fig. 1. Bazant's gap test experimental set-up [1].

In micro-plane models, the strain tensor at a given integration point is projected onto micro-planes oriented to encompass all directions in 3-dimensional space. The structural formulation is defined on the micro-plane as a function of the micro-plane strain components, and the resulting micro-plane stress components are integrated to obtain the stress tensor. The micro-plane approach has several key advantages. First, structural equations do not need to be defined in terms of stress and strain tensor invariants or prime values, which, although often becoming overly complex, provide little improvement in model predictions. Instead, they are defined more simply as strain and stress vectors acting on the micro-plane, which naturally reduces

complexity. However, such invariants and prime values can still be used in micro-plane structural relationships if needed. Furthermore, micro-planes oriented to encompass all possible directions in 3-dimensional space represent potential shear planes at material microstructure scales larger than 100 μm. Therefore, the micro-plane approach results in a multifaceted plasticity model where yield surfaces are automatically activated according to kinematic constraints, without the need for complex rules for selective activation of yield surfaces depending on applied stress and strain tensors. The interactions of inelastic deformations in different micro-planes are automatically captured through dependence on parameters such as the triaxial nature of stress. Another advantage is that this structure allows for the capture of fracture and damage with post-peak softening behavior. Since a micro-plane model is, in principle, a multifaceted plasticity model, it should be able to capture the peak effect. This effect is observed when an axially loaded ductile material suddenly bends while the axial load is kept constant. This load path is also called lateral loading with reference to the yield surface. During lateral loading, the material response is much less rigid than the elastic response, which still indicates that inelastic deformation is occurring. This situation cannot be explained by a single yield surface but requires the activation of multiple yield surfaces.

In order for the model to be presented in a way that includes micro effects, the previously developed M7 concrete micromaterial model in [6, 7] is used in the ABAQUS software. This model, having gone through various stages, is quite advanced and is known in the literature as the model that best reflects the behavior of concrete materials. For this model to be used in the software, the material must be introduced to the program correctly. Introducing the material as M7FCONCRETE and using USER MATERIAL is an important step. Also, since the model used includes micro-planes, the DEPVAR value must be entered as 189 to correctly introduce the parameters used in creating the material model to the program. All these steps are necessary adjustments for the M7 material model to work seamlessly with ABAQUS. The M7 micromaterial model is introduced to the program as a Subrotine file. The first analyses in this regard are aimed at determining that the material model works correctly in the program.

3 Results and Validation

Fig. 2 presents the distributions of the minimum principal stress obtained from the gap test analysis at different time steps. At the beginning of loading (t = 0.2 s), the compressive stresses are concentrated within a narrow and localized region along the loading axis. Stress concentration begins to develop at the tip of the existing notch. As the loading progresses (t = 0.4 and 0.6 s), the compressive stress field propagates into the specimen, the stress concentration at the notch tip becomes more pronounced, and higher compressive stresses accumulate around the crack tip. At t = 0.8 s, the compressive stress zone expands laterally around the crack, indicating that the applied load is transferred not only along the loading axis but also through the intact material surrounding the crack. At the final loading stage (t = 1.0 s), the compressive stresses spread over a wider region, resulting in a more uniform stress distribution and the load transfer is redistributed as crack propagation progresses. The symmetric stress distribution observed throughout all time steps confirms that the boundary conditions and contact definitions have been properly implemented. Furthermore, the compressive stresses acting parallel to the crack plane compress the crack faces, delaying crack propagation and consequently increasing the apparent fracture toughness of the material. These results successfully demonstrate the fundamental mechanism of the gap test.

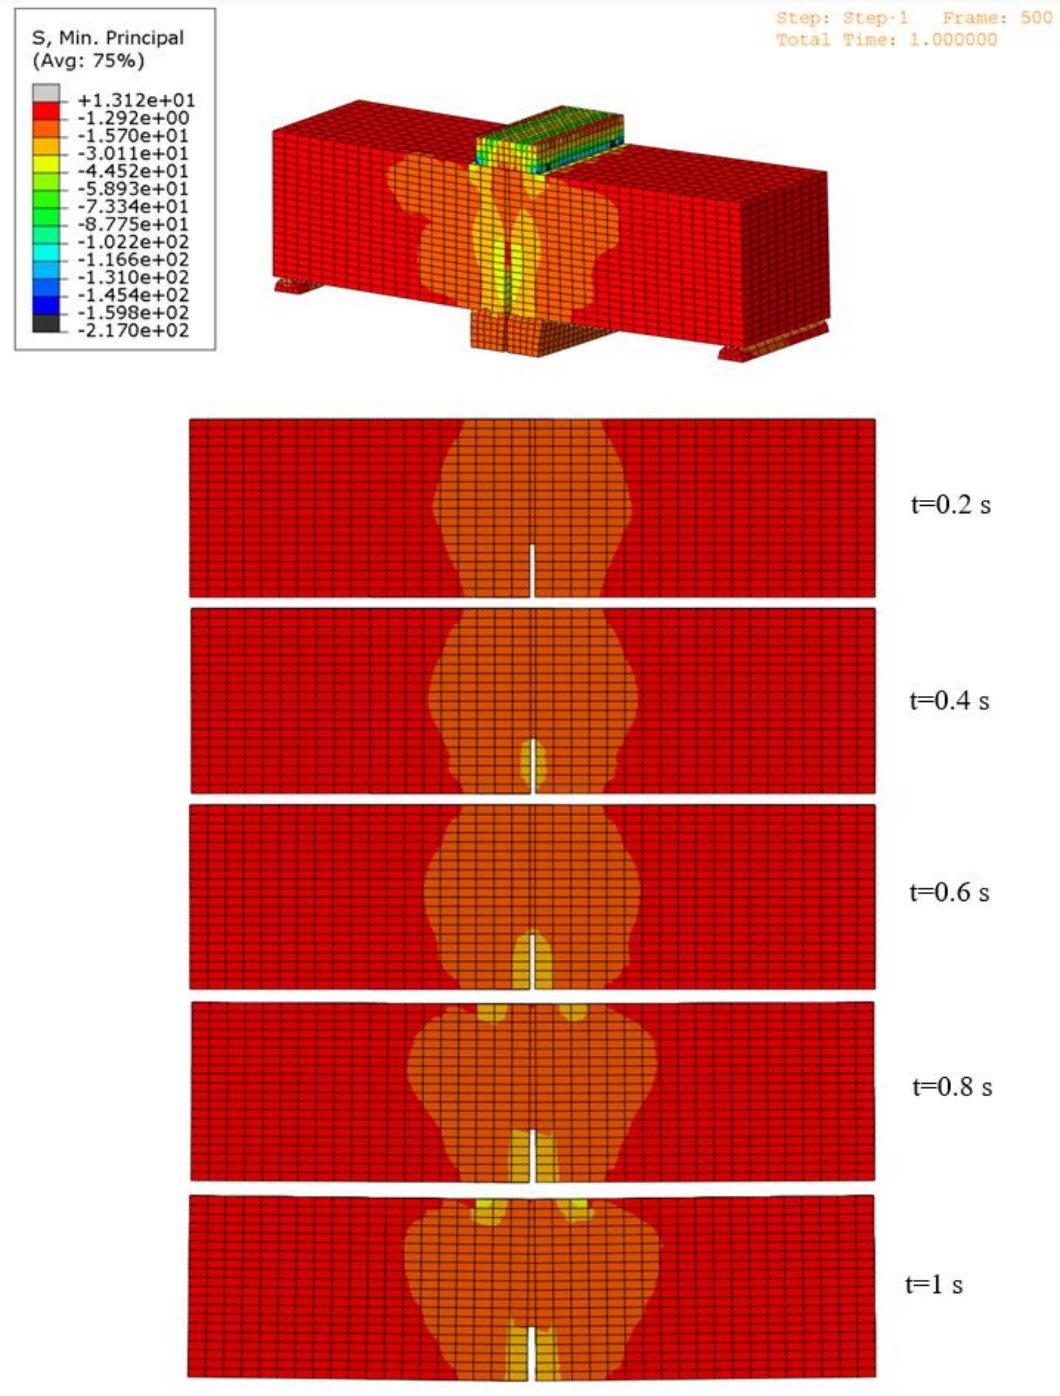

Fig. 2. Minimum principal stress distributions at different time steps of the gap test.

The load displacement curve in Fig. 3 shows that the applied load increases rapidly with displacement during the initial stage in a nonlinear manner. Between approximately 0 and 1 mm of displacement, the specimen exhibits high stiffness and predominantly elastic behavior. As loading continues, the slope of the curve gradually decreases while the load continues to increase, indicating that the specimen is still able to carry the applied load despite the initiation of microcracks within the material. After approximately 4 mm of displacement, several small load drops are observed, representing local damage events and stress redistribution associated with crack propagation. No significant loss of load carrying capacity occurs, and the load continues to increase until reaching approximately 41 kN. This behavior demonstrates that the compressive stresses acting parallel to the crack plane keep the crack faces closed, thereby preserving the load carrying capacity of the specimen.

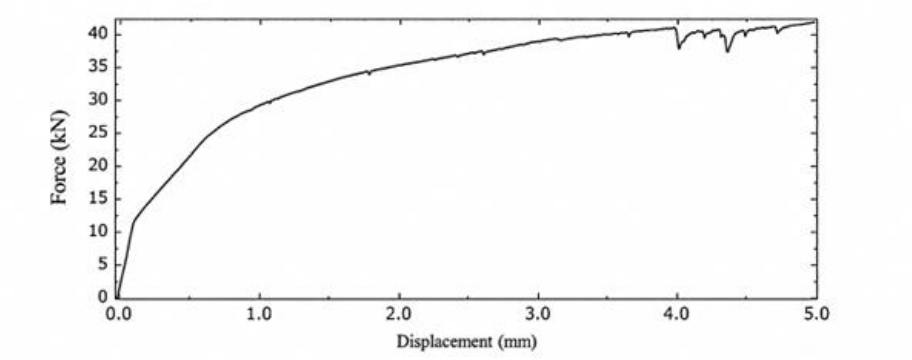

Fig. 3. Force-displacement graph at the end of the analysis.

The load and crack mouth opening displacement curve in Fig. 4 further indicates that crack opening remains relatively limited throughout the analysis. Although the crack mouth opening displacement reaches approximately 0.8 mm, the applied load remains nearly constant. The small oscillations and local load drops observed along the curve correspond to intermittent crack growth and progressive damage evolution at the crack tip. Overall, the combined interpretation of both curves demonstrates that the specimen undergoes a stable and controlled fracture process. The ability to obtain this behavior at advanced levels demonstrates the superiority of the M7 material model used in the model.

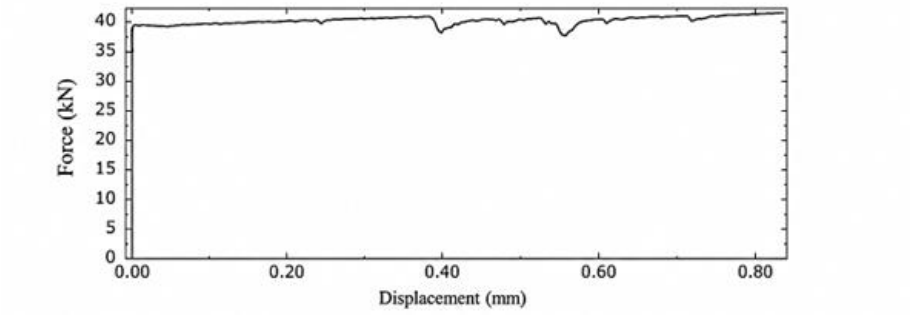

Fig. 4. Force and crack tip opening displacement graph.

4 Conclusion

In this study, the gap test is successfully analyzed by generating a three-dimensional finite element model using the M7 micro-plane damage model. To capture the effects of stresses parallel to the crack, it is necessary to model the fracture as a band in front of the crack and to use a micro-plane that can reproduce oriented microcracks or slips. Furthermore, loading should be applied gradually for accurate gap test results. Explicit dynamic analyses can be performed with the created model. A crack, by its nature, is not a line but a three-dimensional fracture zone. The three-dimensional model created in this study is found to be suitable for investigating real crack behavior. Model parameters can be calibrated for different materials and used in CPS analyses. Thanks to the effective use of the generated finite element models, it is possible to analyze the effects of stresses parallel to the crack, a crucial topic in fracture mechanics, on the fracture mechanisms of structures more accurately.

Abstract. This study presents a comprehensive investigation of the optimal sensor placement (OSP) problem for structural health monitoring (SHM) using a 17-member planar steel truss system. The primary objective is to examine the theoretical basis of OSP and to evaluate the influence of three modal assurance criterion (MAC)-based placement strategies, max-MAC, ave-MAC, and rms-MAC, on sensor configuration outcomes. This work focuses on understanding the behavior of MAC-based objective functions and their role in determining effective sensor locations. The structural model consists of 17 truss elements and 10 nodes arranged in a single plane, with translational degrees of freedom considered in both x and y directions. A MATLAB-based computational framework was developed to perform a complete combinatorial evaluation of all possible sensor configurations for varying sensor numbers. For each configuration, objective function values corresponding to the three MAC-based criteria were calculated, and the configurations minimizing modal correlation were identified as optimal. The results indicate that increasing the number of sensors consistently reduces the off-diagonal terms of the MAC matrix, leading to improved modal independence. While the three criteria generally yield different sensor placement patterns for lower sensor counts, their solutions tend to converge as the number of sensors increases. Furthermore, it is observed that configurations with very few sensors, particularly a single sensor, are insufficient to capture the modal characteristics of the system effectively. The study provides a clear and systematic framework for applying OSP techniques to planar truss systems and highlights the impact of different MAC-based criteria on sensor placement strategies.

Keywords: Optimal sensor placement; Structural health monitoring; Truss system; Modal assurance criterion.

1 Introduction

The construction sector occupies an important place in our lives, and a great variety of structures are continuously being built. However, construction alone is not sufficient; these structures must also be preserved and kept under control. Structural health monitoring (SHM) systems are being used with growing frequency in civil engineering to enable the safety and performance of structures to be monitored [1]. SHM is a method based on the continuous observation of a structure's dynamic behavior through sensors, allowing the early detection of damage caused by external effects such as temperature, earthquakes, traffic loads, and wind. The success of an SHM system depends to a large extent on the number and location of the sensors installed on the structure. Placing sensors at incorrect locations results in erroneous or incomplete data.

When too few sensors are used, data cannot be collected from some critical regions of the structure, problems within the system may go unnoticed for longer, and the early-warning capability of the system is weakened. On the other hand, using more sensors than necessary increases hardware, installation, maintenance, and data-processing costs, while the excessive volume of data generated complicates the processing and analysis procedures and hinders access to meaningful information. For this reason, determining the optimum number of sensors to be used in a structure and their most suitable locations stands out as optimum sensor placement (OSP) problem in the design of SHM systems [2].

Bridge-type structures occupy a particularly important place in OSP literature, given that they are among the most critical components of transportation infrastructure. In these structures, placing sensors in the correct number and at the correct locations plays a decisive role in reliably monitoring the structure's dynamic behavior and in detecting possible damage at an early stage. Accordingly, the literature contains a considerable number of OSP studies addressing different bridge types and scales. Sun and Büyüköztürk applied a discrete artificial bee colony algorithm, combined with a MAC-based objective function, to a 27-element truss bridge [3]. Working on the Nottingham Wilford suspension bridge, Meo and Zumpano compared several placement techniques, including effective independence, driving-point residue, and the eigenvalue vector product [4]. Studying the I-40 Bridge in Albuquerque, New Mexico, Li et al. compared the modal kinetic energy and effective independence methods and established the mathematical relationship between the two approaches [5]. Examining the historic Saint Francesco da Paola bridge in Italy, Quaranta et al. combined finite element modelling with various placement criteria to determine the minimum number of sensors required to represent the structure, verifying their results using the MAC criterion [6]. Chang and Pakzad proposed a framework based on a MAC-derived variance criterion and showed that this method achieved superior performance compared with other approaches on the Northampton Street Bridge and the Golden Gate Bridge [7]. Li et al further emphasized that, due to the limited number of sensors that can be used on suspension bridges, determining the optimal placement is of critical importance, four different placement methods were evaluated using criteria such as the Fisher information matrix, MAC, and condition number [8]. In more recent work, Kaveh et al. compared a Q-learning-based water strider algorithm (QWSA) with other metaheuristic methods on dome-truss structures [9]. Meng et al., for their part, proposed a deep-reinforcement-learning-based algorithm that uses the MAC criterion to evaluate the quality of sensor configurations, and demonstrated that this algorithm achieved more successful results than genetic algorithms and particle swarm optimization on a 10-story frame structure and the Haicang Bridge [10]. Chioccarelli et al. combined effective-independence-based sensor placement with modal analysis methods in ambient vibration tests of an existing bridge, accurately determining the bridge's natural frequencies and mode shapes using a minimal number of accelerometers [11].

Prior research in this area has predominantly emphasized algorithmic performance, leaving the underlying theoretical basis of the OSP problem comparatively underexplored. Rather than deploying an optimization algorithm, this study instead sets out to clarify the basic reasoning behind the OSP problem and to illustrate, through a straightforward example, how different placement criteria influence the outcome. A further goal is to provide the literature with an instructive, easily interpretable reference model that can support future optimization-based research. To this end, a 17-member planar steel truss bridge is adopted as the test structure, and three MAC-derived criteria, max-MAC, ave-MAC, and rms-MAC, are used to guide sensor placement. A MATLAB [12] code exhaustively evaluated every feasible sensor combination, identifying the optimum configuration under each of the three criteria.

2 Structural Model Description

The 17-member planar steel truss bridge is a truss bridge model consisting of 17 bars and 10 nodal points located in the same plane [13]. In this system, the translational degrees of freedom in the x and y directions are taken into account. In the model shown in *Fig. 1*, node 6 is held by a fixed support and therefore does not possess any degree of freedom. Node 10, on the other hand, is fitted with a roller support, so only its degree of freedom in the y-direction is restrained. Overall, the system has a total of 17 degrees of freedom, 9 of which are in the x-direction and 8 of which are in the y-direction. Within the scope of the OSP problem, the three MAC-based functions were employed for this simple system with the aim of identifying the most suitable sensor locations for different numbers of sensors. A program developed in MATLAB was used to obtain the best solution among all possible combinations.

For all elements in the system, the cross-sectional area is A = 10 in², the modulus of elasticity is E = 30×10⁶ lb/in², the mass per unit length is $\bar{m}$ = 0.1 lb·sec²/in², and the element length is L = 60 in.

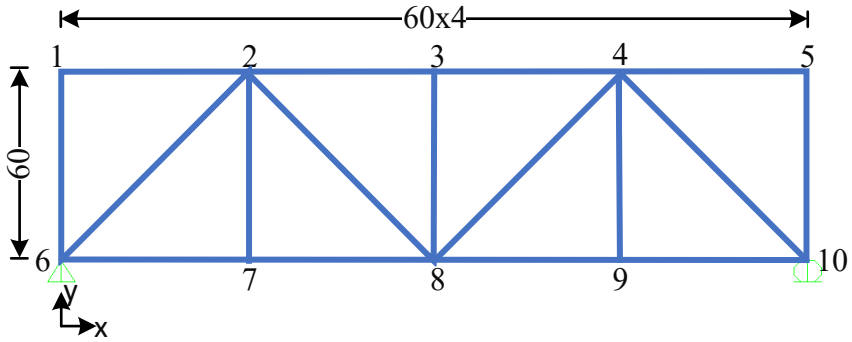

Fig. 1. 17-member planar steel truss bridge.

3 Methodology

To identify the most appropriate degrees of freedom (DOFs) for sensor placement, this study relies on the Modal Assurance Criterion (MAC), a widely used index for quantifying the correspondence between two mode shapes [14]. The MAC value ranges from 0 to 1: values approaching unity indicate that the compared modes are nearly identical, while values close to zero denote modes that are essentially independent of one another. From a sensor-placement standpoint, the underlying goal is to minimize the resemblance among mode shapes so that the selected measurement locations can capture the structure's modal information as distinctly as possible. The MAC between two mode-shape vectors, Φ_i and Φ_j, is defined as

$$MAC_{ij} = \frac{(\Phi_i^T \Phi_j)^2}{(\Phi_i^T \Phi_i)(\Phi_j^T \Phi_j)} \tag{1}$$

where the subscripts i and j denote the corresponding column vectors of the modes being compared.

Three objective functions related to the Modal Assurance Criterion were employed for sensor placement. The first is the max-MAC method, which aims to minimize the maximum similarity between mode shapes by considering the largest value among the off-diagonal elements of the MAC matrix. In this way, the max-MAC method seeks to maximize the independence of the mode-shape vectors throughout the optimization process. The second objective function minimizes the average of all off-diagonal MAC elements, thereby reducing the overall degree of correlation among the mode shapes. The third objective function computes the root-mean-square (rms) of the off-diagonal elements of the MAC matrix. This formulation

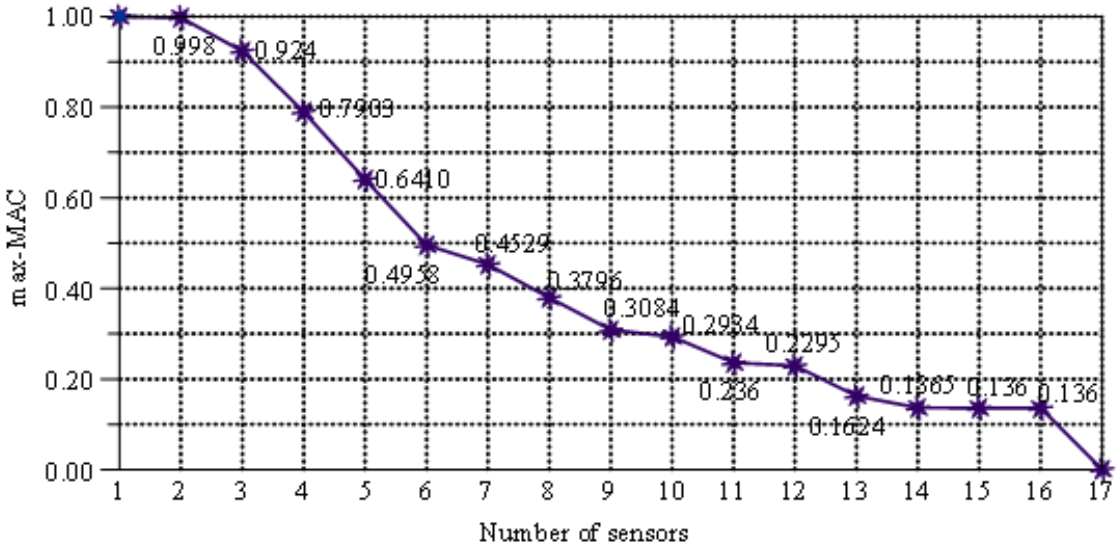
is used to quantify the overall level of inter-modal dependence, with a lower rms value indicating greater independence among the modes. Because each formulation weighs modal correlation differently, comparing all three enables the most effective sensor locations to be identified from complementary perspectives. The mathematical formulations of the max-MAC, ave-MAC, and rms-MAC methods are given in Eqs. (2), (3), and (4), respectively.

$$f_a(x) = max\{MAC_{ij}(x)\} \quad i \neq j \tag{2}$$

$$f_b(x) = ave\{MAC_{ij}\} = \frac{1}{mode(mode-1)} \sum_{i=1}^{mode} \sum_{j=1}^{mode} (MAC_{ij}) \quad i \neq j, j \neq i \tag{3}$$

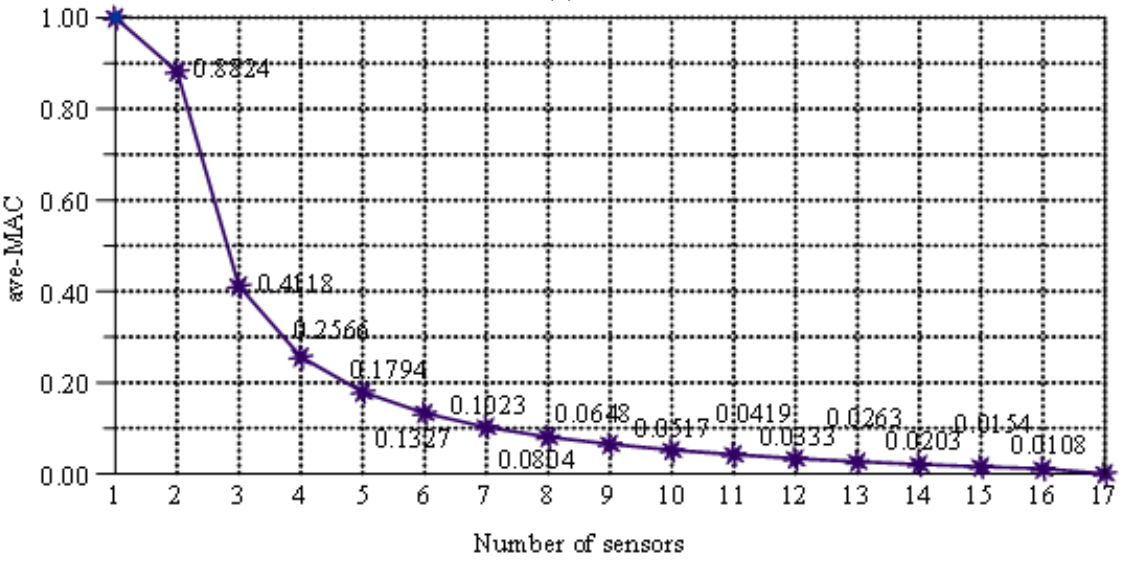
$$f_c(x) = rms\{MAC_{ij}\} = \sqrt{\frac{1}{mode(mode-1)} \sum_{i=1}^{mode} \sum_{j=1}^{mode} (MAC_{ij})^2} \quad i \neq j, j \neq i \tag{4}$$

The primary aim of this study is to demonstrate the underlying theory of the optimum sensor placement problem on a simple structural system. For this purpose, rather than relying on an optimization algorithm, a MATLAB code was developed that exhaustively evaluates all possible sensor combinations for each objective function and identifies the configuration yielding the best value along with its corresponding objective-function result. This exhaustive search procedure was repeated separately for each of the three objective functions: max-MAC, ave-MAC, and rms-MAC. For every objective function, the number of sensors increased incrementally from 1 up to the total number of degrees of freedom of the structure; since the system considered in this study has 17 degrees of freedom, sensor numbers ranging from 1 to 17 were examined. For each sensor count, the optimal sensor configuration and its associated objective-function value were determined according to the criterion being evaluated.



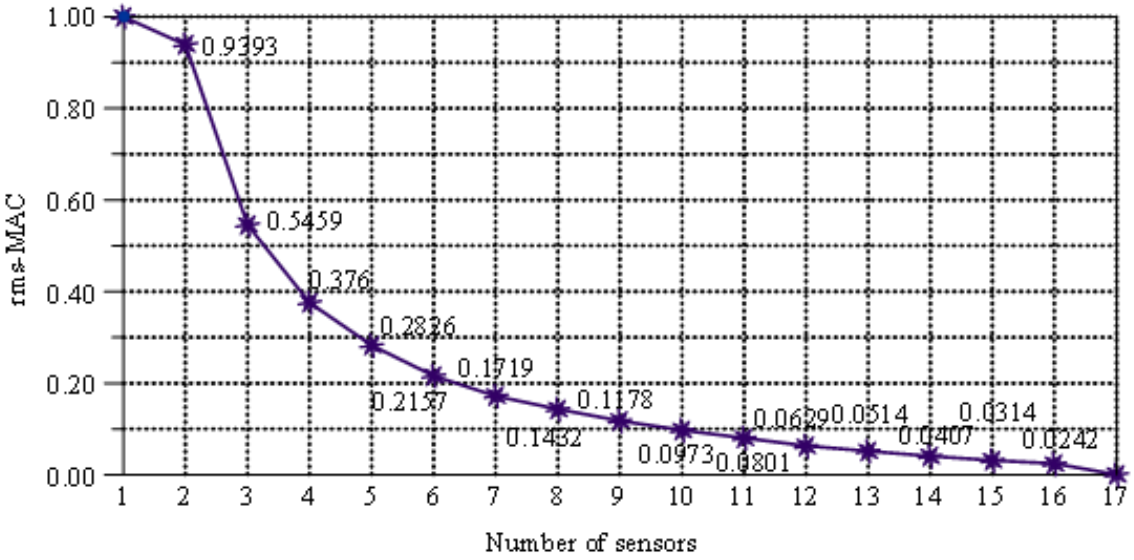
4 Numerical Results

Since the 17-member planar steel truss bridge system possesses 17 degrees of freedom, its modal analysis yields a total of 17 mode shapes; in this study, all of these modes were taken into account without any reduction, so as to fully capture the dynamic behavior of the structure. In this context, the objective function of the max-MAC method defined in Eq. (2), $f_a(x)$, was used to minimize the largest off-diagonal value of the MAC matrix. Analyses performed for different numbers of sensors revealed that the largest off-diagonal value of the MAC matrix decreases as the number of sensors increases. This indicates that a denser distribution of sensors enhances modal independence and improves monitoring capability. The variation in the max-MAC value with respect to different numbers of sensors is presented in *Fig. 2(a)*.



In addition, using the objective function of the ave-MAC method given in Eq. (3), $f_b(x)$, the sensor combinations that minimize the average of the off-diagonal values of the MAC matrix for different numbers of sensors were determined. The analyses showed that the average of the off-diagonal values of the MAC matrix decreases as the number of sensors increases. This finding reveals that modal measurement sensitivity improves as sensor density increases. The variation in the ave-MAC value with respect to different numbers of sensors is shown in *Fig. 2(b)*.

Finally, using the objective function of the rms-MAC method defined in Eq. (4), $f_c(x)$, the sensor combinations that minimize the root-mean-square of the off-diagonal values of the MAC matrix were examined. The analyses demonstrated that the rms-MAC value decreases as the number of sensors increases and that modal independence is markedly improved. The variation in the rms-MAC value with respect to different numbers of sensors is presented in *Fig. 2(c)*. Collectively, these analyses clearly demonstrate the effect of sensor number on modal analysis and the contribution of different MAC-based approaches to sensor placement.



When only a single sensor is placed on the system, 17 different combinations arise, and in every case the largest off-diagonal value of the MAC matrix is equal to 1. This result shows that a single sensor is insufficient to ensure the independence of the mode-shape vectors. It was observed that more meaningful and reliable results can be obtained as the number of sensors is increased. However, once two or more sensors are placed on the system, the number of possible combinations grows substantially, making the identification of the best sensor arrangement a considerably more complex problem.

(b)

(c)

Fig. 2. Convergence of objective functions at different sensor numbers: (a) max-MAC, (b) ave-MAC, and (c) rms-MAC.

The optimal sensor configurations obtained for all three objective functions, together with their corresponding max-MAC, ave-MAC, and rms-MAC values for each sensor count, are summarized in *Table 1*. These results once again demonstrate that sensor placement plays a critical role in the success of modal monitoring processes in bridge systems, and that different formulations can lead to markedly different optimization outcomes. The overall results presented in *Table 1* show that, as the number of sensors increases, the objective-function value of each method decreases steadily and modal independence improves. In particular, it was observed that as the number of sensors increases, the sensor locations recommended by the max-MAC, ave-MAC, and rms-MAC methods converge to a greater number of common points. This indicates that although method-dependent differences in sensor placement are pronounced at low sensor densities, these differences diminish as sensor density increases. As a representative example, the optimal sensor configurations obtained for a five-sensor arrangement under each of the three criteria are illustrated in *Fig. 3*.

Although the fundamental objective of each method is to increase the linear independence among the mode-shape vectors, the proposed sensor placements were found to vary due to differences in the strategies employed. This finding indicates that the choice of sensor placement method should be made in accordance with the dynamic characteristics of the structure and the intended monitoring objective. Accordingly, the careful selection of sensor placement strategies in SHM systems is of critical importance for obtaining reliable and effective results.

5 Conclusion

This study presents a numerical example developed to explain the working principle of the optimum sensor placement (OSP) problem and to compare how different placement criteria influence the resulting sensor configurations. A 17-member planar steel truss bridge served as the test structure for demonstrating the OSP procedure on a simple, easily interpretable system. Three MAC-derived criteria, max-MAC, ave-MAC, and rms-MAC, were applied to identify the most suitable degrees of freedom for sensor installation. A dedicated MATLAB code exhaustively searched every feasible sensor arrangement for sensor counts between 1 and 17, reporting the best configuration obtained under each criterion.

- A configuration with only one sensor cannot guarantee independence among the mode-shape vectors; consequently, the off-diagonal MAC value remains equal to 1 in every case.
- As additional sensors were introduced, the objective-function value associated with each of the three criteria declined steadily, reflecting a growing degree of linear independence among the mode shapes.
- Although the three criteria typically point to different sensor arrangements when the sensor count is fixed, their recommended locations increasingly overlap once the number of sensors becomes sufficiently large.
- Because max-MAC, ave-MAC, and rms-MAC rely on distinct mathematical formulations, each pursuing linear independence in a different way, the sensor layouts they propose are not identical even though they share the same underlying objective.

Abstract. This study comparatively investigates the seismic and environmental performance of a four-story reinforced concrete structure using conventional concrete and a geopolymer concrete mixture designated GPCM8, both with the same compressive strength. In both models, the story plan, number of stories, structural system arrangement, cross-sectional dimensions, and loading conditions were kept constant; thus, only the effect of the material type on the structural behaviour was evaluated. The seismic performance of the structures was determined using the response spectrum analysis method, in accordance with the Turkish Building Earthquake Code (TBEC 2018). Due to its lower modulus of elasticity, the GPCM8 model exhibited 16.80% longer natural vibration periods, 13.92% lower base shear, and 16.09% greater roof displacement than the C30/37 model. Additionally, there was an approximately 16% increase in interstory drift and story displacements, suggesting greater deformation demands. Nevertheless, GPCM8 reduced carbon emissions by approximately 37.6%. The findings indicate that GPCM8 geopolymer concrete is a sustainable and promising alternative to conventional concrete. Nevertheless, in structural design, the modulus of elasticity and the corresponding displacement demands must be considered in addition to compressive strength. It is determined that GPCM8 concrete can offer adequate seismic performance in reinforced concrete structures when designed appropriately, taking these parameters into consideration.

Keywords: Geopolymer concrete; Seismic performance; Environmental performance; Sustainability

1 Introduction

Concrete's high compressive strength, broad availability, and low production cost make it one of the most popular building materials in the construction sector. However, substantial energy consumption and CO_2 emissions are produced during the manufacture of Portland cement, the primary binder in ordinary concrete. These emissions are caused by the direct release of CO_2 during the calcination of limestone as well as by manufacturing activities such as the processing and transportation of raw materials, the use of fossil fuels to reach high temperatures, and the usage of electricity [1]. In fact, producing one ton of cement is thought to release roughly the same amount of CO_2 into the environment. Reducing the environmental impact of cement-based concrete manufacturing has become a crucial demand for a sustainable construction sector, given that global carbon emissions reached 36.8 billion tons in 2023 and that cement production accounts for about 7–8% of these emissions [2]. Thus, geopolymer concrete (GPC) stands out as a substitute binder system made by reacting industrial byproducts

such as fly ash (FA), blast furnace slag (BFS), and metakaolin, which have high concentrations of silica and alumina, with alkali activators, in place of Portland cement (PC) [3, 4]. This approach reduces the environmental impact of concrete by limiting PC use [5].

The mechanical properties of geopolymer concretes are substantially influenced by the mix design, curing conditions, alkali activator type and concentration, and the ratio of FA and granulated BFS used. The compressive strength and elasticity modulus of GPC containing FA and granulated BFS were experimentally investigated by Bellum et al. (2020) [3]. The results showed that at the same 28-day compressive strength level, the modulus of elasticity of GPC was approximately 15–28% lower compared to PC concrete. Moreover, Nath and Sarker (2017) [6] compared ordinary PC concrete and low-calcium FA-based GPC cured at ambient temperature. They found that the modulus of elasticity of the GPC was approximately 25–30% lower at the same compressive strength level. Similar results were obtained in the experimental study conducted by Liu et al. (2022) [7] on GPC with a triple binder system produced using BFS, FA, and zeolite powder; it was reported that the modulus of elasticity of GPC was 25.8% lower than that of ordinary PC concrete with the same compressive strength. These investigations indicate that GPCs may exhibit a lower modulus of elasticity than conventional concrete (CC), despite attaining comparable compressive strengths. This distinction should be considered when assessing the material's dynamic behaviour and structural rigidity.

Using concretes with different modulus of elasticity at the same compressive strength level can affect seismic behaviour parameters such as stiffness, natural vibration period, base shear force, story displacements, and relative story drift ratios at the structural scale. The literature indicates that changes in concrete stiffness and strength affect the dynamic seismic behaviour of reinforced concrete (RC) frame structures, and that structural stiffness is a determining factor in the natural vibration period and seismic demands [8, 9]. Therefore, for GPC to be considered an alternative to CC, it needs to be examined not only in terms of compressive strength and environmental sustainability but also in terms of seismic performance [10]. Studies on the mechanical properties of GPC and the behaviour of RC elements show that the bending and shear behaviour of GPC beams is generally comparable to that of conventional PC-concrete beams [11, 12].

Regarding column behaviour, several studies have investigated the effects of parameters such as axial load, fiber reinforcement, reinforcement type, and confinement effect on the load-carrying capacity and damage evolution of geopolymer RC columns [13, 14]. In addition, the behaviour of beam-column connections, a critical area under earthquake effects, under reversible cyclic loads has been investigated; in these studies, seismic performance indicators such as load-carrying capacity, stiffness reduction, ductility, energy dissipation, and damage mechanisms have been evaluated [15, 16]. However, a significant portion of current studies remains limited to the material level, individual RC elements, or beam-column connection regions. Although research evaluating the potential of GPC in terms of seismic resistance has accelerated in recent years, it is emphasized that studies conducted at the structural scale are still limited [10, 17].

The limited number of studies comparing RC structures modelled with CC and GPC, both at the same compressive strength level, in terms of natural vibration period, base shear force, story displacements, and relative story drift ratios using regulation-based dynamic analysis methods constitutes a significant gap in the literature. Therefore, GPC needs to be evaluated not only in terms of compressive strength, durability, and sustainability, but also in terms of its effects on structural rigidity and global structural behaviour under seismic influence. This study comparatively investigates the seismic behavior of a four-story regular RC structure designed using CC and GPC with the same compressive strength level. The reference model was created based on C30/37, while the alternative model utilized the experimental material properties of the M8 geopolymer concrete (GPCM8) mix given by Bellum et al. [3]. In both models, the story

plan, story number, structural system arrangement, cross-sectional dimensions, loading conditions, and unit weight were kept the same; thus, the effect of the change in elasticity modulus on the structural behavior was evaluated. In addition, the potential of GPC in terms of environmental sustainability was discussed, as it reduces the use of PC and allows for the utilization of industrial by-products such as FA and BFS.

2 Materials and Methods

This study comparatively investigates the seismic behaviour of a four-story RC structure modelled using CC and GPC with the same compressive strength. To enable comparison solely based on concrete type, the story plan, story height, structural system arrangement, element cross-sections, reinforcement properties, boundary conditions, and loading conditions were kept identical in both structural models. The C30/37 concrete class was employed as the CC. For the GPC model, the cube compressive strength of the M8 mixture, as described in the study by Bellum et al. (2020) [3], was considered and referred to as GPCM8. Furthermore, the environmental impacts of producing both concrete types were comparatively evaluated using CO_2-equivalent emissions.

2.1 Structural Model Characteristics

The structure under investigation is designed as a regular four-story RC frame system in plan. The story height is 3 m, and the total building height is 12 m. The building plan measures 12 m x 12 m, and the load-bearing system consists of RC columns and beams in both directions. Column cross-sections are 40 cm x 40 cm, beam cross-sections are 25 cm x 50 cm, and the slab thickness is 15 cm. Column and beam elements are modelled with bar elements. It is assumed that the floor slabs have sufficient rigidity within their own planes, and rigid diaphragms are defined at the story levels. The column supports at the foundation level are considered fixed. The story plan and 3D view of the building model are shown in Fig. 1. The SAP2000 [18] finite element analysis program was used to create the structural models and perform the analyses.

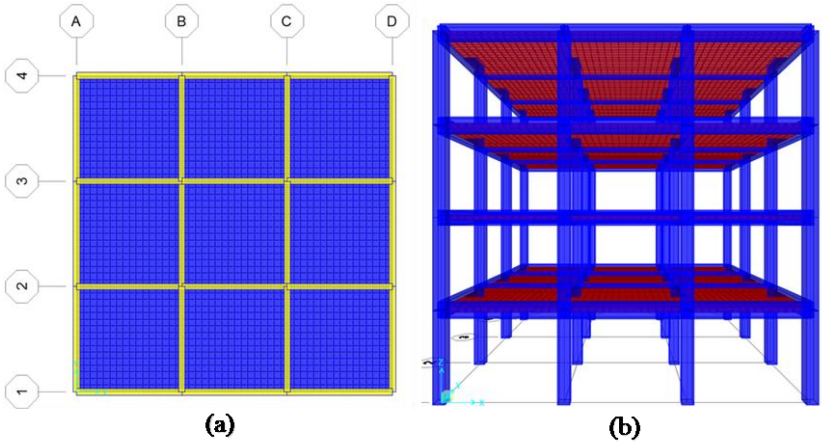

Fig. 1. (a) Story plan and (b) 3D view of the building model.

The behavior of buildings under seismic effects was investigated using the Response Spectrum Analysis (RSA) method, applied in accordance with the provisions of the 2018 Turkish Building Earthquake Code (TBEC 2018) [19].

2.2 Material Properties

In the reference structural model, CC with a characteristic cylinder compressive strength of 30 MPa was used. In the GPC model, the material properties of the M8 mix, experimentally

investigated by Bellum et al. (2020) [3], were used as the basis. The 28-day cube compressive strength of this mix is 38.25 MPa, which is quite close to the characteristic cube compressive strength of 37 MPa defined for the C30/37 concrete class. Therefore, it was assumed that the M8 mix has approximately the same compressive strength as C30/37, and an equivalent cylinder compressive strength of 30 MPa was adopted for the GPC in the structural analysis. Thus, the two concrete types were compared at nominally similar compressive strength levels. For both concrete types, the unit volume mass was accepted as 2392 kg/m³, as reported by Bellum et al. for the M8 mix. The corresponding unit volume weight was calculated to be 23.47 kN/m³, using a gravitational acceleration of 9.81 m/s². Although the compressive strength of the concrete was kept constant in both models, the modulus of elasticity of CC and GPC was defined separately. The modulus of elasticity of CC was calculated using Equation 1 according to ACI318-19 [20], while the modulus of elasticity of GPC was obtained from the results of the reference experimental mixture. Thus, in both structural models, the geometry, loading conditions, and structural weight were held constant, and the concrete types were assumed to have approximately equivalent compressive strength levels. This approach aimed to determine the effect of differences in material properties, primarily the modulus of elasticity, on the structure's natural vibration periods, displacements, and internal force demands.

$$E_c = {w_c}^{1.5} 0.043 \sqrt{f_c'} \quad (1)$$

Here, $E_c$represents the modulus of elasticity of concrete (MPa); w_c represents the unit volume mass of concrete (kg/m³); and f_c' represents the cylinder compressive strength (MPa) used in the design.

The necessary mechanical properties of the concrete materials used are presented in Table 1.

Table 1. Properties of the concrete used in the building model.

Material property	**C30/37**	**GPCM8**
Concrete cylinder compressive strength (MPa)	30	30
Modulus of Elasticity of Concrete (GPa)	27.553	20.196
Unit Weight (kN/m³)	23.47	23.47
Poisson's Ratio	0.20	0.20
Reinforcement Yield Strength (MPa)	420	420
Modulus of Elasticity of Reinforcement (GPa)	200	200

2.3 Load Definition

The dead and live loads acting on the structure were determined by considering the relevant load standards and intended use. Dead loads due to floor finish layers, partition walls, and other non-structural elements were modelled as equivalent uniformly distributed loads. An additional dead load of 2.00 kN/m² and a live load of 2.00 kN/m² were applied to the floor slabs. The weights of the infill and partition walls in the structure were modelled as uniformly distributed loads acting on the beams. A wall load of 6.00 kN/m was applied to the frame beams where the exterior walls are located, and a wall load of 4.00 kN/m was applied to the interior beams where the interior partition walls are located. The same load values and loading arrangement were used in both structural models. The mass source used in the seismic analysis of the analysis model was created as in Equation (2), based on the sum of all dead loads and 30% of the live loads.

$$M = G + 0.30Q \quad (2)$$

Here, G represents the dead loads, while Q represents the live loads. The live-load participation factor of 0.30 used for the mass source was determined based on the structure's intended use

and the provisions of TBEC 2018 [19]. The analysis results from the structural models developed for conventional C30/37 and GPCM8 were evaluated under the G + Q + E load combination, which considers gravity loads and seismic effects simultaneously.

2.4 Definition of Earthquake Effects

The seismic behaviour of the structures was determined using the RSA method in accordance with the TBEC 2018 [19]. The seismic parameters used in the analyses were determined assuming that the buildings are located in Pazarcık district of Kahramanmaraş province and are presented in Table 2.

Table 2. Earthquake parameters.

Parameters	**Assumptions**
Earthquake ground motion level	DD-2
Soil class	ZC
Peak ground acceleration (PGA)	0.477 g
Peak ground velocity (PGV)	32.487 cm/s
Latitude of the region	37.489371°
Longitude of the region	37.229512°

Seismic effects were applied separately along the two orthogonal principal directions of the structure. In the modal analysis, a sufficient number of vibration modes were included to achieve a cumulative effective modal mass participation ratio of at least 95% in each horizontal direction. The Complete Quadratic Combination (CQC) method was used to combine the modal responses. Since the two systems have the same number of spans, the same axis spacing, identical cross-sections, and symmetrical placement of structural elements in the X and Y directions, comparative evaluations were conducted using the global X-direction U1 (UX) responses. The effects of concrete type-dependent variations in the modulus of elasticity on the seismic behaviour of the structure were evaluated by comparing the natural vibration periods, horizontal displacements, interstory drifts, base shear forces, and internal force demands obtained from the response spectrum analyses of the C30/37 and GPCM8 models.

2.5 Environmental Assessment Methodology

The environmental impacts of CC and GPC were compared based on estimated carbon emissions. The assessment was conducted for 1 m^3 of concrete encompassing all processes from raw material extraction and processing through concrete production. The calculations considered the amounts of binder, aggregate, water, and alkali activator. The amount of each concrete component in 1 m^3 of mix was multiplied by the relevant unit emission factor obtained from the literature; the total carbon emission was determined by summing the emission values calculated for all components. The unit emission factors used in the calculations were taken from the study conducted by Tushar et al (2025) [5]. The mix components and component amounts of the geopolymer concrete were determined based on the M8 mix developed by Bellum et al. (2020) [3]. The CC mix was formulated to represent the C30/37 concrete class, with a water/cement ratio of 0.45. This value was chosen based on the maximum water/binder ratio limits specified in ACI 318-19 [20] for certain environmental exposure classes.

In order to keep the effect of aggregate quantity and total unit volume mass constant in the comparison, the unit volume mass of the C30/37 reference concrete was assumed to be equal to the experimentally reported value of 2392 kg/m^3 for the GPCM8 mix. Similarly, the amounts of fine and coarse aggregate in the C30/37 mix were determined as 610 and 1221.5 kg/m^3, respectively, based on the values reported in the M8 mix developed by Bellum et al. Thus, the total aggregate amount became 1831.5 kg/m^3, and the total amount of cement and water to reach

the target unit volume mass was calculated as 560.5 kg/m³. Assuming a water/cement ratio (W/C) of 0.45, the amounts of cement and water were calculated as approximately 386.6 kg/m³ and 174.0 kg/m³, respectively, from Equation (3) and Equation (4). This mixture is a reference mix, not an experimental concrete mix design, intended to consistently determine material quantities in environmental comparisons. Emissions from transportation distances and on-site applications were treated as the same for both concrete types and were excluded from the comparison.

$$W = 0.45C \quad (3)$$

$$C + W = 560.5 \quad (4)$$

3 Results and Discussion

This section comparatively evaluates the modal analysis, RSA, and approximate carbon emission results obtained from four-story reinforced concrete frame models constructed using C30/37 and GPCM8. In both structural models, the plan geometry, load-bearing element cross-sections, reinforcement properties, loads, mass source, boundary conditions, and seismic parameters were held constant. In addition, the compressive strength and unit weight of the two concrete types were assumed to be identical. Therefore, the differences observed in the structural analysis results can primarily be attributed to the variation in the modulus of elasticity between C30/37 and GPCM8.

3.1 Natural Vibration Periods

Modal analysis showed that the first two periods were 0.740105 s for C30/37 and 0.864455 s for GPCM8, while the third periods were 0.619974 s and 0.724141 s, respectively (Table 3).

Table 3. Fundamental periods of the structure.

Models	**T_1 (s)**	**T_2 (s)**	**T_3 (s)**
C30/37	0.740105	0.740105	0.619974
GPCM8	0.864455	0.864455	0.724141
Relative change (%)	+16.80	+16.80	+16.80

The first three natural vibration periods of the GPCM8 model were approximately 16.80% longer than those of the C30/37 model. Since the mass and geometric properties of the structure were kept constant, this increase was primarily attributed to the GPCM8 model's lower lateral stiffness, resulting from the lower modulus of elasticity of GPC. Specifically, the elasticity modulus of GPCM8 was approximately 26.70% lower than that of C30/37, thereby reducing overall structural stiffness and consequently increasing the natural vibration periods. The fact that the first and second mode periods are equal in both models can be explained by the structure having equal spans in the X and Y directions, the same cross-sectional properties, and symmetrical placement of structural elements. This result indicates that the structure exhibits similar dynamic characteristics in the two principal horizontal directions.

3.2 Base Shear and Roof Displacement

The base shear and roof displacement values in the X direction obtained from the response spectrum analysis of the structures are compared in Table 4.

Table 4. Comparison of analysis results in the X direction.

Models	**Base shear (kN)**	**Roof displacement (mm)**
C30/37	490.738	13.415
GPCM8	422.420	15.574
Relative change (%)	−13.92	+16.09

In the C30/37 model, the base shear was calculated to be 490.738 kN, whereas in the GPCM8 model, it was 422.420 kN. Accordingly, the base shear of the GPCM8 model is approximately 13.92% lower than that of the C30/37 model.

The fundamental structural periods of both models are located in the region of decreasing spectral acceleration, between the corner period (TB) of 0.328 s and the long period (TL) of 6.00 s in the design spectrum used. In this region, the spectral acceleration decreases with increasing period. The lower modulus of elasticity of GPCM8 has extended the fundamental structural period, resulting in a lower spectral acceleration ordinate. The decrease in base shear is consistent with this spectral change.

The roof displacement in the C30/37 model was 13.415 mm. In the GPCM8 model, the roof displacement was calculated as 15.574 mm. The roof displacement of the GPCM8 model is approximately 16.09% higher than that of the C30/37 model. This increase can be explained by the GPCM8 model's lower horizontal rigidity and longer natural vibration period.

3.3 Story Displacement and Interstory Drift

Table 5 and Fig. 2 show that, in both structural models, the story displacements increase linearly with height. The largest displacement values were obtained on the fourth story, at 13.415 mm and 15.574 mm for the C30/37 and GPCM8 models, respectively.

Table 5. Story displacement and interstory drift values of the structures in the X direction.

Story	Story Displacement (mm)		Interstory Drift (mm)	
	C30/37	GPCM8	C30/37	GPCM8
1	3.298	3.850	3.298	3.850
2	7.734	8.988	4.436	5.138
3	11.246	13.053	3.512	4.065
4	13.415	15.574	2.169	2.521

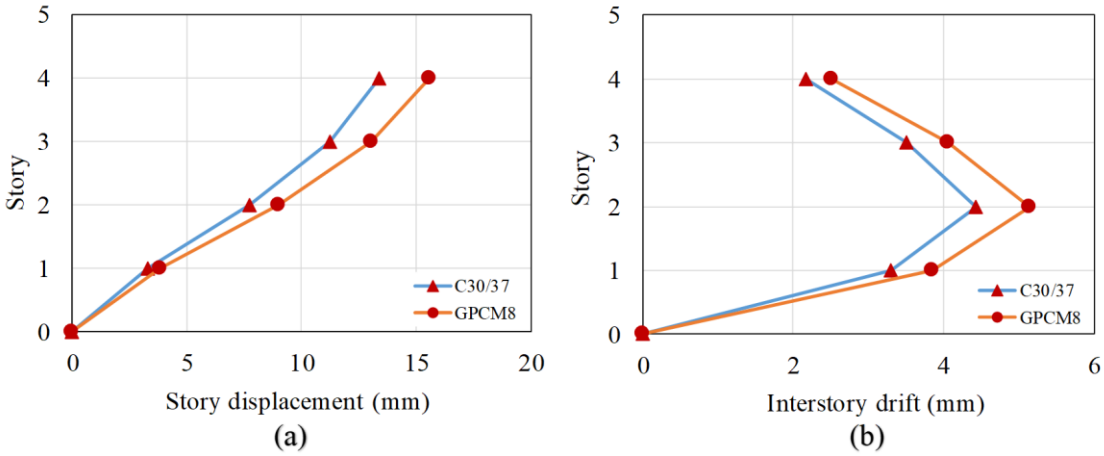

Fig. 2. (a) Story displacement and (b) interstory drift of the structures in the X direction.

The peak displacement of the GPCM8 model is approximately 16.09% higher than that of the C30/37 model. Similarly, the story displacements in the GPCM8 model are approximately 16.07%–16.74% greater than those in the C30/37 model at all stories. Interstory displacements reached their maximum value on the second story in both models; calculated as 4.436 mm and 5,138 mm for the C30/37 and GPCM8 models, respectively. After the second story, interstory displacements decrease with height along the structure. Interstory displacements in the GPCM8 model are approximately 15.75%–16.74% higher than in the C30/37 model across all stories.

These results can be explained by the lower elastic modulus of GPCM8, which leads to reduced horizontal rigidity and greater displacement demands under seismic loading.

3.4 Comparison of Carbon Emissions

A comparison of CO_2-eq emissions for C30/37 and GPCM8 is given in Table x. The total CO_2-eq emissions for the C30/37 and GPCM8 mixtures were calculated to be 365.90 and 228.46 kg CO_2-eq/m³, respectively. Accordingly, the GPCM8 mixture produced approximately 37.6% lower CO_2-eq emissions than the C30/37 concrete.

Table 6. Mix proportions and CO_2-equivalent emissions of concrete mixtures.

Component	**Emission factor (kg CO_2-eq/kg component)**	**C30/37 content (kg/m³)**	**C30/37 emission (kg CO_2-eq/m³)**	**GPCM8 content (kg/m³)**	**GPCM8 emission (kg CO_2-eq/m³)**
Portland cement	0.901	386.6	348.33	-	-
Fly ash	0.0277	-	-	122.10	3.38
GGBS	0.0613	-	-	284.90	17.46
Water	0.0010	174.0	0.17	-	-
Sodium hydroxide (NaOH)	1.8224	-	-	46.51	84.76
Sodium silicate (Na_2SiO_3)	0.9068	-	-	116.29	105.45
Fine aggregate	0.0031	610.0	1.89	610.00	1.89
Coarse aggregate	0.0127	1221.5	15.51	1221.50	15.51
Total CO_2-eq emission		-	365.90	-	228.46

Approximately 95.2% of the total emissions in CC result from Portland cement. While the use of fly ash and GGBS in the GPCM8 mix reduced binder-related emissions, alkali activators were the primary source of emissions. The total emission contribution of sodium silicate and sodium hydroxide was 190.21 kg CO_2-eq/m³, accounting for approximately 83.3% of GPCM8's total emissions. Since the amounts of fine and coarse aggregates were kept the same in both mixes, emissions from aggregates did not affect the comparison result. Therefore, it appears that the emission reduction in GPCM8 is primarily due to the absence of Portland cement, but the high emissions from alkali activators partially offset this advantage.

4 Conclusion

This study compares the seismic behaviour and approximate carbon emissions of four-story reinforced concrete structures modelled using C30/37 and GPCM8, both with the same compressive strength and unit weight.

The approximately 26.70% lower modulus of elasticity of GPCM8 compared with C30/37 resulted in a reduction in structural stiffness and an approximately 16.80% increase in the first three natural vibration periods. Consistent with this increase in the vibration periods, the base shear of the GPCM8 model decreased by 13.92%, while the roof displacement increased by 16.09%.

Story displacements increased progressively with height in both models, while the maximum interstory displacement occurred at the second story. In the GPCM8 model, story displacements were approximately 16.07%–16.74% higher and interstory displacements were 15.75%–16.74% higher compared to the C30/37 model. These results demonstrate that the lower modulus of elasticity of geopolymer concrete increases the structural deformation demands.

In the environmental assessment, the total emissions of C30/37 and GPCM8 were calculated to be 365.90 and 228.46 kg CO_2-eq/m³, respectively. Accordingly, the GPCM8 mixture

produced approximately 37.6% lower carbon emissions than C30/37. However, sodium silicate and sodium hydroxide in the GPCM8 mixture accounted for a significant portion of the total emissions.

In conclusion, GPCM8 represents a promising environmental alternative due to its lower carbon emissions. However, in structural design, not only compressive strength but also the modulus of elasticity and the associated displacement demands should be taken into account. The findings indicate that, when these parameters are properly considered in the design process, GPCM8 has the potential to provide satisfactory seismic performance in reinforced concrete structures.

Abstract. This paper introduces a data-driven framework to assess the energy dissipation characteristics of reinforced concrete columns subjected to cyclic loading. Specifically, total dissipated energy was selected as the target parameter for the assessment method. A comprehensive dataset of flexure-controlled reinforced concrete columns was compiled from open-access sources and used to train and evaluate multiple machine learning models based on key input parameters such as material properties, reinforcement ratios, and deformation-related parameters. Several machine learning algorithms were implemented and compared, including ensemble learning methods such as Extreme Gradient Boosting, Random Forest models, and LightGBM, as well as kernel-based methods and artificial neural networks (i.e., Support Vector Machines, and Multilayer Perceptron). The influence of the selected input features on dissipated energy level was assessed through a model interpretability analysis. Each model performance was evaluated using k-fold cross-validation and commonly-used statistical metrics. Furthermore, an external validation study was performed for the best-performing model to assess the accuracy level. Results show that all models provide satisfactory predictive capability, while ensemble-based approaches generally provided superior accuracy and robustness. As a result, the study demonstrates the potential of machine learning techniques to predict the energy dissipation capacity in reinforced concrete columns, supporting future developments in data-driven, energy-based structural assessment and design methodologies.

Keywords: Data-driven approach; Energy dissipation; Energy-based design.

1 Introduction

The seismic performance of reinforced concrete (RC) columns is mainly governed by their ability to dissipate the input energy via inelastic deformation. Specifically, the energy dissipation capacity of a member is considered as a key performance point, as well as the deformation and strength capacities, in the design/assessment of earthquake resistant structures. In this respect, an accurate quantification of the capacity plays a vital role in understanding the response of a member subjected to cyclic loading and enabling the improvement of performance-based seismic design frameworks. Therefore, studies on the energy dissipation capacity of reinforced concrete members have received considerable attention over the past decades, through studies generally focusing on several key aspects.

Experimental studies have been commonly performed to assess the cyclic behavior and the energy dissipation mechanisms under different loading cases [1-5]. For instance, Park and Eom [1] proposed a nonlinear finite element-based method for predicting the energy dissipated by RC columns subjected to flexural actions. Validation against existing experimental results

confirmed the accuracy of the proposed approach, demonstrating good predictive performance. A non-parametric empirical approach was proposed by Poljanšek et al. [2] to predict the dissipated energy and deformation capacity deterioration. Results demonstrated that axial load, confinement, and longitudinal reinforcement significantly influence the energy dissipation and deformation capacity of reinforced concrete columns. Additionally, numerous analytical and empirical models have been proposed to predict energy dissipation capacity, including a wide range from simplified regression-based formulations to mechanics-based approaches. Among these, Liu et al. [6] developed a two-parameter analytical fatigue-based model that takes into account the dissipated energy and cumulative hysteretic energy under cyclic loading, while Zhang et al. [7] proposed an energy-based hysteretic model for RC columns that is based on cumulative energy dissipation, displacement amplitude, and loading direction. Furthermore, the influence of key parameters (e.g., axial load ratio, concrete strength, confinement, and reinforcement configuration) has been investigated in detail [8-9]. More recently, machine learning-based approaches have arisen as alternative data-driven tools for predicting the energy dissipated by reinforced concrete members, presenting improved accuracy and efficiency compared to traditional models [10-12].

Although previous studies have provided valuable insights into the behavior of RC members during the dissipation process, a comprehensive assessment of the energy dissipation characteristics of RC columns using cumulative energy dissipation capacity remains limited. In particular, most existing approaches rely on simplified empirical formulations, while data-driven techniques such as machine learning have not been fully exploited for this purpose. Furthermore, the relative importance of key design parameters governing energy dissipation capacity has not yet been systematically quantified. Therefore, this study uses machine learning techniques to assess the energy dissipation characteristics of RC columns through cumulative energy dissipation capacity, and to quantify the influence of key design parameters using a large experimental database.

2 Proposed Data-Driven Framework

This proceeding aims to propose a data-driven framework for assessing the energy dissipation characteristics of flexure-controlled reinforced concrete (RC) columns subjected to cyclic loading via the total dissipated energy level. The total dissipated energy capacity of structural members subjected to cyclic loading is quantified by the area inside a force–displacement hysteresis loops. This capacity is typically evaluated through analytical models, experimental testing, or a combination of both. In this study, a machine learning approach is incorporated into a prediction-based analytical framework to predict the total dissipated energy capacity of structural members. Therefore, the framework is based on predicting the total dissipated energy using supervised machine learning models trained on experimentally derived dataset compiled from open-access literature sources. Specifically, the overall workflow of a framework consists of four main phases: i) data collection and preprocessing, ii) selection&definition of model features, iii) development of a model&training, iv) performance evaluation and comparison. A basic representation of the workflow of proposed framework is presented in Fig. 1.

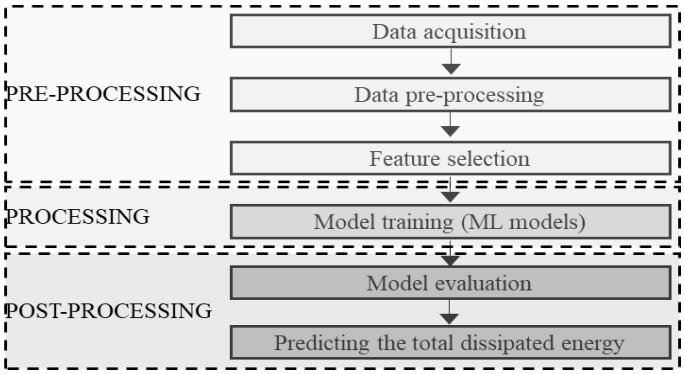

Fig. 1. Schematic representation of the workflow of proposed data-driven framework.

2.1 Data Collection

A comprehensive dataset of 160 flexure-controlled RC column specimens was assembled from open-access experimental studies [13,14]. The dataset consists of column specimens tested under cyclic loading actions to ensure a consistent failure mode classification. The compiled dataset includes fundamental input variables such as material properties (e.g., concrete compressive strength and steel yield strength), geometric properties, reinforcement ratios, and deformation-related parameters.

2.2 Feature Definition and Selection

In this study, total dissipated energy, E_{cd} was implemented as a target variable to represent the energy dissipation capacity of RC columns subjected to cyclic loading. Moreover, the input features were selected based on their relevance to the energy dissipation behavior of RC columns under cyclic loading. Specifically, 7 input features such as the concrete compressive strength, f_c, yield strength of longitudinal rebar, f_{yl}, longitudinal rebar ratio, ρ_l, shear span-to-depth ratio, a/d, volumetric ratio of transverse rebar, ρ_t, equivalent damping ratio, ζ_{eqv}, and peak drift ratio, Δ_{max} were considered during the analyses. A correlation-based analysis was conducted to evaluate the relationship between input features and a target variable [15]. A violin plot representing the normalized distributions of selected features and the target parameter is given in Fig. 2 (e.g., 0 and 1 corresponds to the normalized values where minimum and the maximum value in a range -as given in figure- is considered, respectively). Figure indicates that the parameters exhibit different levels of dispersion, reflecting the diversity of the collected samples. Here, the wide ranges observed for the material and geometric parameters ensure that the machine learning models are trained over a sufficiently diverse design space, improving their ability to capture complex relationships between the input variables and the target response.

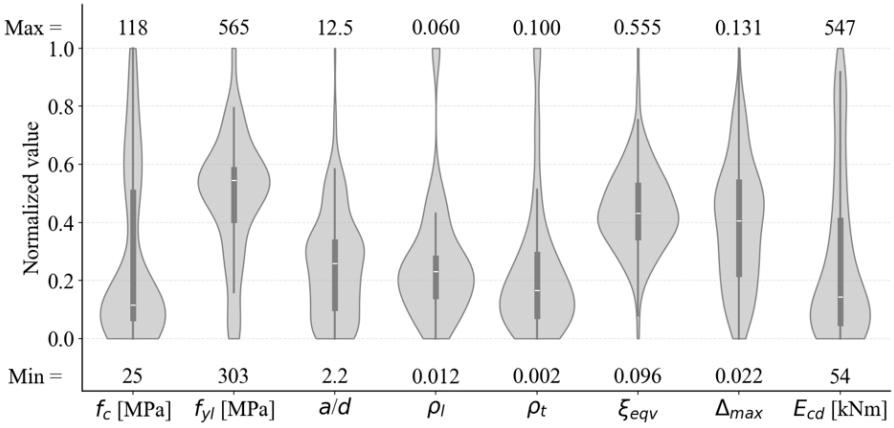

Fig. 2. Distribution characteristics of the dataset variables.

2.3 Development of a Machine Learning Model

Commonly-used supervised machine learning techniques were implemented to construct the relationship between selected input features and total dissipated energy. These models include ensemble learning methods such as *Extreme Gradient Boosting* (*XGBoost*), *Random Forest* (*RF*), and *Light Gradient Boosting Machine* (*LightGBM*), as well as kernel-based methods and artificial neural networks, including *Support Vector Machines* (*SVM*), and *Multilayer Perceptron* (*MLP*).

2.4 Evaluation Methodology

The performance of a model was assessed via K-Fold cross-validation approach [16] to get robustness and reduce bias related to data splitting. Here, the parameter, *K* denotes the number of folds into which the dataset is separated. Following the random partitioning process, cross-validation is performed by taking into account (*K*-1) folds to train and test the remaining fold. Moreover, commonly-used statistical performance metrics were employed to obtain the predictive accuracy, including the normalized root mean square error (*NRMSE*), the mean absolute percentage error (*MAPE*), and the coefficient of determination (R^2). Furthermore, the Pearson correlation coefficient [17], $\rho_{a,p}$ was calculated to quantify the correlation between the actual and predicted energy dissipation capacities, providing additional insight into the consistency of model predictions (Eq. 1).

$$\rho_{FT} = \frac{\sigma_{FT}}{\sigma_F \sigma_T} \tag{1}$$

where σ_{FT} denotes the covariance measure describing the relationship between the feature and target variables, whereas σ_F and σ_T represent the corresponding standard deviations of the feature and target parameters, respectively. Specifically, a comparative analysis allowed identification of the most effective modeling approach for predicting energy dissipation in RC columns.

3 Predicting the Total Dissipated Energy

This section provides preliminary results based on the prediction of total dissipated energy using different machine learning techniques. Specifically, ensemble learning methods (Extreme Gradient Boosting, Random Forest, and LightGBM), Support Vector Machines, and Multilayer Perceptron Networks, are implemented and compared. The predictive performance of each model is evaluated based on the mean values of performance indicators obtained from K-Fold cross-validation. Here, a six-fold cross-validation strategy was employed to evaluate the proposed model. The dataset comprising 160 samples was divided into six subsets. During each iteration, approximately 83% of the data (about 133 samples) were used for training, whereas the remaining 17% (~27 samples) were used for testing. The process was repeated six times, allowing each subset to be utilized as the test set once, and the performance metrics were averaged across all iterations. Furthermore, an external validation process was applied for the best-performing model to assess the accuracy level of a framework.

3.1 Performance Assessment of ML Models within the Proposed Framework

The implementation of the considered machine learning models is carried out within a proposed framework. For each model, a grid search-based optimization procedure is performed over a predefined hyperparameter space to determine the optimal parameter values. The resulting configurations are subsequently used for performance evaluation and comparative analysis. The investigated ranges and the optimal hyperparameter values that resulted in the best cross-validation performance are presented in Table 1. The results demonstrate that the proposed framework, particularly when stayed with ensemble learning methods, achieves high predictive

accuracy for total energy dissipation level, as evidenced by the high R^2 and consistently low NRMSE and MAPE values.

Table 1. Comparative performance assessment of the implemented machine learning models.

Model ID	Hyperparameter			R^2	NRMSE	MAPE
	Name	**Search range**	**Optimal value**			
XGBoost	n_{est}; objective; max_d; r_l	[50,1000]; [reg:logistic,binary:logistic]; [1,20]; [0.001,1.0]	50; reg:logistic; 6; 0.5	0.74	0.37	0.28

* n_{est}: number of estimators, max_d: maximum tree depth, r_l: boosting learning rate.

This finding is further validated by evaluating the Pearson correlation coefficient between the predicted and actual energy dissipation capacities, $\rho_{p,a}$ presented in Fig. 3. The results indicate a strong correlation between the predicted and measured values, demonstrating the high predictive accuracy and reliability of the developed models for an ensemble learning method supported framework, XGBoost.

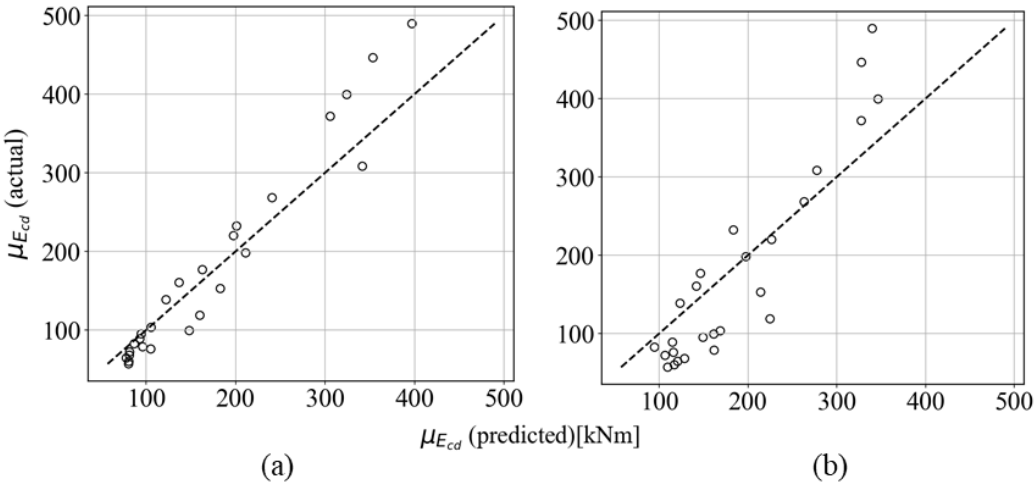

Fig. 3. Predicted versus actual values obtained via: a) XGB ($\rho_{p,a\text{-}XGB}$=0.98), b) SVM ($\rho_{p,a\text{-}SVM}$=0.93) models

3.2 Investigating the Accuracy Level of Predicted Results

Following the assessment of implemented ML techniques via selected performance metrics, the global feature importance and the predictive accuracy of the best-performing model, XGBoost, are further investigated. Specifically, the mean absolute SHAP (Shapley Additive Explanations) [18] of each feature is evaluated. Here, the mean absolute SHAP value quantifies the average contribution magnitude of each input variable to the prediction of target parameter, E_{cd} and higher values indicate stronger influence on the XGBoost-based predictions. Results

indicate that, peak drift ratio and longitudinal steel strength were identified as the most influential parameters, whereas transverse reinforcement ratio exhibited comparatively lower influence (Fig. 4a).

Finally, the developed XGBoost-based model was further evaluated using an independent validation dataset consisting of 15 reinforced concrete columns that were not included during model development. The Pearson correlation coefficient between the predicted and measured values is 0.90, compared with 0.98 obtained during cross-validation (Fig. 4b). The relatively small reduction (~8%) in correlation indicates that the proposed model preserves a strong agreement between predicted and measured responses when applied to unseen specimens. Nevertheless, the validation dataset comprised only 15 specimens. Future validation using a larger and more diverse dataset would enable a more comprehensive assessment of the model's robustness and generalization capability.

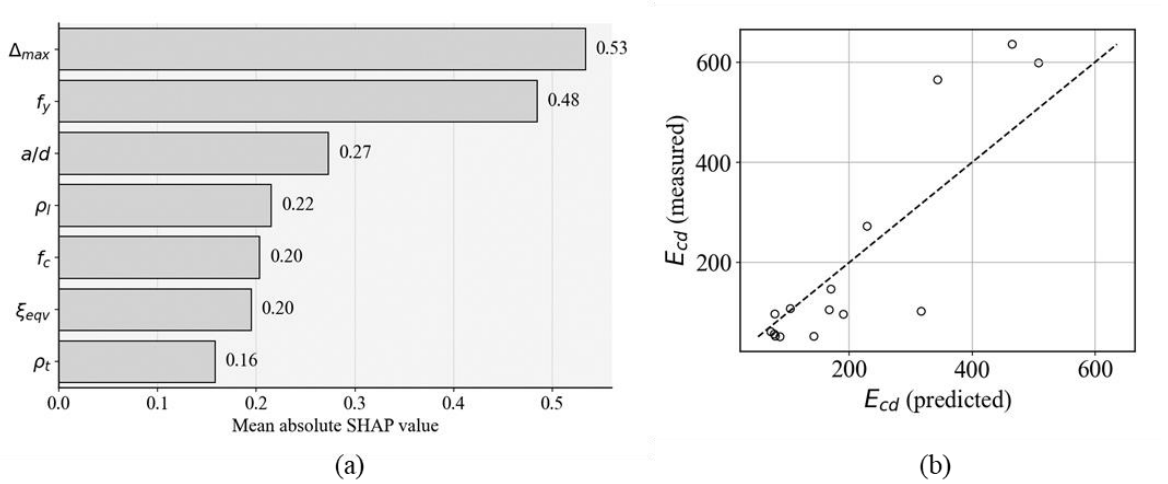

Fig. 4. Results based on post-processing phase: a) SHAP-based global feature importance of the implemented XGBoost model, b) comparison between the predicted and measured dissipated energy for the independent validation dataset.

4 Conclusions

Details of a data-driven framework based on commonly-used machine learning (ML) techniques are presented in this paper. The total dissipated energy, quantified by the area inside the force–displacement hysteresis loops, is adopted as the target parameter to quantitatively evaluate the energy dissipation characteristics of reinforced concrete columns under cyclic loading. Five enhanced ML techniques are implemented to predict this parameter using a comprehensive dataset of 160 specimens. Furthermore, the predictive performance of the best-performing model is investigated. The main findings of this study are summarized as follows:

- All ML-based models showed satisfactory predictive capability, with ensemble-based methods (i.e., XGBoost and LightGBM) providing the best overall accuracy and robustness.
- Following the evaluation of mean absolute SHAP values, it was observed that the peak drift ratio and longitudinal reinforcement strength were the dominant features to be considered in the process, whereas the transverse reinforcement ratio contributed comparatively less to the model predictions within a selected feature set.
- The predictive capability of the best-performing model, XGBoost, was further assessed via an independent validation study. Specifically, 15 reinforced concrete columns that were not included in the model development process were used for validation. The relatively small reduction (approximately 8%) in the correlation coefficient between the model development and validation stages shows that the proposed model keeps a

strong agreement between predicted and experimental responses when applied to independent specimens.

As a summary, it can be concluded that ML-supported data-driven frameworks (e.g., especially with ensemble-based approaches) can be utilized to assess the energy dissipation characteristics of reinforced concrete columns based on different target parameters. Increasing the size and using more diverse dataset would enable a more comprehensive assessment of the implemented model's generalization capability.

Abstract. This study investigates the effect of prefabricated lightweight steel wall panel systems designed as an alternative to traditional masonry infill walls to enhance the seismic performance of reinforced concrete frames. Conventional brick infill walls significantly increase seismic mass to the structure and cause substantial environmental post-earthquake waste. In contrast, the proposed lightweight steel panel systems are considerably lighter than traditional infill walls that offer a sustainable and innovative solution with fully recyclable nature. Within the scope of the research, a comprehensive experimental program was conducted on a total of four specimens, including a reference frame, brick infilled frame, and frames with lightweight steel wall panels, under constant axial load and quasi-static cyclic lateral loading. The results demonstrate that the integration of lightweight steel walls significantly increases frame strength, exhibits stable cyclic behavior, and provides a ductile structural response. Unlike traditional masonry infills, lightweight steel walls provide a controllable seismic behavior by preventing sudden and brittle failures occurring at low drift levels. Consequently, it has been determined that lightweight steel walls are an eco-friendly infill solution that minimizes structural weight, limits brittle damage mechanisms, and can be safely implemented in seismically prone regions.

Keywords: Lightweight steel wall, Reinforced concrete, Cyclic loading

1 Introduction

In current design practice, infill walls are generally considered non-structural elements and are only taken into account as dead loads in structural analyses. However, these elements significantly influence the lateral stiffness and seismic response of reinforced concrete frames [1,2]. Due to their low cost and widespread availability, masonry infill walls are commonly used in construction. Although they contribute to the elastic behavior of structures by providing initial stiffness at low drift levels, their brittle nature results in sudden strength degradation, cracking, and eventual collapse under increasing deformation demands [3,4]. Consequently, the behavior of masonry infill walls cannot be effectively controlled during seismic events. Furthermore, their additional mass increases the seismic demands acting on the structure. This situation not only poses risks to life safety but also leads to significant economic losses due to high repair costs and post earthquake debris generation.

From an environmental perspective, brick production contributes substantially to global carbon emissions, while the recycling of brick debris generated after earthquakes remains highly limited due to logistical and energy-related constraints [5–7]. The tens of millions of tons of debris generated during the 2023 Kahramanmaraş earthquakes clearly highlighted the need for more sustainable alternative systems.

Prefabricated lightweight steel wall panels have emerged as a promising solution due to their high strength-to-weight ratio, rapid installation, and 100% recyclability. Existing studies have primarily focused on the individual behavior of these panels and the effects of parameters such as sheathing type, fastening systems, and panel configurations on their cyclic performance. In addition, their interaction with steel framing systems has also been investigated [8–11]. However, their influence on the behavior of reinforced concrete frames remains largely unknown.

In this study, the effects of prefabricated lightweight steel wall panels and conventional masonry infill walls on the behavior of reinforced concrete frames were experimentally investigated through a comparative approach. The results demonstrate that lightweight steel wall panels provide a more ductile and environmentally sustainable alternative for structures subjected to seismic loading.

2 Experimental Studies

2.1 Material Properties

The average compressive strength of the concrete used in the production of the reinforced concrete frames was 30.15 MPa, while the yield and ultimate tensile strengths of the reinforcing bars were 431 MPa and 545 MPa, respectively. For the lightweight steel wall panel system, cold-formed steel (CFS) profiles of S235JR grade were selected, with yield and ultimate tensile strengths of 247 MPa and 313 MPa, respectively. For the masonry infill wall, perforated clay bricks measuring 135 × 190 × 190 mm with a characteristic compressive strength of 5.7 MPa and ready-mixed medium-strength mortar with a compressive strength of 15.2 MPa were used [12].

2.2 Test Specimens

Fig. 1 illustrates the infill configurations of the four single-story, single-bay reinforced concrete (RC) frame specimens. The specimen designated as Ref represents the bare frame used as the reference specimen (*Fig. 1a*), while the specimen labeled BRK represents the frame infilled with a brick masonry wall (*Fig. 1b*). The specimens denoted as CFS-Br-Stf and CFS-PL are frames infilled with lightweight steel wall panels of different configurations (*Figs. 1c and 1d*). In both wall systems, the primary framing consists of horizontal and vertical cold-formed steel (CFS) C-section profiles with a thickness of 1.5 mm. In addition, the CFS-Br-Stf system includes C-section diagonal bracing members, whereas the CFS-PL system incorporates 1.5 mm thick steel sheathing. The CFS profiles have a flange width of 50 mm and different web depths: 135 mm for vertical members, 130 mm for horizontal members, and 125 mm for diagonal members. The CFS profiles were assembled using self-drilling screws in accordance with previous studies [9,10]. The wall panels were anchored to the reinforced concrete frame using concrete nails. The geometric and reinforcement details of the reinforced concrete frames are presented in *Fig. 2.*

Fig. 1. Test Specimens

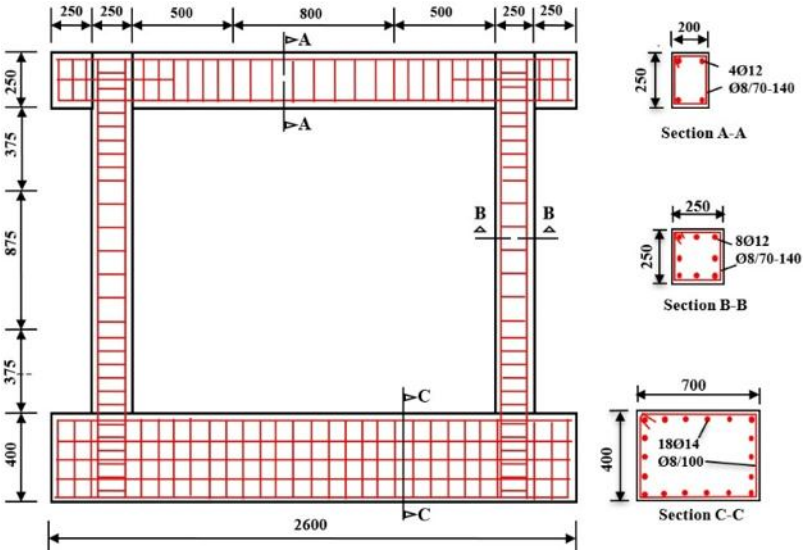

Fig. 2. Reinforced Concrete Frame Details

2.3 Test Setup, Instrumentation, and Loading Protocol

A schematic view of the test setup is presented in *Fig. 3*. Throughout the experiments, a constant axial load corresponding to 10% of the axial load capacity of the columns was applied. During the lateral loading stage, a displacement-controlled quasi-static cyclic loading protocol was

adopted in accordance with [13]. The loading sequence was initiated at a minimum interstory drift ratio of 0.15%, at which damage initiation was expected, and the displacement amplitudes were subsequently increased by 40% at each drift level. The first displacement amplitude was repeated six times, whereas all subsequent amplitudes were repeated twice. Throughout the tests, lateral load data were recorded using a load cell, while displacement measurements were simultaneously obtained through linear potentiometric displacement transducers.

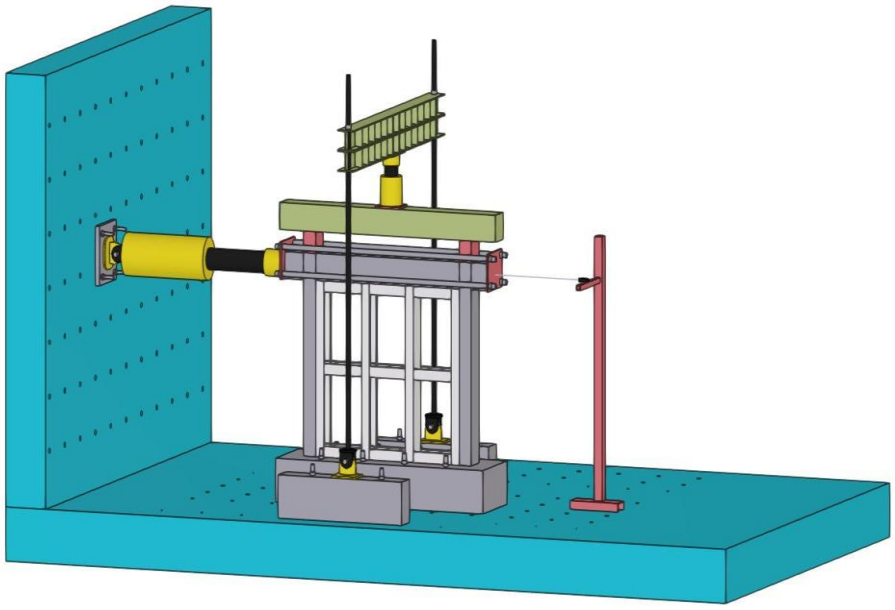

Fig. 3. Experimental Setup

3 Results and Discussion

The damage patterns observed in the test specimens are presented in *Fig. 4*, while the envelope curves, energy dissipation capacities, and stiffness degradation diagrams obtained from the cyclic loading tests are shown in *Fig. 5*. The experimental results reveal significant differences in the structural performance of the specimens.

The reference specimen (Ref) reached a peak lateral load of approximately 132 kN at a drift ratio of 2.21%. Damage progressed in the form of flexural cracks within the column confinement regions and shear cracks at the beam–column joints. In contrast, the masonry infilled specimen (BRK) exhibited a high initial stiffness, reaching approximately 251 kN nearly twice the capacity of the Ref specimen at very low drift levels of 0.29–0.41%. However, a sudden loss of capacity occurred at later stages due to crushing of the masonry wall and its separation from the surrounding frame.

The proposed lightweight steel panel systems exhibited a considerably more stable and consistent response compared to the BRK specimen. The CFS-Br-Stf specimen provided an average increase in lateral load capacity of 51% relative to the Ref specimen at a drift ratio of 2.21%. The energy dissipation was achieved through the progressive failure of screw connections and local/global buckling of the compression diagonals. The steel-sheet-sheathed panel system (CFS-PL) demonstrated the highest performance among all specimens, reaching a maximum lateral load of approximately 305 kN at a drift ratio of 1.13%. Local buckling was observed in both the steel sheathing and the longitudinal framing members. Furthermore, the shear failure of most anchorage screws at a drift ratio of 3% indicated a high degree of interaction between the panel and the reinforced concrete frame.

The total energy dissipated by the Ref, CFS-Br-Stf, BRK, and CFS-PL specimens was approximately 24 kJ, 33 kJ, 35 kJ, and 45 kJ, respectively. While the masonry infill wall

dissipated most of its energy at low drift levels, the lightweight steel panel systems primarily dissipated energy during the intermediate and large displacement stages.

Fig. 4. Damage Patterns of the Test Specimens

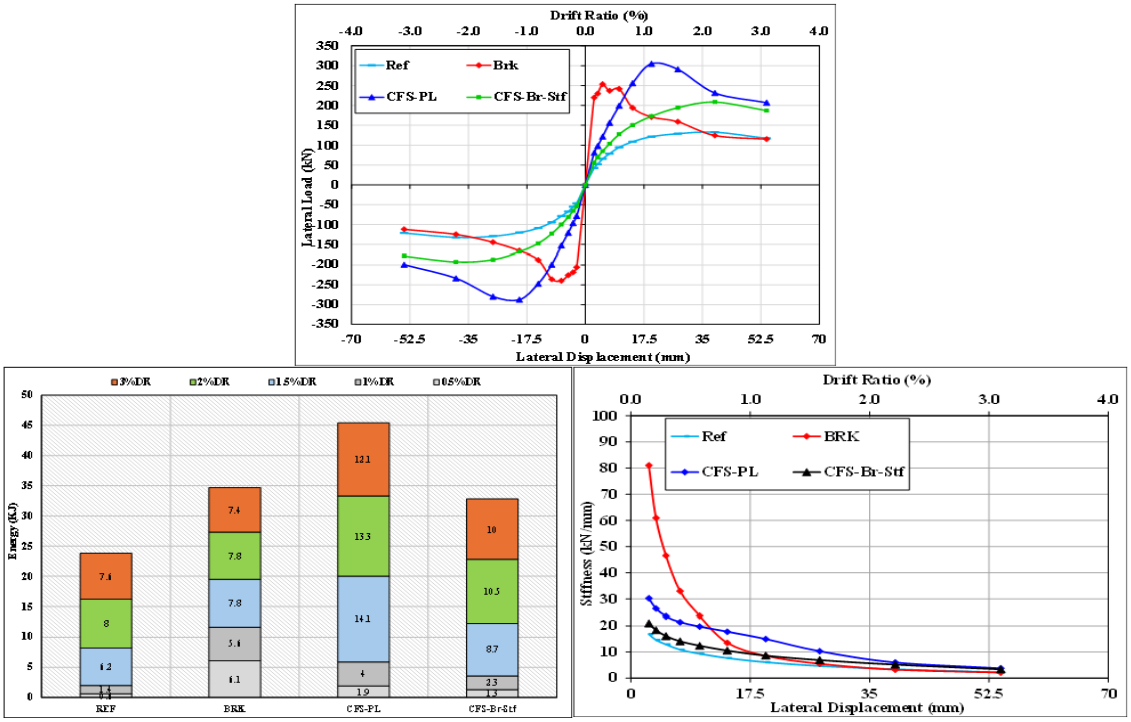

Fig. 5. Experimental Results

4 Conclusions

The results of this study demonstrated that the integration of lightweight steel wall panels significantly enhanced the strength of the reinforced concrete frame, provided a stable cyclic response, and promoted a ductile structural behavior. In contrast, although the masonry infill wall substantially increased the initial stiffness of the frame, the sudden and brittle failures observed at very low drift levels revealed that the seismic response of conventional masonry infills is unstable and difficult to control.

Overall, lightweight steel wall panels represent an environmentally friendly wall solution that minimizes structural weight while preventing brittle failure mechanisms within the wall system. The proposed approach demonstrates that by enabling the framing components commonly used in dry-wall construction systems to actively participate in load resistance, the seismic performance of reinforced concrete structures can be significantly improved.

Monitoring the Transformation of Residential Typology from Building Permit Data in Trabzon (2010–2025)

Abdullah BOSTANCI[1] and Sina ATABEY[2]
[1] 0000-0002-5306-9795, Department of Construction, Vocational School, Avrasya University, Trabzon, Türkiye, abdullah.bostanci@avrasya.edu.tr

Abstract. Building permits are widely regarded as one of the most reliable leading indicators of the future urban environment, since the decision to permit a structure precedes its construction and reflects demographic pressure, investor expectations, regulatory cycles, and local planning policy. This study reveals the transformation of residential typology in Trabzon over 2010–2025 using such data. Trabzon is selected because its constrained coastal-mountainous geography, sustained tourism investment, and recent multi-storey development make its building stock particularly sensitive to typological change. Open data published by the Turkish Statistical Institute (TurkStat) under the Classification of Types of Constructions (CC), at provincial level and annual frequency, were used. Permits are disaggregated at the three-digit CC level, and the yearly share of each subcategory in total permits is computed. Trend significance is tested with the Mann-Kendall test and Sen's slope estimator, while structural breaks are examined with the Pettitt test. Robustness is checked under sensitivity scenarios excluding the two non-comparable boundary years — the anomalously compiled 2010 and the scope-expanded 2025 — while the 6 February 2023 Kahramanmaraş earthquake is weighed in interpreting late-period dynamics. Contrary to the national apartmentation trend, the findings indicate a statistically significant rise in the share of one-dwelling permits and a corresponding decline in the share of multi-dwelling buildings, with a common structural break around 2018; hotel permits trend significantly upward, consistent with a tourism-investment cycle. The study provides a province-specific empirical baseline for Trabzon and a transferable, data-driven methodology to support evidence-based decisions on densification, parking provision, and social-facility allocation.

Keywords: Building permit; Residential typology; Time series analysis.

1 Introduction

Building permits are among the most widely used leading indicators of the future built environment: the administrative decision to authorise a structure precedes its physical completion, so permit records register demographic pressure, investor expectations, regulatory cycles and planning policy well before these forces become visible in the standing stock [1], and the time-series analysis of archived permit data is an established means of tracking shifts in the size, value and type of authorised construction [2]. What a permit series reveals, however, depends on the level at which it is read. Aggregate counts capture the volume of anticipated construction and move largely with the macroeconomic and credit cycle, but they are silent about its composition; it is the disaggregated, typology-level series — the relative weight of single-dwelling, multi-dwelling and non-residential categories — that exposes structural

transformation in how a settlement is being built, and a surge of multi-unit permits that outpaces population or employment growth can be an early signal of looming oversupply [3].

In the Turkish context this indicator is tightly coupled to the financing environment: analyses of 2005–2015 monthly data report that sectoral-credit and building-permit series are cointegrated, with causality running from credit to permits [4]. The dominant mode of residential production over the same decades has been "apartmentation" — the progressive replacement of low-rise dwellings by multi-storey apartment blocks — which the Turkish housing literature treats as a defining feature of the urbanisation process [5]; against this national baseline, a provincial series that moves in the opposite direction is analytically significant. Interpreting such a series nonetheless demands methodological care, because TurkStat periodically revises the concept, scope and method of its statistics and maintains a register of the resulting series breaks [6].

Trabzon offers a particularly instructive setting in which to examine these dynamics. Its constrained coastal-mountainous geography limits the supply of developable central land, while sustained tourism investment subjects the building stock to simultaneous and partly opposing pressures. Remote-sensing studies of the province document pronounced urban-fringe expansion, with development pushed outward from the saturated centre [7]; the broader coastal-Turkey literature attributes much recent land-use change to tourism and residential development [8]; and comparable Black Sea cases link migration-driven sprawl to measurable land-use/land-cover change [9]. These spatial accounts strongly suggest that the typological composition of Trabzon's permits should be changing, but they neither quantify the shift in typology shares nor identify when it occurred.

This study addresses that gap by reconstructing the transformation of residential typology in Trabzon over 2010–2025 directly from permit data. Open TurkStat data under the Classification of Types of Constructions (CC) are disaggregated to the three-digit level at provincial scale and annual frequency, and the yearly share of each subcategory in the relevant reference total is computed; working with shares rather than raw counts isolates compositional change from the underlying volume cycle. Trend significance is assessed with the non-parametric Mann-Kendall test together with Sen's slope estimator, and structural breaks are located with the Pettitt test. Because the two boundary years — the anomalously compiled 2010 and the scope-expanded 2025 — could distort the series, every result is re-examined under sensitivity scenarios that successively exclude them, and only findings that remain significant across all scenarios are reported as robust; the 6 February 2023 Kahramanmaraş earthquake, interior to the series, is weighed in interpretation.

Contrary to the national apartmentation narrative, the analysis reveals a robust reversal at the provincial scale: within residential permits the share of one-dwelling buildings rises significantly while the share of multi-dwelling buildings declines, both with a common structural break around 2018, and hotel permits exhibit a significant upward trend consistent with a tourism-investment cycle. Stable across every sensitivity scenario, these results provide a province-specific empirical baseline and a transferable, data-driven monitoring methodology for evidence-based planning on densification, parking provision and social-facility allocation.

2 Materials and Methods

2.1 Study area and data

The study area is the province of Trabzon (TurkStat code 61) on the eastern Black Sea coast of Türkiye, where a narrow coastal plain backed by a steep mountainous hinterland sharply constrains the supply of developable central land. The empirical basis is the open Building Permit Statistics published by the Turkish Statistical Institute (TurkStat) under the

Classification of Types of Constructions (CC), retrieved at provincial level and annual frequency for the sixteen years from 2010 to 2025. The unit of observation is the number of buildings for which a building permit was issued in a given year; floor area and dwelling counts are not used, so the series measures the count and composition of authorised structures rather than their physical size. Figure 1 situates the province in this physical setting and illustrates the outward, fringe-ward expansion of its built-up area between 2000 and 2025.

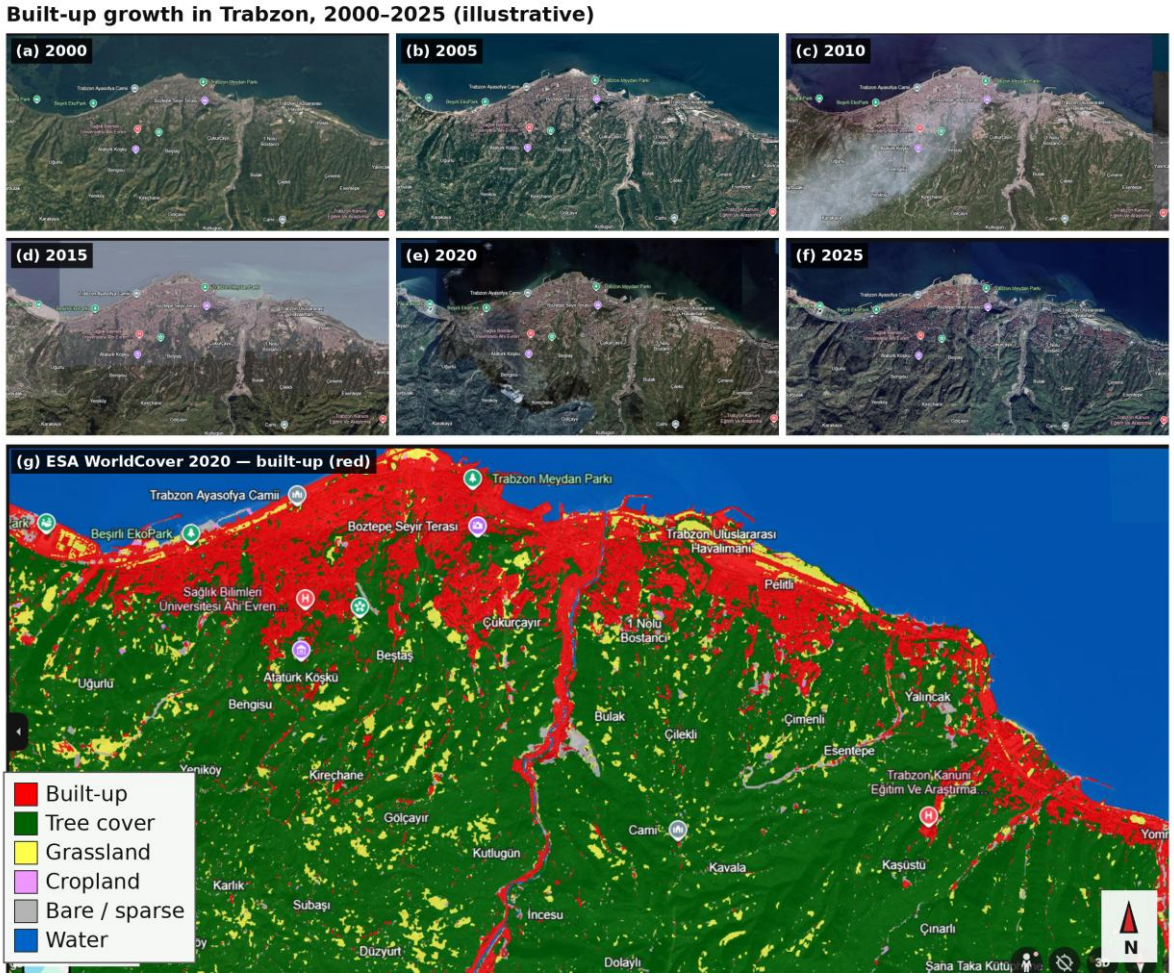

Fig. 1. Built-up growth in central Trabzon and its southern fringe, 2000–2025. Panels (a)–(f) are Google Earth historical imagery (acquisition years as labelled; 2025 = 31 Oct 2025); panel (g) is ESA WorldCover 2020 land cover, with built-up areas in red, over a slightly wider extent reaching Yomra. The figure is qualitative: frames are not co-registered and scales are approximate. Permits are disaggregated to the three-digit CC level. Within the residential class (CC 11) three subcategories are distinguished — one-dwelling buildings (111), two-or-more-dwelling buildings (112) and residences for communities (113) — while the non-residential class (CC 12) is resolved into hotels and similar buildings (121), office buildings (122), wholesale and retail trade buildings (123), traffic and communication buildings (124), industrial buildings and warehouses (125), public-entertainment, education, hospital or institutional-care buildings (126) and other non-residential buildings (127). Together with the residential, non-residential and overall totals, this yields thirteen raw count series spanning the study period; these categories and the share series derived from them are listed in Table 1.

Table 1. Building permit categories analysed at the three-digit CC level and the seven share series derived from them. Within-residential shares use residential permits (CC 11) as denominator; sectoral shares use all permits (CC 1).

CC code	Building category	Derived share series
1	All buildings (total)	(reference total)
11	Residential buildings	Residential % of total
111	One-dwelling buildings	One-dwelling % of residential
112	Two-or-more-dwelling buildings	Multi-dwelling % of residential
113	Residences for communities	Communal % of residential
12	Non-residential buildings	Non-residential % of total
121	Hotels and similar buildings	Hotels % of total
122	Office buildings	–
123	Wholesale and retail trade buildings	–
124	Traffic and communication buildings	–
125	Industrial buildings and warehouses	Industrial % of total
126	Public-entertainment, education and health buildings	–
127	Other non-residential buildings	–

Two features of the data require caution and motivate the robustness checks reported below. First, the 2010 figures are anomalously high across almost all categories, consistent with a different compilation basis in that year, so the opening observation is treated as potentially non-comparable. Second, from the second quarter of 2025 the statistics were expanded beyond municipal authorities to incorporate permits issued by other bodies—special provincial administrations, organised-industrial-zone directorates, free-zone authorities and the like—so the closing observation may not be fully comparable with the municipally based earlier years. The 6 February 2023 Kahramanmaraş earthquake, which reshaped construction demand nationally, falls within the interior of the series and is taken into account when the late-period dynamics are interpreted. The full set of annual permit counts analysed is openly available from TurkStat [6].

2.2 Permit typology shares

Raw permit counts conflate two distinct signals: the overall volume of anticipated construction, which moves with the macroeconomic and credit cycle, and the typological composition of that construction, which is the object of this study. To separate composition from volume, each category is expressed as an annual share of an appropriate reference total, following standard compositional-data practice [11]. For category i in year t the share is

$$share_{i,t} = (n_{i,t} / N_t) \times 100 \tag{1}$$

where $n_{i,t}$ is the number of permitted buildings in category i and N_t the corresponding reference total. Two reference bases are used. The internal composition of residential construction is captured by expressing the one-dwelling, multi-dwelling and communal subcategories as percentages of residential permits (CC 11), while the sectoral composition of construction is captured by expressing residential, non-residential, hotel and industrial permits as percentages of all permits (CC 1). This procedure produces seven derived share series, analysed alongside the thirteen count series and plotted in Figure 2. In panel (a), the communal series is interrupted at 2017, when no communal-residence permits were recorded – a missing observation, not a structural break.

2.3 Trend and change-point detection

Because annual permit series of sixteen points are short, non-normal and unlikely to satisfy parametric assumptions, trends and breaks are assessed with non-parametric procedures established in the environmental time-series literature. The presence and direction of a monotonic trend are tested with the Mann-Kendall test [12,13], which is based on the signs of all pairwise differences within a series and yields the statistic S, a standardised normal variate Z, a two-sided p-value and Kendall's τ as a scale-free measure of association; a trend is reported as significant at $p < 0.05$.

The magnitude of any trend is estimated with Sen's slope [14], the median of the slopes formed by all data pairs, which provides a robust estimate of change per year in the units of the series (percentage points per year for the share series). A single structural break in the mean is located with the Pettitt test [15], a rank-based change-point procedure that identifies the most probable break year together with its significance; where a break is detected, the associated level shift is illustrated by fitting linear trends to the pre- and post-break sub-periods. All tests were computed in Python, using the *pymannkendall* package (original test) for the Mann-Kendall and Sen procedures and the *pyhomogeneity* package for the Pettitt test.

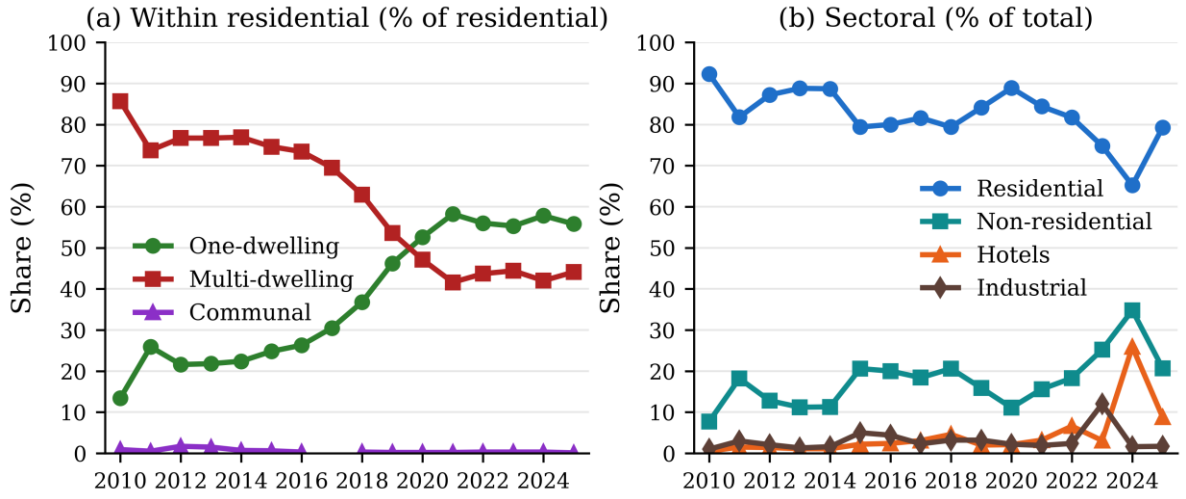

Fig. 2. Derived permit-share series for Trabzon, 2010–2025. (a) one-dwelling, multi-dwelling and communal buildings as percentages of residential permits (CC 11); (b) residential, non-residential, hotel and industrial buildings as percentages of all permits (CC 1). Series are shown without trend fitting; the statistical analysis is reported in Section 3.

2.4 Sensitivity analysis

To ensure that the reported trends and breaks are not artefacts of the two non-comparable boundary years, every test is repeated under three nested scenarios. Scenario S0 uses the full series (2010–2025); S1 excludes the anomalous opening year (2011–2025); and S2 excludes both boundary years (2011–2024), thereby removing the 2025 scope expansion as well. A finding is reported as robust only when it remains statistically significant, with a consistent sign, across all three scenarios; results that lose significance once a boundary year is removed are reported as fragile and are not over-interpreted.

3 Results

3.1 Trends and structural breaks

Table 2 reports the Mann-Kendall, Sen and Pettitt results for the seven share series over the full period (S0). Three of them show strong, highly significant trends. The one-dwelling share of

residential permits rises steeply ($Z = +4.37$, $p < 0.001$) at a Sen slope of +3.13 percentage points per year, while the multi-dwelling share falls almost symmetrically ($Z = -4.10$, $p < 0.001$; -3.08 pp/yr). Both are dated by the Pettitt test to a common change-point in 2018 ($p < 0.001$), so that within little more than a decade the composition of residential permits is effectively inverted: multi-dwelling buildings fall from about 86% of residential permits in 2010 to roughly 44% in 2025, and one-dwelling buildings rise from about 13% to 56% over the same span (Figs. 3 and 4).

The hotel share of all permits also trends significantly upward ($Z = +3.65$, $p < 0.001$; +0.39 pp/yr), with a Pettitt break in 2016 ($p = 0.003$) and a pronounced 2024 spike of 314 permits, by far the largest annual count in the series. The communal-residence share declines ($Z = -3.27$, $p = 0.001$; Pettitt break 2016) but from a very low base and with negligible magnitude (Sen slope ≈ -0.05 pp/yr), so it carries little substantive weight. By contrast, the residential and non-residential shares of total permits show only a weak full-period signal ($Z = -2.21$ and +2.21 respectively, $p = 0.027$) with no significant Pettitt break ($p \approx 0.06$), and the industrial share shows no trend at all ($Z = +0.41$, $p = 0.685$).

Table 2. Trend and change-point results for the share series over the full period (S0, 2010–2025). Z and p are the Mann-Kendall standardised statistic and two-sided p-value; Sen is the Theil–Sen slope in percentage points per year. The Pettitt break year is reported only where the test is significant ($p < 0.05$); – otherwise.

Share series	n	Trend	Z	p	Sen (pp/yr)	Pettitt p	Break
One-dwelling % of residential	16	increasing	+4.37	<0.001	+3.13	<0.001	2018
Multi-dwelling % of residential	16	decreasing	-4.10	<0.001	-3.08	<0.001	2018
Communal % of residential	15	decreasing	-3.27	0.001	-0.05	<0.001	2016
Residential % of total	16	decreasing	-2.21	0.027	-0.79	0.063	–
Non-residential % of total	16	increasing	+2.21	0.027	+0.79	0.061	–
Hotels % of total	16	increasing	+3.65	<0.001	+0.39	0.003	2016
Industrial % of total	16	no trend	+0.41	0.685	+0.03	0.202	–

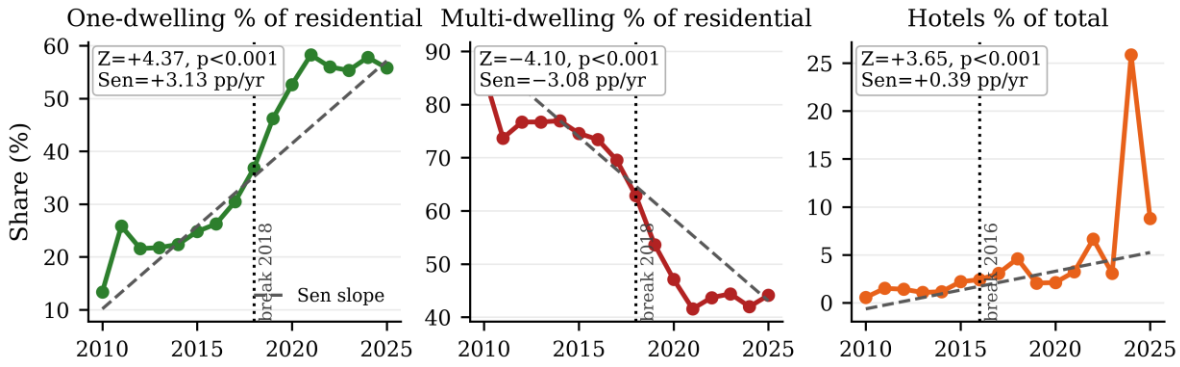

Fig. 3. The three statistically robust share series with Theil–Sen trend lines (dashed) and Pettitt change-points (dotted vertical lines). Mann-Kendall Z, two-sided p and the Sen slope (percentage points per year) are annotated in each panel. The 2024 value in the hotel panel corresponds to the 314-permit spike.

3.2 Robustness across scenarios

To separate genuine structure from artefacts of the two non-comparable boundary years, every test was repeated under scenarios S0, S1 and S2 (Table 3 and Fig. 5). The three headline findings are robust: the one-dwelling increase, the multi-dwelling decrease and the hotel increase remain significant at $p < 0.01$ in every scenario, keep their sign and magnitude, and retain the same break years (2018, 2018 and 2016).

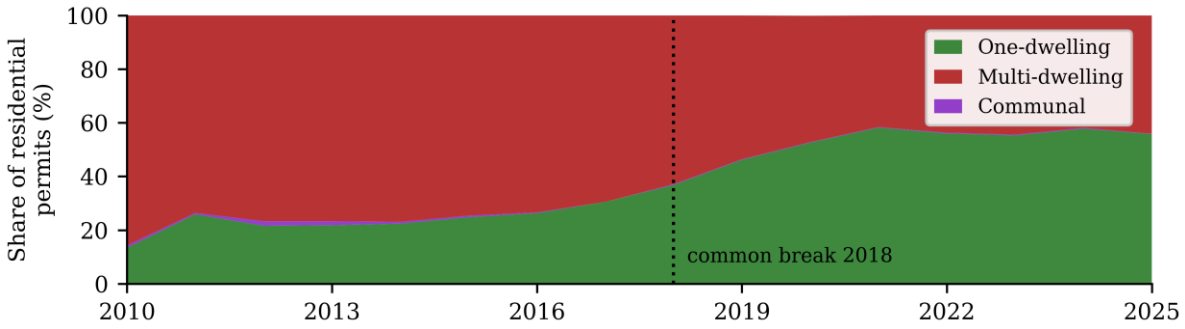

Fig. 4. Residential permit composition as a 100% stacked area, 2010–2025: one-dwelling, multi-dwelling and communal buildings as shares of residential permits. The crossover of the one-dwelling and multi-dwelling bands around the common 2018 break (dotted line) is the headline transition.

Table 3. Sensitivity of the Mann-Kendall trend test across scenarios (two-sided p-values). S0 = 2010–2025; S1 = 2011–2025 (excluding the anomalous 2010); S2 = 2011–2024 (excluding 2010 and 2025). A finding is robust when significant ($p < 0.05$) with consistent sign in all three scenarios.

Share series	p (S0)	p (S1)	p (S2)	Assessment
One-dwelling % of residential	<0.001	<0.001	<0.001	Robust (increase)
Multi-dwelling % of residential	<0.001	<0.001	<0.001	Robust (decrease)
Communal % of residential	0.001	0.002	0.009	Robust (decrease, small)
Residential % of total	0.027	0.093	0.189	Fragile
Non-residential % of total	0.027	0.093	0.189	Fragile
Hotels % of total	<0.001	0.001	0.003	Robust (increase)
Industrial % of total	0.685	0.843	0.913	No trend

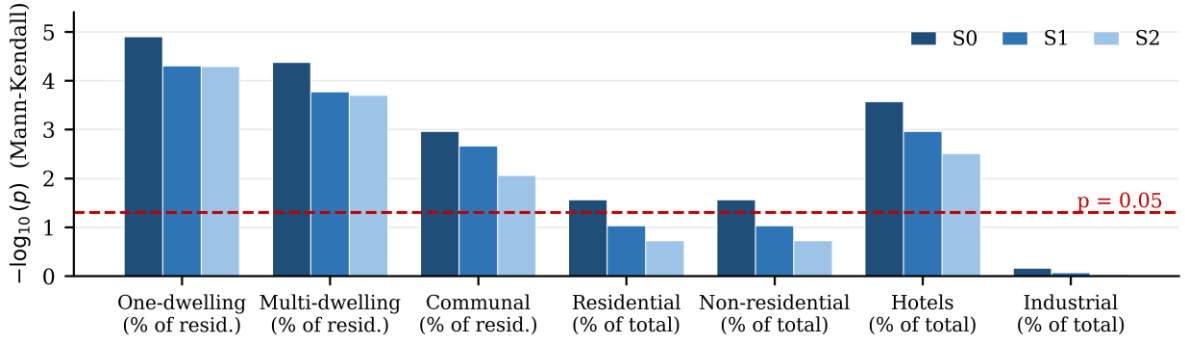

Fig. 5. Robustness of the Mann-Kendall trend across scenarios, shown as $-\log_{10}(p)$ for each share series under S0, S1 and S2. Bars above the dashed line ($p = 0.05$) are significant. The one-dwelling, multi-dwelling and hotel signals clear the threshold in every scenario, whereas the residential and non-residential signals fall below it once 2010 is excluded.

The residential-versus-non-residential shift is significant only when 2010 is retained (S0: $p = 0.027$; S1: $p = 0.093$; S2: $p = 0.189$), with no significant Pettitt break; it is reported as fragile — an artefact of the unusually multi-dwelling-heavy 2010 observation.

4 Discussion

4.1 A regional reversal of apartmentation

The central result of this study is a robust inversion of residential permit composition in Trabzon between 2010 and 2025. The one-dwelling share rises by roughly three percentage points per year and the multi-dwelling share falls at almost the same rate, both pivoting around a common 2018 change-point and surviving removal of the two non-comparable boundary years. At face value this runs counter to the apartmentation narrative that the Turkish housing literature treats

as the defining feature of the country's urbanisation [5]: Trabzon is not de-densifying in absolute terms, but at the margin the balance of new permits has shifted decisively toward lower-density forms. Table 4 summarises how each finding relates to the literature.

Table 4. Synthesis of the robust and fragile findings against the literature. Citation numbers refer to the reference list.

Finding	Key statistics	Literature link	Interpretation
One-dwelling share rises (within residential)	$Z = +4.37$, $p < 0.001$; Sen +3.13 pp/yr; break 2018; robust in S0–S2	Fringe and peri-urban expansion [7], [9]; counter to apartmentation [5]	Regional reversal of the apartmentation norm; satellite-corroborated
Multi-dwelling share falls (within residential)	$Z = -4.10$, $p < 0.001$; Sen −3.08 pp/yr; break 2018; robust in S0–S2	Credit-to-permit causality [4]; post-2017 financing tightening	Symmetric counterpart; 2018 break tied to the credit shock and central saturation
Hotel share rises (of total)	$Z = +3.65$, $p < 0.001$; Sen +0.39 pp/yr; break 2016; 2024 spike (314); robust	Tourism-driven coastal land-use change [8]	Tourism-investment cycle; 2024 spike flagged for scrutiny
Residential vs non-residential shift	Significant in S0 only ($p = 0.027$); non-significant in S1 and S2	TurkStat series-break guidance [6]	Fragile; not interpreted – a 2010 boundary-year artefact

Two independent lines of evidence make this reversal interpretable. First, it is spatially corroborated: remote-sensing studies document peri-urban expansion pushed outward from a topographically confined centre [7, 9], and the built-up sequence in Fig. 1 concentrates along the coastal fringe and lower slopes, where detached and low-rise construction is feasible. Second, the timing is economically interpretable: credit-to-permit causality is documented for Türkiye [4], and the 2018 change-point coincides with the post-2017 tightening of the credit and currency environment, which weighed most on the capital-intensive multi-dwelling segment; the reversal is thus plausibly the joint product of a binding land constraint and a financing shock to large-scale apartment production.

4.2 Tourism dynamics and the limits of the sectoral signal

The second robust finding – an upward trend in the hotel share with a 2016 change-point – aligns with the coastal-Turkey literature attributing much recent land-use change to tourism pressure along the shoreline [8]. The 2024 spike of 314 hotel permits warrants scrutiny; whether it reflects a genuine investment wave, a reporting effect or the 2025 scope change cannot be resolved from the aggregate series.

Equally important is what the analysis declines to claim: as Section 3.2 shows, the residential-versus-non-residential shift is fragile — an artefact of the anomalous 2010 boundary year, consistent with the series breaks TurkStat documents [6] — and is therefore reported as inconclusive.

4.3 Contribution, implications and limitations

Methodologically, the contribution is not the tests themselves – standard in environmental time-series analysis – but their transfer to provincial permit typology shares and the attached robustness protocol. Permit-based monitoring has been pursued elsewhere [2], but typically on counts or valuations; three-digit CC shares instead isolate the compositional transition that count-based monitoring would miss.

For local authorities this is a reproducible early-warning signal: a sustained move toward one-dwelling permits implies lower density, greater per-capita infrastructure demand and more dispersed social-facility need, and the methodology tracks such shifts annually from open data.

Several limitations bound these conclusions. The data are provincial: variation between the constrained centre and expanding districts is not resolved; the unit is the permitted building, not floor area or dwelling count, so building-type change need not map one-to-one onto housing supply; the short series (sixteen points) limits statistical power and restricts Pettitt to a single change-point; and the 2010 anomaly and the 2025 scope expansion remain uncertainties that the sensitivity analysis mitigates but cannot remove, and together they define the agenda for follow-up work.

5 Conclusions

Analysing sixteen years of TurkStat building-permit data for Trabzon with the Mann-Kendall, Sen and Pettitt tests, this study finds a statistically robust reversal of residential permit composition: the one-dwelling share rises and the multi-dwelling share falls, both breaking around 2018, while the hotel share trends upward from a 2016 break. The results are stable across every sensitivity scenario, run counter to the national apartmentation norm, are consistent with satellite evidence of outward, fringe-ward and tourism-linked growth, and pivot on breaks that predate the February 2023 Kahramanmaraş earthquake.

The study contributes a province-specific baseline for Trabzon and a transferable, open-data methodology for monitoring typological change in the building stock, supporting evidence-based planning on densification, parking and social facilities. Extending it to district-level, spatially explicit data enriched with land-cover and terrain information is the natural next step.

Abstract. Fire is a loading effect that is often not explicitly considered in the analysis and design of engineering structures. Reinforced concrete structures exposed to fire are at significant risk in terms of their mechanical, physical, and durability properties depending on the temperature level and duration of fire exposure. Therefore, understanding the behavior of concrete under elevated temperatures is of great importance for evaluating the fire resistance of reinforced concrete structures. This study presents a literature-based review of the design principles for reinforced concrete structures subjected to fire exposure. Experimental and analytical studies conducted to date have been comparatively evaluated, and the effects of elevated temperatures on concrete behavior as well as the residual load-carrying capacity after fire exposure have been examined in detail. In addition, the influences of critical parameters such as aggregate type, moisture content, water-to-cement ratio, concrete cover thickness, and fiber reinforcement on fire performance have been investigated. The reviewed studies indicate that elevated temperatures lead to severe deterioration in the microstructural and mechanical properties of concrete due to dehydration, thermal incompatibility, pore pressure development, and progressive cracking mechanisms. Nevertheless, it has been determined that appropriate material selection and fire-resistant design approaches can significantly improve the thermal stability and post-fire performance of reinforced concrete structures. The findings of this review contribute to a better understanding of fire-induced concrete deterioration and provide a useful guide for the design of safer and more durable reinforced concrete structures under fire conditions.

Keywords: Fire exposure; Concrete structures; Fire-resistant design; Mechanical properties;

1 İntroduction

Fire is one of the most significant factors affecting the structural integrity, safety, and service life of concrete structures. Unlike conventional design actions—such as dead, live, wind, snow, and seismic loads—that threaten the intended performance of concrete structures primarily through mechanical effects, fire causes substantial changes in many properties of concrete, particularly its mechanical properties, owing to elevated temperatures [1–4]. Concrete has traditionally been regarded as a fire-resistant construction material because of its low thermal conductivity and non-combustible nature [5]. However, prolonged exposure to elevated temperatures causes deterioration in concrete, resulting in reductions in stiffness, strength, modulus of elasticity, durability, and load-bearing capacity [6]. Therefore, understanding the behaviour of concrete under fire exposure and designing fire-resistant concrete have become important considerations in structural engineering.

The behaviour of concrete under fire exposure is more complex than that of many other construction materials. This complexity arises from the heterogeneous nature of concrete, which consists of cement paste, aggregates, pores, and moisture, each responding differently to

increasing temperatures. As the temperature rises, concrete undergoes interrelated physical, chemical, and mechanical transformations, including the evaporation of internal moisture, dehydration of cement hydration products, thermal incompatibility between the aggregate and cement paste, and the formation of microcracks. These transformations increase the permeability and degree of damage in concrete while adversely affecting its mechanical properties, particularly its compressive strength, modulus of elasticity, and stiffness [5].

Over the past decade, numerous studies have investigated the behaviour of concrete under fire exposure using experimental, analytical, and numerical approaches. Although these studies have contributed significantly to understanding the fundamental mechanisms responsible for fire-induced deterioration in concrete, the available findings have generally focused on isolated material-level responses or a limited number of parameters. Comparative assessments of the effects of critical parameters—such as aggregate type, moisture content, water-to-cement ratio, fibre reinforcement, and concrete cover thickness—based on combined experimental and analytical findings remain limited. Therefore, a comprehensive literature-based investigation is needed to evaluate the influence of these parameters on the fire performance of concrete from a holistic perspective and to provide a valuable reference for structural engineering practice and future research.

2 Behavior of Concrete Under Fire Exposure

Concrete exposed to fire undergoes a series of interrelated processes that alter its properties and critically affect its structural performance. As the temperature increases, its behaviour is governed by physicochemical changes in the aggregate and cement paste, thermal incompatibility arising from differences in the thermal expansion of these constituents, moisture migration, and changes in the pore structure. These phenomena collectively lead to the progressive deterioration of the concrete microstructure. Therefore, the behaviour of concrete under fire exposure cannot be attributed to a single deterioration mechanism [5]. Instead, it results from the combined effects of multiple interacting processes that occur simultaneously as the temperature rises. The severity of these processes is influenced by both the characteristics of the concrete mixture and the prevailing environmental conditions. This complex interaction makes it difficult to accurately predict the performance of concrete under fire exposure.

One of the most significant responses of concrete to elevated temperatures is the evaporation of free water and the gradual release of chemically bound water from cement hydration products. As the temperature continues to rise, dehydration of the cement matrix, differential thermal expansion between the aggregate and cement paste, and the build-up of internal vapour pressure promote the formation and propagation of microcracks within the concrete. Once the temperature reaches critical levels, explosive spalling may occur, directly exposing the reinforcing steel in reinforced concrete members to fire and thereby dramatically accelerating structural deterioration. Overall, these transformations alter the internal structure of concrete and significantly affect its mechanical performance both during and after fire exposure [7–9].

The deterioration of concrete at the microstructural level is directly reflected in its mechanical behaviour. Numerous experimental and numerical studies have reported that increasing temperature leads to reductions in the compressive strength, tensile strength, modulus of elasticity, stiffness, and residual load-bearing capacity of concrete. However, the extent of this deterioration depends not only on the maximum temperature attained but also on the heating rate, duration of thermal exposure, cooling conditions, moisture content, aggregate characteristics, and mixture proportions. Consequently, concrete specimens exposed to similar temperatures may exhibit markedly different performance depending on their material composition and structural configuration.

Although fire-induced deterioration mechanisms have been extensively investigated in the literature, the fire resistance of concrete results from the interaction of several material- and design-related parameters acting simultaneously. Therefore, understanding both the individual and combined effects of these parameters is essential for accurately assessing fire-induced damage and improving the thermal stability of reinforced concrete structures. Accordingly, the following section examines the effects of aggregate type, moisture content, water-to-cement ratio, concrete cover thickness, and fibre reinforcement, which are among the parameters most frequently investigated in the literature.

3 Evaluation of the Parameters Affecting the Fire Performance of Concrete

3.1 Aggregate Type

The type of aggregate used in concrete production is one of the most important parameters influencing the fire performance of concrete. This is primarily because aggregates constitute approximately 60–75% of the total volume of concrete and largely govern its mechanical and thermal behaviour at critical temperatures. During fire exposure, the heat-transfer characteristics, thermal expansion, and moisture-related behaviour of aggregates influence crack development and the stability of the interfacial transition zone (ITZ). All these factors also affect the residual mechanical properties of concrete after cooling. Although recent studies examining the influence of aggregate type have traditionally focused on the distinction between commonly used siliceous and calcareous aggregates, the findings indicate that fire performance is governed not merely by the selection of a particular aggregate type but also by its mineralogical composition, crystallinity, pore structure, thermophysical properties, and interaction with the cementitious matrix. Consequently, selecting suitable aggregates for fire-resistant concrete design requires a comprehensive understanding of both the intrinsic thermal properties of the aggregates and their compatibility with the cementitious matrix during heating.

Conventionally used calcareous aggregates have generally been considered more suitable than siliceous aggregates for concrete exposed to elevated temperatures because of their relatively lower thermal expansion and lower susceptibility to quartz-related phase transformations at intermediate temperatures [6]. Nevertheless, comparative findings indicate that a simple classification into calcareous and siliceous aggregates is insufficient. In particular, another study reported that quartzite aggregates remained relatively stable despite the α-to-β quartz transformation, whereas moisture-sensitive, low-permeability flint particles experienced substantial internal damage and caused extensive cracking in the surrounding concrete.

Furthermore, the relative performance of the aggregates varied with the quality of the cementitious matrix. Concrete containing calcareous aggregates exhibited more favourable performance when used with a normal-strength matrix, whereas quartzite aggregate concrete demonstrated better residual behaviour when incorporated into a denser, high-performance matrix. At even higher temperatures, the advantage of calcareous aggregates observed at intermediate temperatures may diminish because calcination and the subsequent hydration of calcium oxide after cooling can trigger delayed deterioration. These findings demonstrate that aggregate performance depends on both the temperature level and matrix characteristics and, therefore, cannot be reliably predicted solely on the basis of broad mineralogical classifications [10].

Aggregate mineralogy strongly influences the thermal behaviour of aggregates. Previous studies have shown that the behaviour of concrete at elevated temperatures is governed by the relationship between the mineral composition of the aggregate and its microstructural characteristics. Aggregates with similar mineralogical compositions may exhibit different fire performance depending on their crystallinity, permeability, pore structure, and moisture condition. This indicates that the mechanisms governing fire-induced damage extend beyond

mineral composition and are closely associated with moisture transport and aggregate–cement paste interactions during heating [10,11]. Furthermore, thermal incompatibility between the aggregate and cement paste, arising from differences in their thermal expansion, promotes microcrack formation within the interfacial transition zone. In contrast, calcareous and lightweight aggregates may limit such damage because of their greater thermal compatibility with the cementitious matrix. Microstructural observations have demonstrated that improved thermal compatibility preserves the integrity of the interfacial transition zone and thereby enhances the residual strength of concrete [1,2,11].

Recent studies have demonstrated that lightweight aggregates can improve the fire performance of concrete through mechanisms that differ from those associated with normal-weight aggregates. Their relatively high porosity, low thermal conductivity, and ability to alleviate the build-up of internal vapour pressure reduce temperature gradients and thermally induced stresses. Consequently, concrete containing lightweight aggregates generally exhibits greater residual strength and a lower risk of spalling. However, these advantages should be evaluated in conjunction with the potential reduction in the mechanical strength of lightweight concrete at ambient temperature. Indeed, a higher residual strength ratio does not necessarily correspond to a higher absolute strength after fire exposure [1,2,6].

3.2 Moisture Content

Moisture content is a critical parameter governing the fire performance of concrete because it simultaneously influences heat transfer, the development of pore pressure, crack formation, and spalling behaviour. During the initial stages of heating, moisture can temporarily slow the temperature increase by absorbing thermal energy. However, as the temperature rises, the resulting water vapour may be unable to migrate through the pore network, leading to a build-up of pore pressure. The combined effects of this pressure, thermally induced stresses, and the progressive reduction in the tensile strength of concrete may eventually exceed the material's resistance, thereby causing cracking and spalling. Therefore, the influence of moisture cannot be evaluated independently of permeability, pore connectivity, matrix density, heating rate, and cross-sectional dimensions [7–9]. This interaction also links moisture-related behaviour to the aggregate-related mechanisms discussed in Section 3.1, since aggregate porosity, interfacial characteristics, and thermophysical properties influence both moisture transport and thermally induced cracking [1,10,11].

The influence of moisture varies considerably with temperature. At moderate temperatures, internal moisture may provide temporary thermal buffering through latent heat absorption and may support ongoing hydration or pozzolanic reactions. Previous studies have reported either limited strength loss or an increase in strength at approximately 200 °C in specimens with high moisture contents, whereas drier mixtures exhibited earlier deterioration due to dehydration. However, this beneficial effect disappeared as the temperature increased. At approximately 400 °C, the decomposition of hydration products, pore coarsening, thermal incompatibility, and cracking within the interfacial transition zone became dominant. At 600 °C, a higher moisture content generally resulted in lower residual strength and more severe physical damage [7–9]. Therefore, moisture should not be regarded as either entirely beneficial or entirely detrimental to the fire performance of concrete.

In one of the studies reviewed, fully saturated normal-strength concrete did not exhibit spalling, whereas saturated high-strength concrete experienced significant spalling and a sudden loss of strength between 400 and 600 °C [7]. Similarly, another study reported that larger high-strength concrete specimens suffered severe damage under moist and saturated conditions, whereas dry specimens maintained their integrity more effectively [9]. These findings were attributed to the connected pore network of normal-strength concrete, which facilitates the continuous transport and release of water vapour, and to the dense and less

interconnected pore structure of high-strength concrete, which restricts vapour migration and pressure dissipation. This observation provides a direct link to the influence of the water-to-cement ratio discussed in Section 3.3. Although a low water-to-cement ratio improves strength and durability at ambient temperature, the resulting dense microstructure may increase susceptibility to fire-induced spalling when sufficient internal moisture is present.

Because water is generally distributed heterogeneously within concrete, total moisture content alone cannot fully explain its fire performance. Studies have shown that partial drying primarily removes moisture from the outer layers of concrete, while the inner regions remain relatively moist, thereby creating steep surface-to-core moisture gradients. Furthermore, larger specimens experienced more severe damage at 600 °C because water vapour had to travel a greater distance to reach the surface, resulting in moisture becoming trapped within the inner regions [9]. Direct pore-pressure measurements revealed that the maximum pressure did not occur at the heated surface but at an intermediate depth, where inward vapour migration and condensation created a moisture-clogged zone. In mixtures that exhibited spalling, peak pore pressures of approximately 3.29–6.03 MPa were recorded at a depth of 30 mm [8]. These results demonstrate that cross-sectional geometry, drying depth, and internal moisture distribution are at least as important as the average moisture content in determining the fire performance of concrete.

The studies reviewed demonstrate that the influence of moisture cannot be evaluated independently of the internal composition of concrete, because vapour transport is governed by aggregate characteristics and matrix permeability. One study reported that concrete containing siliceous–calcareous aggregates rich in flint developed significantly more internal cracking than concrete produced with calcareous or quartzite aggregates. This behaviour was attributed to the lower permeability and greater moisture sensitivity of the flint particles, which promoted localised vapour accumulation and internal damage as the temperature increased [10]. Moreover, another study demonstrated that temperature distribution within concrete depends not only on the thermal conductivity of the aggregates but also on moisture redistribution and the latent heat associated with water evaporation. This finding confirms that the thermal properties of aggregates alone cannot fully explain the fire performance of concrete [11]. By contrast, more favourable behaviour has been observed in lightweight aggregate concrete [1]. Lightweight aggregates have been shown to improve thermal compatibility between the aggregate and cement paste, while other studies have reported less extensive cracking, lower thermal conductivity, and better residual mechanical properties than those observed in concrete containing conventional aggregates [2,6]. Although these studies did not directly measure pore pressure, their findings suggest that, provided they are not fully saturated, porous lightweight aggregates may offer additional internal space for accommodating water vapour and redistributing stresses, thereby reducing thermally induced damage.

3.3 W/C Ratio

The water-to-cement ratio plays a decisive role in the fire performance of concrete by governing its initial strength, porosity, permeability, degree of hydration, and the quality of the interfacial transition zone.

The studies reviewed generally indicate that concrete with a lower water-to-cement ratio retains a higher absolute compressive strength after heating. In one study, reducing the water-to-cement ratio decreased the apparent porosity at ambient temperature and significantly increased both the initial and residual compressive strengths [12]. Another study similarly reported higher residual mechanical capacities for mixtures with lower water-to-cement ratios, although the mixture designs also differed in terms of cement content and initial strength [3].

The studies reviewed indicate that the influence of the water-to-cement ratio varies with temperature. Temporary increases in strength have been observed at approximately 200–300

°C, although the magnitude of these increases differed among studies because of variations in initial moisture content, pre-drying conditions, cement content, aggregate type, and heating method. Above 300 °C, C–S–H dehydration, portlandite decomposition, pore coarsening, and thermally induced microcracking become increasingly dominant. Under these conditions, concrete with a high water-to-cement ratio generally deteriorates more rapidly because its weaker and more porous interfacial transition zone facilitates crack propagation [3,12]. Another study observed similar low-temperature strength fluctuations in hardened cement paste without aggregates, confirming that these changes arise directly from the characteristics of the cementitious matrix rather than solely from aggregate-related mechanisms [13]. However, previous studies have also demonstrated that modifications to the cementitious matrix can alter the relative performance of aggregates at elevated temperatures. Therefore, the effects of aggregate type and water-to-cement ratio should be considered together. Aggregate type governs heat transfer, thermal expansion, and aggregate–matrix incompatibility, whereas the water-to-cement ratio influences matrix quality, permeability, and the integrity of the interfacial transition zone ([3], [10–12]).

The influence of a low water-to-cement ratio at elevated temperatures varies according to the mechanical property under consideration. Concrete with a lower water-to-cement ratio has been observed to retain higher residual compressive strength and fracture energy. By contrast, unstable fracture toughness decreased similarly at elevated temperatures across all mixture types. This finding indicates that a dense cementitious matrix may delay crack initiation and propagation but cannot prevent the widespread thermal damage that ultimately leads to unstable cracking at high temperatures [12]. Furthermore, the dense, low-permeability microstructure produced by a low water-to-cement ratio may increase pore pressure, particularly under moist conditions, thereby increasing the severity of spalling [7–9]. Consequently, although a low water-to-cement ratio may be advantageous under controlled heating or relatively dry conditions, it can increase susceptibility to spalling when rapid heating and high internal moisture levels occur simultaneously.

3.4 Concrete Cover Thickness

Concrete cover enhances the fire resistance of reinforced concrete members by delaying heat transfer to the reinforcing steel and the relatively less-damaged concrete core. However, the studies reviewed indicate that this protective effect is not uniform under all conditions and that increasing the concrete cover thickness does not necessarily result in a proportional increase in residual load-bearing capacity.

An experimental study directly compared concrete cover thicknesses of 20 and 30 mm and found that, particularly at low and moderate temperatures, the thicker cover provided better protection for both concrete integrity and the tensile properties of the reinforcement by extending the heat-transfer path between the exposed surface and the reinforcing steel [14]. Similarly, another study investigated recycled-aggregate reinforced concrete columns with cover thicknesses of 30, 40, and 50 mm. Increasing the cover thickness reduced the temperatures within the concrete core and reinforcement, thereby improving the axial load-bearing capacity. However, the magnitude of this improvement became progressively less pronounced as the cover thickness increased [15]. These findings suggest that concrete cover acts primarily as a thermal barrier during the initial stages of heat exposure. By contrast, another study reported that concrete cover thicknesses ranging from 20 to 50 mm had no statistically significant effect on the post-fire yield and tensile strengths of embedded reinforcing bars exposed to the ISO 834 standard fire curve [16]. This apparent discrepancy can largely be explained by the different response variables considered in the respective studies. Kigha et al. (2015) evaluated reinforcing bars isolated from the surrounding concrete after cooling, whereas Chen et al. (2020) and Khiyon et al. (2019) investigated the performance of composite

reinforced concrete members, in which a thicker cover primarily reduced reinforcement heating and deterioration of the inner concrete rather than directly altering the residual properties of the cooled reinforcing steel. A comparison of these studies clearly demonstrates that the protective role of concrete cover may depend on the duration of thermal exposure and the depth reached by the thermally damaged zone. Chen et al. (2020) observed that prolonged heating at 600 °C significantly reduced the benefit provided by a thicker concrete cover compared with short-term heating, as thermal damage penetrated deeper into the cross-section. Similarly, another study examining conventional and self-compacting concrete beams subjected to different fire durations and cooling regimes showed that the influence of cover thickness depended on the concrete type, heating duration, and cooling method [17]. Water-cooled beams experienced greater strength losses than air-cooled specimens because rapid cooling induced thermal shock and additional cracking. This deterioration was particularly severe in higher-strength self-compacting concrete and was attributed to its denser pore structure, lower permeability, and greater susceptibility to vapour-pressure-induced damage. These findings indicate that increasing the concrete cover thickness may not necessarily improve fire performance when the outer concrete layer is susceptible to thermal cracking or spalling.

3.5 Fibre Reinforcement

Fibre reinforcement can improve the fire performance of concrete through two distinct mechanisms. Steel and glass fibres, which have relatively high melting temperatures, primarily preserve mechanical integrity by bridging thermally induced cracks. By contrast, polymeric fibres with low melting temperatures, such as polypropylene and polyethylene fibres, are incorporated to mitigate pore-pressure-induced spalling by melting during heating and facilitating vapour transport. However, the studies reviewed indicate that fibre effectiveness depends not only on fibre type and dosage but also on melting behaviour, geometry, matrix permeability, initial moisture content, and the continuity of the channels formed within the concrete during heating [8,18,19].

A previous study investigated the physical, mechanical, and microstructural properties of self-compacting concrete mixtures containing different types of fibres—polypropylene, glass, and steel—at elevated temperatures while maintaining the same base mixture composition [18]. The results demonstrated that steel fibres had a pronounced effect on preserving the structural integrity and mechanical properties of concrete. Because steel fibres retained their crack-bridging capacity as the temperature increased, they provided the highest residual compressive and tensile strengths, whereas glass fibres produced more moderate improvements. By contrast, polypropylene fibres exhibited behaviour that differed from that of the other fibre types. At ambient temperature, polypropylene fibres provided only a limited improvement in tensile behaviour compared with the unreinforced specimens, while their residual compressive and tensile strengths generally remained lower as the temperature increased. This outcome was attributed to the melting of polypropylene fibres at approximately 150–170 °C. As the temperature increased further, the fibres largely disappeared from the matrix and left additional voids, thereby reducing the residual mechanical properties of the concrete. Nevertheless, this finding does not imply that polypropylene fibres are ineffective under fire exposure. Their primary function is not to preserve post-fire strength but to melt and form pathways that facilitate vapour release, thereby reducing the risk of explosive spalling. Because the specimens in the study were pre-dried at 105 °C, most of the free moisture was removed before heating. Consequently, the results primarily reflect the influence of fibre melting on the residual mechanical properties rather than the ability of polypropylene fibres to prevent explosive spalling.

A previous study demonstrated that fibre melting does not necessarily provide effective vapour-pressure relief. The study investigated dense, high-strength engineered cementitious

composites containing polyethylene fibres under five different moisture conditions [8]. Severe explosive spalling occurred in specimens with high moisture contents because of the accumulation of internal pore pressure.

Another study compared the thermal and mechanical behaviour of conventional concrete with that of ultra-high-performance fibre-reinforced concrete containing steel microfibres under elevated temperatures [19]. The results showed that increasing the steel-fibre dosage enhanced the initial tensile and flexural properties of the ultra-high-performance fibre-reinforced concrete and improved crack control; however, it did not eliminate the susceptibility of the dense matrix to fire-induced damage. Although a higher fibre dosage contributed to better preservation of concrete integrity, explosive spalling continued to occur at elevated temperatures, and the residual compressive strength decreased markedly at temperatures above approximately 500 °C.

4 Discussion and Conclusions

This section provides a comparative evaluation of the key parameters affecting the fire performance of concrete, as discussed in the preceding section. It further examines the implications of the damage mechanisms governing concrete behaviour at elevated temperatures for fire-resistant concrete design.

The studies reviewed demonstrate that the fire performance of concrete cannot be explained by any single material- or design-related parameter. Aggregate type, moisture content, water-to-cement ratio, concrete cover thickness, and fibre reinforcement influence concrete behaviour through different mechanisms. Because an improvement in one parameter may simultaneously affect another damage mechanism, these parameters must be evaluated in terms of their combined and interacting effects.

Aggregate mineralogy and structure govern phase transformations and thermal expansion at elevated temperatures, whereas aggregate porosity and moisture-retention capacity influence internal vapour transport. Nevertheless, the findings indicate that classifying aggregates solely according to type is insufficient for predicting or improving the fire performance of concrete. A particular aggregate may exhibit satisfactory performance within one cementitious matrix yet promote more extensive internal cracking in another matrix with a different water-to-cement ratio or moisture content. Therefore, the thermal compatibility between the aggregate and cement paste, the integrity of the interfacial transition zone, moisture condition, and matrix permeability should be evaluated collectively. The studies reviewed further demonstrate that not only average moisture content but also drying depth, surface-to-core moisture gradients, and pore-pressure development play significant roles in the behaviour of concrete at elevated temperatures. From a design perspective, the findings indicate that fire-resistant concrete cannot be achieved solely by targeting high initial strength or low permeability. An appropriate mixture design should establish a balance among adequate mechanical strength, thermal compatibility, and controlled vapour-transport capacity. The aggregate should be thermally and mechanically compatible with the cementitious matrix; the water-to-cement ratio should provide the required strength without producing an excessively impermeable microstructure; and fibre type and dosage should be selected according to whether the primary objective is crack control or pore-pressure relief. In this context, hybrid fibre systems combining steel and polymeric fibres may be employed to preserve mechanical performance while simultaneously facilitating vapour release. Further experimental research should therefore investigate the effectiveness of such hybrid fibre systems under fire exposure. A major limitation of the existing literature is that these parameters have generally been investigated independently and that many studies have been conducted using small-scale, unloaded, and pre-dried specimens. Future research should examine their combined effects under more representative conditions, including realistic

moisture states, structural loading, large-scale members, different fire-exposure durations, and various cooling regimes.

Effect of Structural Steel Profile Geometry on the Cyclic Behavior of SRC Columns: A Numerical Investigation

Halit Erdem Çolakoğlu[1]

Abstract. Steel-reinforced concrete (SRC) columns are composite structural members created by embedding structural steel sections into concrete, offering higher ductility and energy dissipation capacity compared to conventional reinforced concrete columns. While the geometric shape of the steel section embedded within the cross-section is a key parameter affecting the cyclic behavior of SRC columns, there are limited studies in the literature that evaluate this effect independently of the amount of steel and cross-sectional properties. In this study, the behavior of 300×300 mm SRC columns containing structural steel sections with box, H, and plus (+) cross-sections—whose cross-sectional areas and moments of inertia were kept similar—under cyclic lateral loading was numerically investigated using the Abaqus finite element program. Concrete was modeled using the Concrete Damaged Plasticity (CDP) model, while the reinforcing steel and structural steel were modeled using multilinear material models derived from experimental stress-strain curves. Cyclic horizontal displacements with gradually increasing amplitude, in accordance with the FEMA 461 protocol, were applied to the columns. The results showed that the model with the plus (+) cross-section achieved significantly higher horizontal load-carrying, displacement, and energy dissipation capacities compared to the other two geometries; while the box and H-section profiles exhibited similar behavior, the H-section profile exhausted its capacity at a lower displacement level. In contrast, no significant difference was observed among the three profile geometries examined in terms of the secant stiffness-displacement ratio. The findings reveal that, in SRC column design, structural steel profile geometry is a critical design parameter that determines ductility and energy dissipation performance, particularly during the advanced deformation stage, while it has only a secondary effect on global stiffness behavior.

Keywords: SRC column, energy dissipation capacity, cyclic loading, steel profile shape.

1 Introduction

Steel-reinforced concrete (SRC) columns are composite load-bearing members in which structural steel sections work in conjunction with reinforcement within a reinforced concrete cross-section. The combined use of concrete and steel can provide higher load-carrying capacity, ductility, and energy dissipation potential compared to reinforced concrete columns; the concrete cover also contributes to protecting the structural steel against fire effects and local buckling. Due to these characteristics, SRC columns have become an important alternative composite structural system, particularly in buildings subjected to both high vertical loads and seismic effects [1, 2, 3, 4].

Experimental and numerical studies on the seismic behavior of SRC columns have revealed the effects of numerous parameters—such as the axial load ratio, steel ratio, cross-sectional shape, transverse reinforcement, concrete confinement conditions, slenderness, shear span, and

concrete strength—on cyclic behavior. In particular, the reduction in horizontal load capacity, strength, and stiffness under cyclic loading, as well as displacement/ductility capacity and energy dissipation capacity, are used as key indicators in evaluating the seismic performance of SRC columns. However, it has been reported that the literature on the seismic behavior of SRC columns remains more limited compared to that for reinforced concrete and steel members, and there is a need to increase experimental data, particularly regarding nonlinear modeling and performance evaluation [5].

The geometry of the steel section within the cross-section is one of the key variables that can influence the behavior of SRC columns. Section geometry can affect not only the distribution of the steel within the cross-section but also the contact and interaction conditions between the steel and concrete, the way the concrete core is enclosed, and the development of nonlinear deformations. Indeed, the cyclic behavior of SRC columns using I-shaped, H-shaped, and cross-section/special-shaped steel profiles has been investigated in the literature; it has been shown that the profile shape can influence performance indicators such as load-carrying capacity, ductility, reduction in stiffness, and energy dissipation [6].

In particular, studies conducted on cross-shaped steel sections indicate that the geometry of steel sections should not be considered merely as a cross-sectional property in the seismic behavior of SRC columns. An experimental study conducted by Mostafa et al. demonstrated that the horizontal load capacity, displacement, and ductility behavior of SRC columns with different steel section configurations vary [7]. Similarly, experimental and numerical studies examining the cyclic behavior of SRC columns with T- and L-shaped steel sections have reported that section geometry and the associated asymmetric confinement conditions influence damage mechanisms and seismic performance [8].

However, a significant portion of existing studies also alter the steel content, cross-sectional area, confinement conditions, or other geometric variables while modifying the profile geometry. Consequently, it is not always possible to distinguish whether the observed performance differences stem directly from the profile geometry or from changes in steel content and cross-sectional properties. A comprehensive literature review on SRC columns has also noted that studies have largely focused on traditional and simple steel profile arrangements, while research on different profile configurations has been more limited [1]. This situation makes the question of how different geometric arrangements of profiles with similar steel quantities and similar cross-sectional inertia properties affect the cyclic performance of SRC columns particularly important. From an engineering perspective, this question is directly related to design optimization: Could selecting a different profile geometry while using the same amount of structural steel alter not only the column's elastic stiffness but also its advanced displacement capacity and the energy it can dissipate during an earthquake? The answer to this question is important for evaluating whether profile selection based solely on steel area, strength, or moment of inertia is sufficient.

In this study, to answer this research question, the behavior of SRC columns with three different structural steel profile geometries—whose cross-sectional areas and moments of inertia were kept similar—under cyclic lateral loading was investigated using the finite element method. In the models created using box, H, and plus (+) section profiles, the concrete, reinforcement, column geometry, axial load level, and loading conditions were kept constant; thus, the steel profile geometry was highlighted as the key variable for comparison. The models were compared in terms of lateral load–displacement behavior, secant stiffness reduction, and cumulative energy dissipation capacity.

The primary objective of this study is to determine which performance indicators are most significantly influenced by different profile geometries—which have similar steel content and inertia properties—in the cyclic behavior of SRC columns. In this context, the study aims to evaluate the effect of profile geometry on global stiffness separately from its effects on

advanced deformation, strength retention, and energy dissipation capacity. It is intended that the results obtained will contribute to the evaluation of structural steel profile selection for SRC columns not only based on cross-sectional area and elastic section properties but also in terms of nonlinear deformation and energy dissipation performance.

2 Numerical Model

2.1 Column Geometry, Reinforcement Arrangement, and Structural Steel Profiles

The SRC column models under investigation were designed with a 300×300 mm square cross-section and a total height of 2,950 mm. The 500-mm-long regions at the top and bottom ends of the column are support/loading head (rigid end) regions, where closely spaced Ø8/50 transverse reinforcement (stirrups) was used. In the 1,950-mm-long middle section of the column, Ø8/100 spaced transverse reinforcement was applied. Eight Ø18 ribbed reinforcing bars were used as longitudinal reinforcement in all cross-sections, and the concrete cover thickness was assumed to be 25 mm. The column geometry, reinforcement arrangement, and the placement of reinforcement and steel profiles in the A-A cross-section are shown in Figure 1.

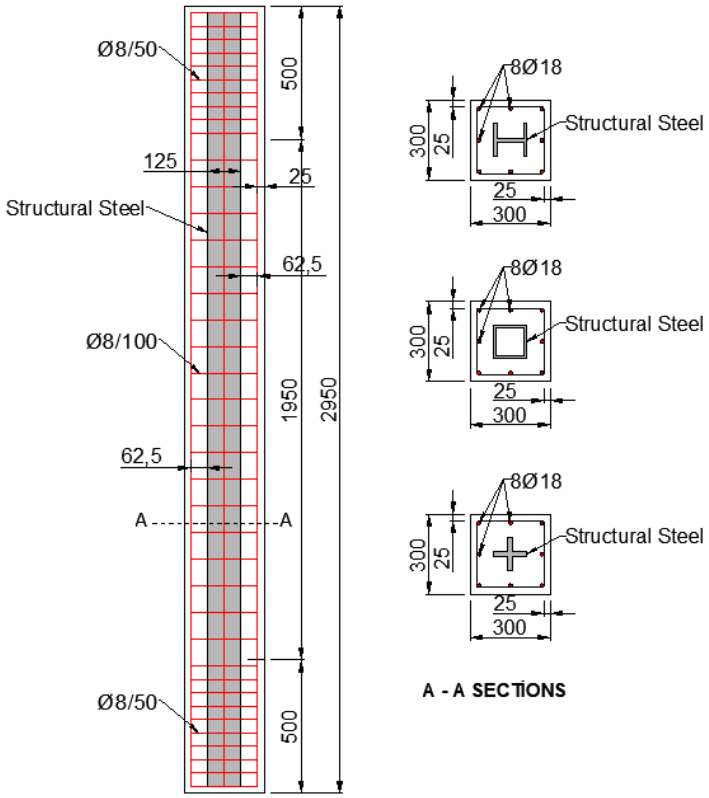

Fig. 1. Column geometry, reinforcement arrangement, and steel profile placement in the A-A cross-sections

Structural steel profiles with different geometries were placed at the center of the cross-section, such that they would fit within a 125×125 mm envelope area in all models: (i) an H-section profile, (ii) a box (square-section) profile, and (iii) a plus (+)-section profile. The outer envelope dimensions of all three profiles were set to 125×125 mm, and the web thicknesses were adjusted so that the cross-sectional areas (approximately 4540–4600 mm²) and, consequently, the moments of inertia would be similar. For the H-section profile, the flange thickness is 13 mm, the web thickness is 13 mm, and the net web height is 99 mm; for the box-section profile, the web thickness is 10 mm (internal opening 105×105 mm); and for the plus-section profile, the leg thickness is 20 mm. The cross-sectional dimensions of the profiles are shown in Figure 2.

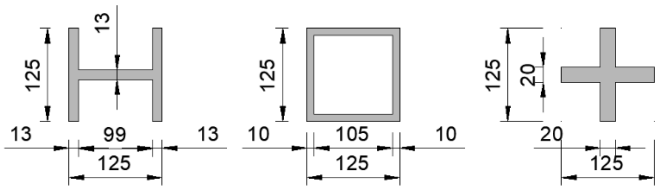

Fig. 2. H, box sections, and plus (+) sections: cross-sectional dimensions of structural steel sections (mm)

2.2 Material Models and Mechanical Properties

Concrete with a compressive strength of 30 MPa was used in all SRC column models considered in this study, and the stress–strain relationships for the concrete under compression and tension are shown in Figure 3.

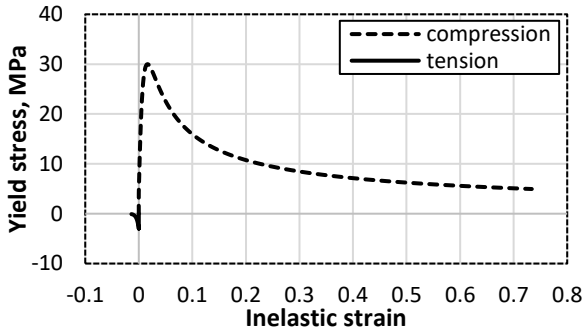

Fig. 3. The stress–inelastic strain relationship for concrete

The reduction in stiffness resulting from cracking and crushing in concrete under cyclic lateral loads was simulated in ABAQUS using stiffness reduction parameters (Figure 4).

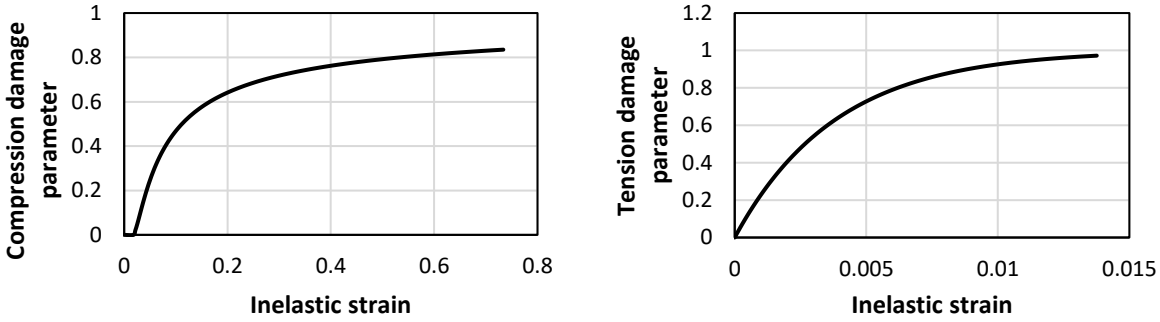

Fig. 4. Stiffness reduction parameters for concrete under compression and tension

The stress-strain behavior of the reinforcing steel and structural steel sections was modeled using a multilinear plasticity model based on the experimental axial tensile curves shown in Figure 5.

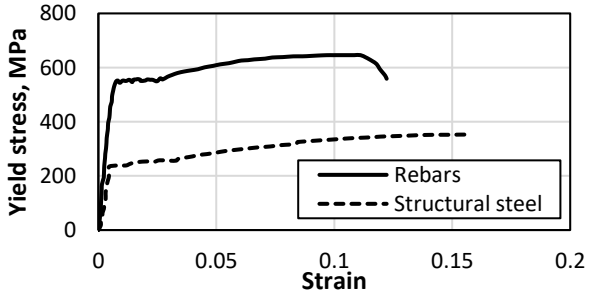

Fig. 5. The stress–strain relationship of reinforcing steel and structural steel

The values for the modulus of elasticity and Poisson's ratio for concrete, reinforcing bars, and structural steel are given in Table 1.

Table 1. Mechanical properties of materials

Materials	Elastic Modulus, E (MPa)	Poisson ratio, ν	Yield stress (MPa)	Tension stress (MPa)
Concrete	26366	0.18	-	-
Rebars	200000	0.30	552	645
Structural steel	200000	0.30	252	350

The concrete material was modeled in Abaqus using the Concrete Damaged Plasticity (CDP) model. Accordingly, the CDP plasticity parameters used in the finite element model are shown in Table 2.

Table 2. CDP plasticity parameters

Dilation angle, ψ	Eccentricity, e	f_{b0}/f_{c0}	K	Viscosity
37°	0.1	1.16	0.667	0.001

2.3 Finite Element Modeling

The column models were created in the Abaqus finite element software. Concrete and structural steel sections were modeled using the C3D8R element, an 8-node, reduced-integration 3D solid element; while longitudinal and transverse reinforcements were modeled using the T3D2 element, a 2-node 3D truss/link element. The reinforcement was defined as embedded within the concrete member using an "embedded region" constraint. The structural steel was simulated in accordance with the friction-based connection interaction model, using a friction coefficient of 0.6 and surface-to-surface interaction (Figure 6). The lower end of the column was fixed in all degrees of freedom; a constant axial compression load was first applied to the upper end, followed by a displacement-controlled cyclic horizontal displacement (Figure 6).

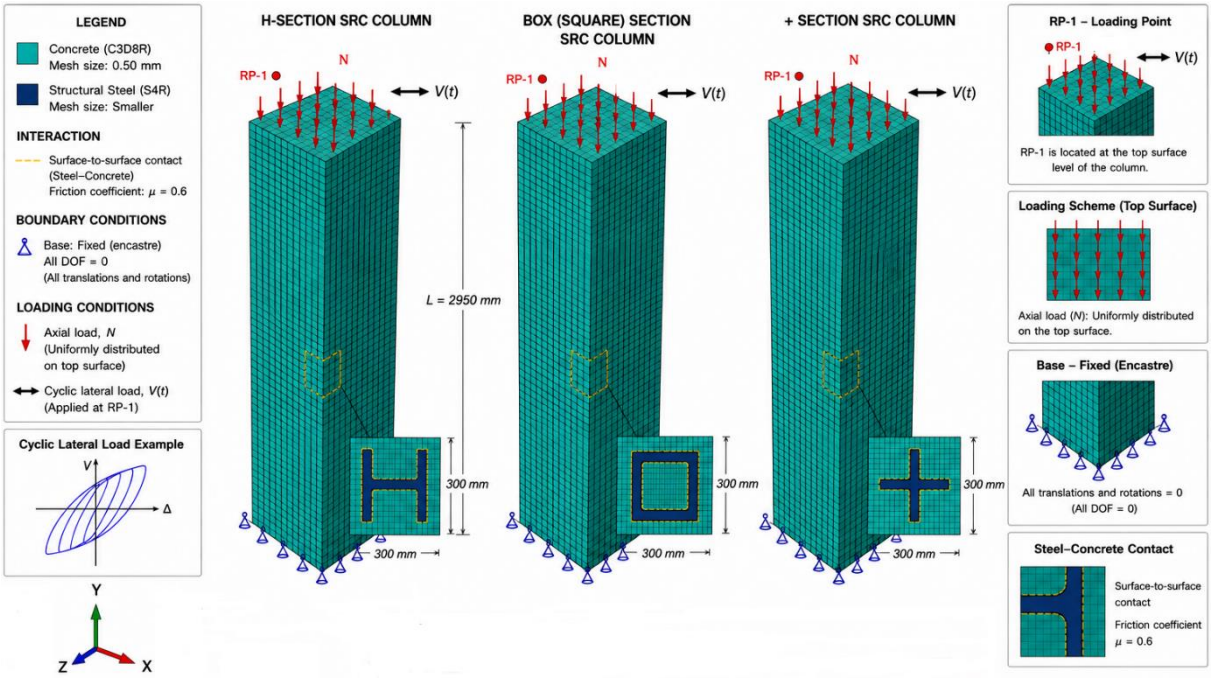

Fig. 6. Finite element models of SRC column members, boundary and loading conditions

2.4 Loading Protocol

In all analyses, a cyclic lateral displacement was applied from the RP-1 point—located at the same level as the column top—to the column top, with displacement control and a gradually increasing amplitude, in accordance with the FEMA 461 loading protocol. In the loading protocol shown in Figure 7, the amplitude was increased at each loading stage, starting with a low-amplitude cycle that would cause the first crack to form in the SRC column. Loading was continued up to the final stage, corresponding to a horizontal displacement ratio of ±12.5%. The same loading protocol and the same axial load level were applied to all three models (SRC_box, SRC_H, SRC_+) to isolate the effect of the cross-sectional steel profile shape.

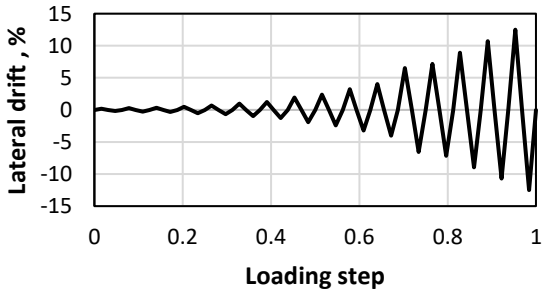

Fig. 7. Circular lateral loading protocol prepared in accordance with FEMA 461

3 Findings and Discussing

The relationships between the lateral load–lateral displacement ratio, stiffness–lateral displacement ratio, and energy dissipation capacity–lateral displacement ratio—obtained from cyclic analyses of SRC column models containing box, H-shaped, and plus (+)-shaped structural steel sections—are presented in a comparative manner in Figures 8–10.

3.1 Lateral Load–Lateral Drift Relationship

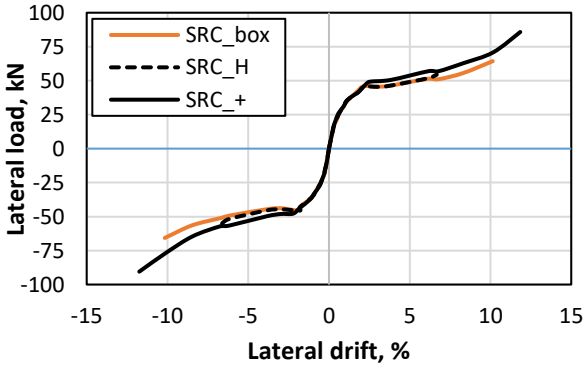

Fig 8. Horizontal load–horizontal displacement ratio envelope curves for the SRC_box, SRC_H, and SRC_+ models

Figure 8 compares the horizontal load–horizontal displacement ratio envelope curves for the SRC_box, SRC_H, and SRC_+ models. The results indicate that the geometric shape of the structural steel section has a significant effect on the horizontal load-carrying capacity and deformation capacity of SRC columns at high displacement levels. In particular, the SRC_+ model, which incorporates a plus (+) cross-section, achieved higher horizontal load levels in both positive and negative loading directions compared to the other two models.

The SRC_+ model maintained its load-carrying capacity up to a lateral displacement ratio of approximately 12% and reached a maximum horizontal load value of approximately 85–90

kN at this level. In contrast, the maximum horizontal load capacities of the SRC_box and SRC_H models remained in the range of approximately 60–65 kN. Thus, although the cross-sectional areas and moments of inertia of the steel sections were kept similar, it is evident that the profile geometry can result in a significant difference in horizontal load-carrying capacity. This result indicates that not only the amount of structural steel used but also its distribution within the cross-section and the manner of its interaction with the concrete may play a significant role in the behavior of composite columns.

While it is noteworthy that the maximum horizontal load capacities of the SRC_box and SRC_H models are similar, it is evident that these two models differ significantly in terms of their deformation capacity. While the SRC_H model exhausted its capacity at a horizontal displacement ratio of approximately 6–7% and was excluded from the analysis, the SRC_box model maintained its load-carrying capacity up to a displacement ratio of approximately 10%. Therefore, although the I-beam and box profiles reached similar horizontal load levels, it can be said that they did not demonstrate equivalent performance in terms of cyclic deformation capacity. This situation demonstrates that profile geometry must be evaluated not only in terms of maximum strength but also in terms of the ability to maintain that strength through advanced deformation levels.

The fact that the SRC_+ model exhibits higher strength and displacement capacity compared to the other two models can be attributed to the geometry of the plus-section profile—which radiates in four directions from the section center—ensuring a more balanced distribution of steel within the composite section. This geometry may have contributed to a more balanced interaction between the steel profile and the surrounding concrete in different directions and to the preservation of composite behavior for a longer duration at advanced displacement levels. The fact that this geometric effect becomes more pronounced during stages where deformations increase under cyclic loading can be considered a possible mechanism explaining the SRC_+ model's ability to maintain its load-carrying capacity up to a 12% displacement level.

3.2 Relationship Between Stiffness and Lateral Drift Relationship

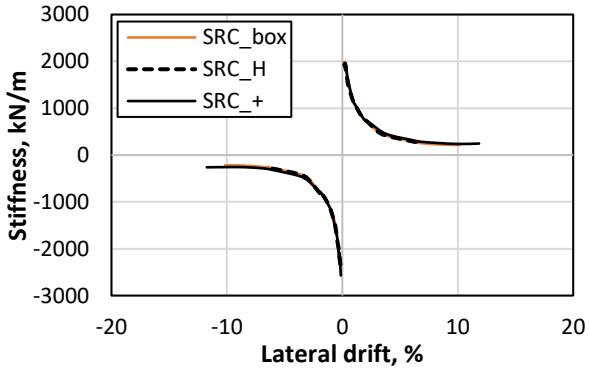

Fig 9. Stiffness–lateral drift relationships for the SRC_box, SRC_H, and SRC_+ models

Figure 9 compares the secant stiffness–lateral displacement ratio relationships for the SRC_box, SRC_H, and SRC_+ models. Secant stiffness was evaluated based on the slope between the load and displacement values for each cyclic displacement level and was used to determine the change in the column's stiffness under cyclic loading. This approach allows for the evaluation of the effects of concrete cracking, material nonlinearity, and damage accumulation on cross-sectional behavior under cyclic loading.

One of the key findings of the study is that the secant stiffness–displacement ratio curves for SRC columns with different structural steel profile geometries are quite similar. Since the cross-sectional areas and moments of inertia of box, H, and plus (+) section profiles are kept close to

one another, it is observed that the profile geometry does not result in a significant difference in secant stiffness. This result suggests that, among the parameters examined, the global section stiffness is controlled more by the overall mechanical properties of the composite section—formed by the concrete, reinforcement, and structural steel—rather than by the geometric shape of the profile itself.

In other words, while all three models may exhibit a similar overall decrease in stiffness during cyclic loading, the level of deformation up to which this stiffness—along with the load-carrying capacity—can be maintained varies depending on the profile geometry. This indicates that the seismic performance of SRC columns should not be evaluated solely based on stiffness loss. Despite similar trends in the reduction of secant stiffness, the differences observed in horizontal load capacity, maximum displacement capacity, and energy dissipation capacity indicate that profile geometry plays a more pronounced role in behavior, particularly during advanced stages of damage and deformation.

The fact that the secant stiffness–displacement relationships are similar for the three models is consistent with the fact that all models were examined under the same conditions in this study in terms of concrete, reinforcement, column geometry, axial load level, and loading protocol. Since the primary variable distinguishing the models is the cross-sectional geometry of the structural steel profile, the fact that the effect of profile geometry on global secant stiffness remains limited—while differences in load-carrying capacity and energy dissipation behavior emerge at advanced displacement levels—suggests that profile geometry may have a greater influence on composite interaction during stages where damage progresses further.

In particular, the fact that the secant stiffness curve of the SRC_H model does not diverge significantly from that of the other models, even though the SRC_H model is excluded from the analysis at a lower displacement level, provides an important insight. This result demonstrates that the secant stiffness of an SRC column at a specific deformation level does not, on its own, represent the element's strength and deformation capacity beyond that deformation level. Therefore, in the evaluation of cyclic behavior, secant stiffness must be considered in conjunction with horizontal load, displacement capacity, and energy dissipation capacity.

In general, under the parameters and loading conditions examined in this study, it was observed that the effect of structural steel profile geometry on the secant stiffness–horizontal displacement relationship of SRC columns is limited. Three different profile geometries, for which the cross-sectional area and moment of inertia were kept similar, exhibited similar trends in secant stiffness reduction. In contrast, significant differences emerged in the horizontal load-carrying capacity, maximum displacement capacity, and cumulative energy dissipation capacity.

3.3 Relationship Between Energy Dissipation Capacity and Lateral Drift

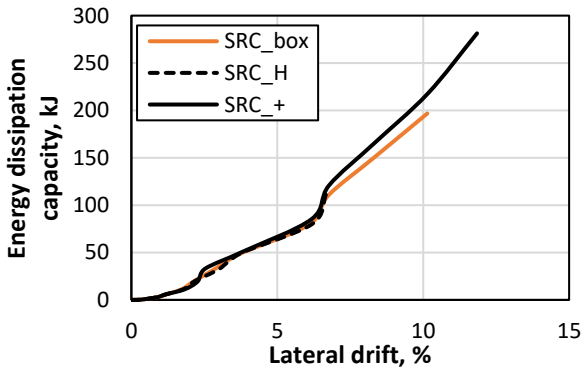

Fig 10. Cumulative energy dissipation capacity–lateral displacement ratio relationships for the SRC_box, SRC_H, and SRC_+ models

Figure 10 compares the energy dissipation capacity–horizontal displacement ratio relationships for the SRC_box, SRC_H, and SRC_+ models. Energy dissipation capacity was evaluated based on the cumulative sum of the areas formed by the load–displacement curves over the course of cycles during cyclic loading. This parameter is important not only for assessing the models' horizontal load-carrying capacity at a specific displacement level but also for evaluating the extent to which externally applied energy can be dissipated throughout the loading process.

Examining Figure 10, it can be seen that as the horizontal displacement ratio increases, there is a continuous increase in the energy dissipation capacity of all models. The primary reason for this is that, as the displacement level increases under cyclic loading, the area enclosed by the load–displacement curve grows with each loading cycle, leading to an increase in cumulative energy consumption. However, it is observed that the differences in energy dissipation among the models become particularly pronounced at higher displacement levels.

While the SRC_+ model achieved the highest energy dissipation capacity at approximately 280 kJ, the SRC_box model remained at approximately 210 kJ, and the SRC_H model at approximately 115 kJ. Accordingly, the energy dissipation capacity of the SRC_+ model is approximately 33% higher than that of the SRC_box model and approximately 59% higher than that of the SRC_H model. The energy dissipation capacity of the SRC_box model is also approximately 45% higher than that of the SRC_H model. These results demonstrate that the geometry of the structural steel profile has a significant effect on the energy dissipation capacity of SRC columns under cyclic loading.

This ranking of energy dissipation capacity is consistent with the horizontal load–displacement behavior shown in Figure 8. The SRC_+ model not only reached higher horizontal load levels but also maintained its behavior up to a displacement ratio of approximately 12%. While the SRC_box model maintained its capacity up to a displacement ratio of approximately 10%, the SRC_H model failed the analysis at a displacement ratio of approximately 6–7%. Therefore, it is understood that high energy dissipation capacity does not stem solely from high maximum horizontal load capacity but is also related to the element's ability to continue bearing loads at higher levels of deformation. In other words, the simultaneous preservation of strength and deformation capacity directly contributes to an increase in cumulative energy dissipation capacity.

From this perspective, it can be said that the effect of the profile geometry becomes more pronounced, particularly during the advanced deformation stage. Models with similar secant stiffnesses at low displacement levels exhibited different horizontal load-carrying and energy-dissipation capacities as the displacement level increased. This behavior suggests that the steel profile geometry, in conjunction with the concrete core and reinforcement, may influence the behavior of the composite section during the advanced deformation stage. However, since the current analysis results do not directly identify which components account for the difference in energy dissipation capacity, the contributions of mechanisms such as concrete damage, plasticization of the steel section, or interactions at the concrete–steel interface cannot be definitively distinguished within the scope of this study.

The fact that the SRC_+ model achieves the highest energy dissipation capacity should be evaluated in conjunction with its higher horizontal load-carrying capacity and higher displacement capacity. The geometric arrangement of the plus (+) cross-section profile, by altering the steel distribution within the composite section and the interaction conditions with the concrete, may have contributed to the load-carrying capacity being maintained for a longer period at advanced displacement levels. However, to verify this interpretation, it is necessary to further examine the profile stresses, plastic deformations, concrete damage variables, and the contact behavior at the concrete–steel interface.

It is also noteworthy that the SRC_H model achieved the lowest energy dissipation capacity, at approximately 115 kJ. Because this model was excluded from the analysis at a lower displacement level, it was able to dissipate energy within a more limited deformation range throughout the cyclic loading. Consequently, the low cumulative energy dissipation capacity obtained for the H-profile is related not only to the profile's low load capacity at a specific displacement level but also to its inability to reach higher displacement levels.

The results show that, among the three profiles examined, the SRC_+ model exhibited the most advantageous behavior in terms of overall cyclic performance, the SRC_box model ranked second, and the SRC_H model demonstrated more limited performance, particularly in terms of forward displacement and energy dissipation capacity. However, it should be noted that this ranking applies only to the concrete strength, steel profile properties, axial load level, cross-sectional geometry, and loading protocol used in this study; the effect of profile geometry must be reevaluated under different design and loading conditions.

4 Conclusions

In this study, the effect of three different structural steel profile geometries—with similar cross-sectional areas and moments of inertia—on the cyclic behavior of SRC columns was investigated numerically. The findings reveal that the effect of profile geometry cannot be explained solely by the elastic properties of the cross-section and becomes more pronounced, particularly during the advanced deformation stage. The main conclusions drawn from the study are summarized below.

The geometry of the steel profile affects the advanced deformation capacity of SRC columns more than their global secant stiffness. The fact that significant differences arise in the models' horizontal load-carrying, displacement, and energy-damping performance—despite similar trends in secant stiffness—points to the role of profile geometry in the composite section, particularly during the nonlinear behavior phase.

Similar amounts of steel and similar moments of inertia do not result in similar cyclic performance. This finding indicates that selecting profiles for SRC columns based solely on cross-sectional parameters—such as steel area or moment of inertia—may not be sufficient. The geometric distribution of steel within the cross-section should be considered as an independent design variable in terms of advanced deformation capacity and energy dissipation performance.

From an engineering design perspective, the selection of profiles for SRC columns—where high deformation is expected, particularly under seismic loads—should not be based solely on the approach of increasing the maximum horizontal load. Maintaining horizontal load capacity at high displacement levels and energy dissipation capacity should also be part of the design decision. In this regard, the behavior exhibited by the plus (+) section profile among the profile geometries examined in this study suggests the potential to optimize profile geometry performance without increasing the amount of steel. However, this conclusion is limited by the scope of the current numerical model and should not be interpreted as a direct design recommendation.

A key limitation of this study is that the effect of the profile geometry was examined only within the context of a single column geometry, material properties, axial load level, and cyclic loading protocol. Therefore, it should be noted that the performance rankings obtained may vary under different design conditions.

In future studies, parametric analyses should be conducted for different axial load ratios, concrete strengths, and steel section sizes and geometries; furthermore, concrete damage, steel plasticity, and the interaction at the concrete–steel interface should be examined in detail. In particular, multivariate studies supported by experimental work can contribute to translating the

effect of profile geometry on the ductility and energy dissipation capacity of SRC columns into generalizable design parameters.

Abstract. Buildings damaged in the 2023 Kahramanmaraş earthquakes exposed persistent vulnerabilities of the Turkish reinforced concrete (RC) stock, notably soft stories and brittle column failures. Buckling-restrained braces (BRBs) offer a low-intrusion retrofit, but their optimal number and placement are hard to determine. This study couples the NSGA-II genetic algorithm with nonlinear response history analysis (NRHA) in OpenSeesPy to optimize BRB retrofits of five 10-story, 4-bay RC archetypes representing the pre-2000 stock (C16 concrete, S220 plain bars): a baseline frame, a pilotis frame, a gravity-consistent uniform pilotis (A4) with constant 400×400 mm columns, a geometric setback and a mid-height weak story, all assessed under a seven-record suite scaled to the TBDY 2018 DD-2 spectrum. A drift-based objective proves inadequate: it reduced drift yet increased collapse-level column hinges. A member-level damage index built from TBDY 2018 sec.15.3.2 hinge damage-zone classification and sec.7.5.2 joint shear checks is therefore adopted, and the knee point of a five-seed pooled Pareto front is taken as the optimal design. The central result is that seismic benefit is not confined to code-flagged irregularity: A4 is formally regular under TBDY 2018 Table 3.6 (max η_{ki} = 1.571 against the 2.0 threshold) yet its optimized retrofit removes collapse-level column damage entirely. An ablation shows that only the pairing of braces and column confinement produces the recovery. Two mechanisms limit the retrofit elsewhere: BRB diagonals amplify adjacent-column axial demands by up to 2.07 times and introduce column tension up to 503 kN, and joint shear demand-capacity ratios change by at most 3.0% between the bare and optimal states (1.31-1.37 in A1, A2, A3; 0.77-0.79 in A0, A4), being set by the 300×300 mm joints, not by brace placement. Optimally placed BRBs must therefore be paired with column confinement and joint strengthening.

1 Introduction

The February 6, 2023 Kahramanmaraş earthquake sequence caused heavy damage to, or the collapse of, a large number of reinforced concrete buildings, with soft or weak stories, insufficient transverse reinforcement, poor concrete quality and beam-column joint failures repeatedly identified among the governing deficiencies [1]. Field surveys in Malatya [2] and Hatay [3] document plain reinforcing bars and concrete strengths below 10 MPa [2], and strong beam-weak column behaviour and joint-shear failures concentrated in the older buildings [3]. These observations renewed attention on the seismic rehabilitation of the pre-2000 Turkish building stock, for which conventional interventions such as added shear walls or systematic column jacketing restore lateral capacity but impose large stiffness increases, foundation demands and severe architectural restrictions.

Buckling-restrained braces offer a less intrusive alternative. By encasing a yielding steel core in a mortar-filled restraining tube, the brace yields symmetrically in tension and compression without global buckling, producing full and stable hysteresis loops [4, 5]. Acting as replaceable structural fuses, BRBs concentrate inelastic deformation in the core while shielding the gravity system. Their component behaviour and frame-level demands are well

documented for steel construction [6, 7], where it is also established that brace yielding, rather than elastic load combinations, governs the axial demands delivered to the columns of braced bays [8, 9]. Applications to existing RC frames have demonstrated the feasibility of BRB retrofits, and Di Sarno and Manfredi, Sutcu et al. and Almeida et al. all stress that the force and stiffness delivered to the existing members must be controlled carefully [10-12].

Determining the optimal number and placement of BRBs in a deficient RC frame is a difficult combinatorial problem. Heuristic placement can relocate drift concentrations, overload the columns and joints at the brace connections, and transfer large forces to elements that were never designed for them. Formal optimization requires an objective function that reflects the failure modes the retrofit is intended to prevent, and an analysis engine rigorous enough to expose them.

Retrofit studies conventionally select case-study frames by their code-recognized irregularity, on the implicit assumption that a code trigger is what identifies a frame as a candidate for bracing. The contribution of this study is to test that assumption directly. Alongside four archetypes that span the irregularity types of TBDY 2018 [13] Table 3.6, a fifth archetype (A4) is included that is geometrically a pilotis, that is, a taller and open ground story, but is detailed with gravity-consistent, constant 400×400 mm columns over the full height. It is formally regular: neither the B1 strength check nor the B2 stiffness check is triggered. It is therefore a full, standalone fifth archetype and a design-sensitivity case, not a fourth irregularity type and not a variant of A1, and the question it answers is whether measurable seismic benefit from optimally placed BRBs requires a code-recognized trigger at all.

2 Methodology

2.1 Archetype frames and numerical modelling

Five 10-story, 4-bay plane RC frames are studied (Fig. 1, Table 1). A0 is the baseline control frame. A1 introduces a pilotis: a 4.5 m open ground story with 300×300 mm columns against 400×400 mm above, giving a strength ratio η_{ci} = 0.562 and triggering the B1 check. A4 retains the 4.5 m ground story but keeps 400×400 mm columns throughout, so the section schedule follows the gravity demand rather than creating an artificial weak story; it satisfies both B1 and B2 (Table 2). A2 introduces a geometric setback in which stories 7-10 narrow to two bays, and A3 a mid-height weak story with 300×300 mm columns at story 5 only. Materials deliberately represent the pre-2000 stock: C16 concrete and S220 plain bars throughout, with as-built transverse reinforcement of 2-leg D8 hoops at 200 mm.

All frames are modelled in OpenSeesPy [14]. Beams and columns are force-based elements with fibre plastic-hinge regions at both ends and an elastic interior, with hinge length Lp = 0.5h per TBDY sec.5.4.1. Core and cover concrete follow Concrete02 with the Mander et al. [15] confined and unconfined envelopes; reinforcing steel and the BRB core use Steel02 (Giuffre-Menegotto-Pinto). BRBs are corotational truss elements with a 3,000 mm² LYP235 core (fy = 235 MPa, post-yield ratio b = 0.02, yield force Py = 705 kN); the symmetric tension-compression yielding of the restrained core justifies a uniaxial truss representation. Expected material strengths are taken as the characteristic values per the Chapter 15 existing-building assessment assumption with a knowledge factor of 1.0. Rayleigh damping of 5% is anchored at the first two modes. In the retrofitted models, columns are simultaneously upgraded to seismic hoops (4-leg D10 at 100 mm), representing a confinement retrofit installed together with the braces; this doubles the collapse-limit concrete strain of sec.5.8.1 (adopted for existing buildings by sec.15.7.1.3) while leaving shear strength essentially unchanged. The two interventions are separated by the ablation of Section 3.5. Although the plane-frame analysis loads a single critical direction, the physical retrofit is intended to be

installed bidirectionally, with the optimized brace positions and identical member sizes mirrored in the orthogonal direction. That extension is not verified by the present model.

Table 1. Archetype geometry and code classification.

Archetype	Stories	H (m)	Geometry	Lower columns	Upper columns	Table 3.6 verdict
A0 — Baseline	10	30.0	Baseline control frame	400×400 8-D20	400×400 8-D20	B2
A1 — B1 Pilotis	10	31.5	Pilotis, 4.5 m open ground story	300×300 8-D16	400×400 8-D20	B1
A4 — Uniform Pilotis	10	31.5	Pilotis geometry, gravity-consistent sections	400×400 8-D20	400×400 8-D20	Regular
A2 — Geometric Setback	10	30.0	Geometric setback, stories 7-10 at two bays	400×400 8-D20	300×300 8-D16	B2
A3 — B1 Mid-Notch	10	30.0	Mid-height weak story at story 5	400×400 8-D20	400×400 8-D20 (story 5: 300×300 8-D16)	B1+B2

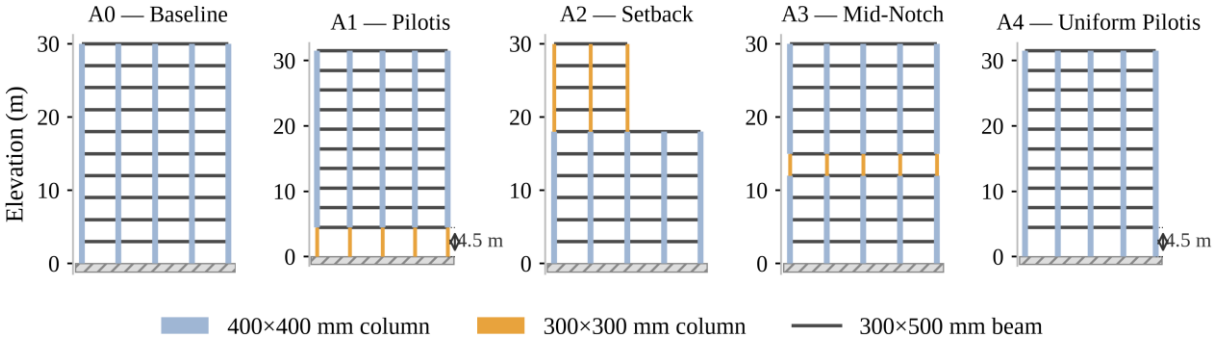

Fig. 1. Bare-frame elevations of the five archetypes, drawn to scale.

2.2 Seismic hazard and ground motions

The site is Bornova, İzmir (38.46 N, 27.22 E), soil class ZD, evaluated at the TBDY 2018 DD-2 hazard level (475-year return period; SDS = 1.148 g, SD1 = 0.542 g), the reference hazard for the Controlled Damage performance objective of existing buildings. Seven records are used: Kocaeli 1999, Düzce 1999, Erzincan 1992, Northridge 1994, El Centro 1940, Kobe 1995 and Chi-Chi 1999 (trimmed to its D5-D95 significant duration). Each is amplitude-scaled so that its mean spectral acceleration over $[0.2T_1, 1.5T_1]$ matches the DD-2 target over the same band. Scale factors are recomputed whenever the fundamental period changes, so bare and retrofitted models are each scaled consistently with the code procedure; Section 3.6 removes this scaling difference as a confound. The three Turkish records form a screening suite used inside the GA loop; all seven form the validation suite, and every quotable value below comes from the validation pass.

2.3 Irregularity classification

The B1 strength and B2 stiffness checks of TBDY 2018 Table 3.6 were computed from the elastic model rather than assumed from the geometry under a code lateral load pattern (Table 2). B1 flags a story whose effective shear area ratio η_{ci} falls below 0.80; B2 flags a stiffness ratio η_{ki} above 2.0. Because η_{ki} depends on the assumed load pattern, every check was repeated under both an inverted-triangular and a uniform pattern; the maximum difference in η_{ki} across all five archetypes is 0.122 and no verdict changes, so the verdicts do not depend on the load pattern. B1 is triggered by A1 and A3. B2 is triggered by A0, A2 and A3; A1 and A4 do not trigger B2. A4 triggers neither, with a maximum η_{ki} of 1.571 against the 2.0 threshold. It is the code-compliant geometry whose retrofit response Section 3.4 examines.

Table 2. TBDY 2018 Table 3.6 checks, both lateral load patterns.

Archetype	B1?	min η_{ci}	B2? (tri)	max η_{ki} (tri)	critical story	max η_{ki} (uniform)	$\lvert\Delta\rvert$
A0 — Baseline	False	1.000	True	2.905	2	2.799	0.105
A1 — B1 Pilotis	True	0.562	False	1.470	8	1.591	0.122
A4 — Uniform Pilotis	False	1.000	False	1.571	2	1.595	0.024
A2 — Geometric Setback	False	1.000	True	2.916	2	2.805	0.111
A3 — B1 Mid-Notch	True	0.562	True	2.910	2	2.805	0.105

2.4 Member-level performance evaluation

Performance is assessed at the member level per TBDY 2018. Envelope section demands from the record suite are classified against the sec.15.7.1 strain limits (sec.5.8.1) into the sec.15.3.2 Limited, Controlled, Significant (IH) and Collapse (G) damage zones; the counts of column hinge ends in the IH and G zones, col_IH and col_G, summarize brittle column damage. Beam-column joint shear is checked per sec.7.5.2: the demand follows Eq. 7.11 with 1.25 fyk overstrength on the beam bars and the column shear taken as the minimum of the values above and below the joint, while the capacity follows Eqs. 7.12-7.13 as $V_n = \gamma \cdot b_j \cdot h \cdot \sqrt{f_{ck}}$ with the characteristic strength under the root and $\gamma = 1.0$. The confined classification of sec.7.5.1 requires beams framing into all four faces of the joint, each covering at least three quarters of the column width, a property of the surrounding beams and not of the column hoops. The plane frame has no transverse beams, so $\gamma = 1.0$ follows for every joint; this is an implication of the two-dimensional idealization, and physical joints may qualify as confined once transverse framing is present. The resulting capacities are $1.0 \times 400 \times 400 \times \sqrt{16} = 640.0$ kN for the 400×400 mm columns framed by a 300 mm beam and 360.0 kN for the 300×300 mm columns. Joints are modelled as rigid, with no joint-panel or shear-spring element, so this is a post-processing check: the beam-bar term of Eq. 7.11 is fixed by the section, and the check measures the frames' pre-existing joint deficiency, not additional shear delivered by the braces. Transient non-convergence is interpreted as numerical collapse and treated as the worst outcome rather than as missing data.

2.5 Optimization framework

Each candidate retrofit is encoded as a 20-bit chromosome in which every bit activates one symmetric pair of BRB diagonals (a bay on the left half of the frame and its mirrored right-half counterpart in the same story), enforcing plan symmetry and reducing the search space to 2^{20} configurations. NSGA-II [16], implemented in DEAP [17] with the selNSGA2 selection operator and tournament-DCD mating selection, evolves a population of 20 individuals for 20 generations with two-point crossover (probability 0.70) and per-bit flip mutation (bit probability 1/20, individual probability 0.20). Fitness is evaluated on the three-record screening suite inside the loop and the resulting Pareto set is re-evaluated under the full seven-record suite.

A population of 20 over 20 generations samples 400 designs from a space of about 1.05 million, so the search is deliberately budget-limited by the cost of embedding full NRHA in the fitness function. Stochastic robustness is therefore addressed by repetition rather than by population size: the entire optimization is run independently with five seeds (7, 21, 42, 99, 1337), the five Pareto sets are pooled, the non-dominated subset of the pool is extracted, and the knee point of that pooled front is reported as the optimal design of the archetype. Designs with zero braces are excluded from knee candidacy, since a null retrofit is not a design.

The first objective is the column damage index of Eq. (1); the second is the number of installed braces, f_2, as the cost proxy:

$$f_1 = n_{IH} + 10\, n_G + 999\, \delta_{nc} + \Sigma_j\, 500\, \max(0,\, DCR_j - 1) \quad (1)$$

where n_{IH} and n_G are the column hinge ends in the sec.15.3.2 Significant Damage and Collapse zones, δ_{nc} equals 1 if any record fails to converge, and DCR_j is the sec.7.5.2 demand-capacity ratio of joint j. The weights encode the code damage hierarchy: one

collapsed column end outweighs ten significantly damaged ones; non-convergence can never be dominated by a converging design; and a single joint 20% over capacity costs the equivalent of ten collapsed column ends. Beams are deliberately excluded, since beam yielding is the intended ductile mechanism.

3 Results and Discussion

3.1 Bare-frame baseline

Table 3 summarizes the pre-retrofit NRHA under the seven-record suite. All five bare frames reach the Collapse performance level under TBDY sec.15.8 and none approaches the Controlled Damage target, so the need for retrofit is established in quantitative terms for the regular and the irregular geometries alike. The three archetypes with 300×300 mm sections additionally enter the assessment with beam-column joints already over the sec.7.5.2 shear capacity.

Table 3. Bare-frame NRHA baseline (seven-record envelope).

Archetype	T_1 (s)	Env. IDR (%)	col_IH	col_G	Max joint DCR	#DCR ≥ 1	Converged
A0 — Baseline	1.616	3.78	0	5	0.766	0	Yes
A1 — B1 Pilotis	1.992	3.48	0	5	1.356	3	No
A4 — Uniform Pilotis	1.755	4.03	0	5	0.771	0	Yes
A2 — Geometric Setback	1.375	3.74	0	8	1.360	4	Yes
A3 — B1 Mid-Notch	1.657	4.19	3	11	1.324	3	No

3.2 Inadequacy of a drift-based objective

The first optimization round minimized the envelope peak inter-story drift ratio, the most common objective in the retrofit-optimization literature. It succeeded on its own terms and failed as engineering: drift decreased, yet sec.15.3.2 hinge-zone inspection revealed more collapse-level column ends in three of the four archetypes then studied. Drift is a story-level metric that cannot distinguish ductile beam yielding from brittle column failure, and an optimizer given a blind metric exploits its blindness. A co-location analysis identified the mechanism: 25-60% of the newly collapsed column ends shared a node directly with a brace, and every new collapse occurred in the story immediately above a braced story. This was the first appearance of the force-couple mechanism quantified in Section 3.6, and the damage index of Eq. (1) was adopted in response.

3.3 Optimal designs and verification

Figure 2 shows the pooled Pareto fronts with their knee points and Fig. 3 the corresponding brace placements. Table 4 reports the seven-record verification of each knee-point design against its bare baseline. Collapse-level column damage falls for A0 — Baseline, A1 — B1 Pilotis, A4 — Uniform Pilotis and A3 — B1 Mid-Notch, and rises for A2 — Geometric Setback. A2 needs an explicit note because the two suites disagree: on the three-record screening suite used in the optimization the knee-point design appears to help (collapse-zone column ends fall from 5 to 2), but under the seven-record validation the count rises from 8 to 11. The screening-stage gain does not survive validation, so A2 is reported as the one archetype where the retrofit does not help; the reason is visible in the objective decomposition, where the joint-shear penalty, which brace layout changes only marginally, dominates the knee-point score.

Table 4. Seven-record verification of the knee-point designs against the bare frames.

Archetype	#BRB	T_1,opt (s)	Env. IDR (%)	col_IH	col_G (bare → opt)	Max joint DCR	Converged
A0 — Baseline	18	0.558	0.96	0	5 → 0	0.789	Yes
A1 — B1 Pilotis	4	1.549	3.66	1	5 → 2	1.374	Yes
A4 — Uniform Pilotis	18	0.583	1.13	2	5 → 0	0.789	Yes
A2 — Geometric Setback	2	1.300	4.80	1	8 → 11	1.358	Yes
A3 — B1 Mid-Notch	6	1.546	3.71	0	11 → 5	1.314	Yes

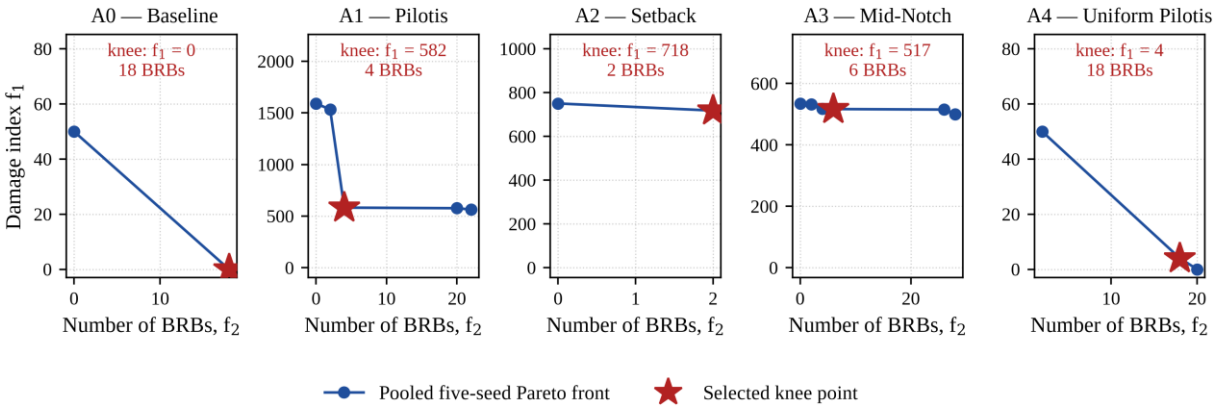

Fig. 2. Pooled five-seed Pareto fronts with the selected knee points.

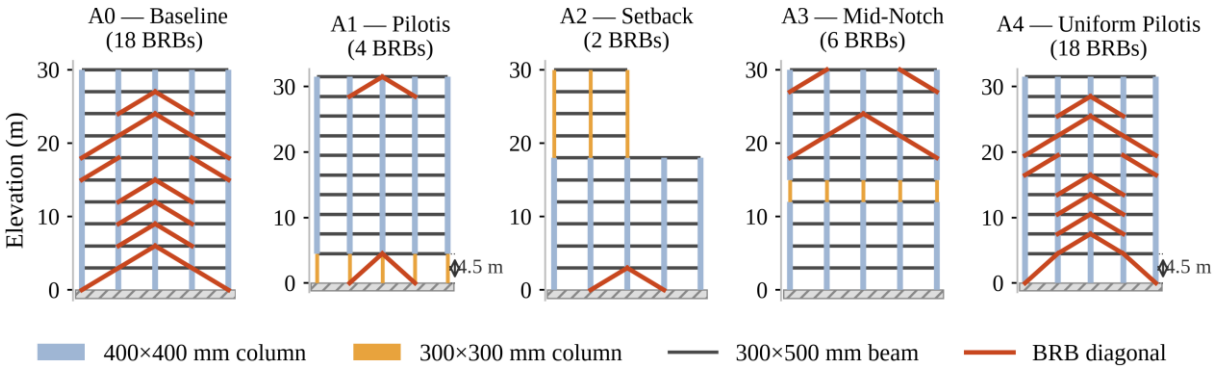

Fig. 3. Knee-point optimal BRB placements.

3.4 Seismic benefit without a code trigger: the A4 case

A4 — Uniform Pilotis is the archetype a code-based screening would not select. Its columns are constant 400×400 mm over the full height, its section schedule follows the gravity demand, and both Table 3.6 checks are negative, with a maximum η_{ki} of 1.571 against the 2.0 threshold. Its only departure from A0 is the taller ground story, which is an architectural fact rather than a detailing deficiency. Nevertheless the bare frame reaches Collapse under the record suite with 5 collapse-zone column ends and an envelope drift of 4.03%, and its optimized retrofit reduces these to 0 and 1.13% respectively, with all joints below the sec.7.5.2 capacity in both states (max DCR 0.771 bare, 0.789 optimal). Under the common-period diagnostic of Section 3.6, which removes the scaling difference between the bare and retrofitted models, its drift falls from 4.03% to 1.16%.

The implication is not that TBDY Table 3.6 is deficient, since its checks flag the strength and stiffness discontinuities they are written to flag, but that the absence of a trigger is not evidence that a frame will not benefit from bracing. A geometrically sound, gravity-consistent pilotis whose columns are nowhere weaker than the story above still concentrates deformation demand in a tall ground story, and an optimally placed BRB layout still removes that concentration. Retrofit prioritisation schemes that use code irregularity as an inclusion criterion will therefore systematically overlook frames of this kind.

3.5 Separating the braces from the confinement upgrade

Because the retrofitted models carry both BRBs and upgraded column hoops, an ablation over the two interventions is required before either can be credited (Table 5). Four conditions are analysed per archetype: as-built bare, braces with as-built hoops, confinement upgrade alone, and both together. The two interventions work together rather than add up, and the effect differs by archetype. For A0 — Baseline, braces alone leave the collapse-zone count unchanged (col_G 5 → 5) and the confinement upgrade alone likewise (5 → 5), while the pair together eliminates collapse damage entirely (5 → 0). For A4 — Uniform Pilotis a single

intervention is worse than ineffective: braces alone make the frame worse (5 → 7) and confinement alone leaves it unchanged (5 → 5), yet the pair again eliminates collapse damage (5 → 0). For A2 — Geometric Setback the pair improves but does not resolve the frame on the screening suite, reducing col_G from 5 to 2 (not confirmed by the seven-record validation, Section 3.3). The mechanism is the one Table 5 is built to show: braces redistribute deformation demand away from the critical story, and the doubled sec.5.8.1 collapse-limit strain is what allows the remaining hinge demand to be classified below the collapse threshold.

Table 5. Ablation over braces and column confinement (screening suite; nc = non-convergent).

Archetype	Bare, as-built	BRBs only	Confinement only	BRBs + confinement
A0 — Baseline	0/5	0/5	0/5	0/0
A1 — B1 Pilotis	0/5 (nc)	1/2 (nc)	0/5 (nc)	0/2
A4 — Uniform Pilotis	0/5	1/7	0/5	4/0
A2 — Geometric Setback	0/5	3/5	0/5	1/2
A3 — B1 Mid-Notch	1/8 (nc)	2/3 (nc)	1/7	0/5

3.6 The BRB-column axial force couple

A braced story resists lateral load like a story of a vertical truss: the diagonal force P delivers a horizontal component P cos θ as story shear and injects a vertical component P sin θ into the columns at the brace end nodes. Under cyclic loading the columns bounding a braced bay therefore carry an alternating axial couple superimposed on gravity, accumulating over the height of a braced stack exactly as overturning demands accumulate in shear-wall boundary elements. The mechanism is well established for steel BRBFs [6, 8, 9] and directly controls in RC retrofit design procedures [10-12]. Its magnitude here is severe relative to the existing members: at core yield each brace injects approximately 363 kN vertically (472 kN in the 4.5 m pilotis story), about 63% of the entire gravity axial load of a base column.

The extracted column axial envelopes confirm the mechanism empirically (Table 6, Fig. 4). Columns are classified as BRB-adjacent when they share a node with a brace. Where braces are few and concentrated the adjacent columns carry up to 2.07 times (A2 — Geometric Setback) the axial peaks of the remaining columns, and the largest single column force is of the order of the brace yield force itself. Where the optimizer disperses braces over many columns the per-column amplification dilutes toward unity, so dispersion is itself a mitigation of the couple (A3, with a ratio below one, carries less axial load in its adjacent columns than in the others). The tension side is equally real: the optimized designs pull columns to as much as 503 kN net tension, a demand the bare frames never see and a governing anchorage and lap-splice check for plain S220 bars.

Table 6. Column axial envelopes of the optimal designs (seven-record envelope).

Archetype	BRB-adjacent cols	Mean |N| adj. (kN)	Mean |N| other (kN)	Amplification	Max |N| any col (kN)	Max tension (kN)
A0 — Baseline	34	605.8	450.4	×1.35	1380.4	503.0
A1 — B1 Pilotis	9	346.7	332.1	×1.04	793.7	0.0
A4 — Uniform Pilotis	34	583.9	453.9	×1.29	1216.9	488.7
A2 — Geometric Setback	4	552.6	266.9	×2.07	632.1	174.2
A3 — B1 Mid-Notch	16	167.1	392.1	×0.43	603.3	0.0

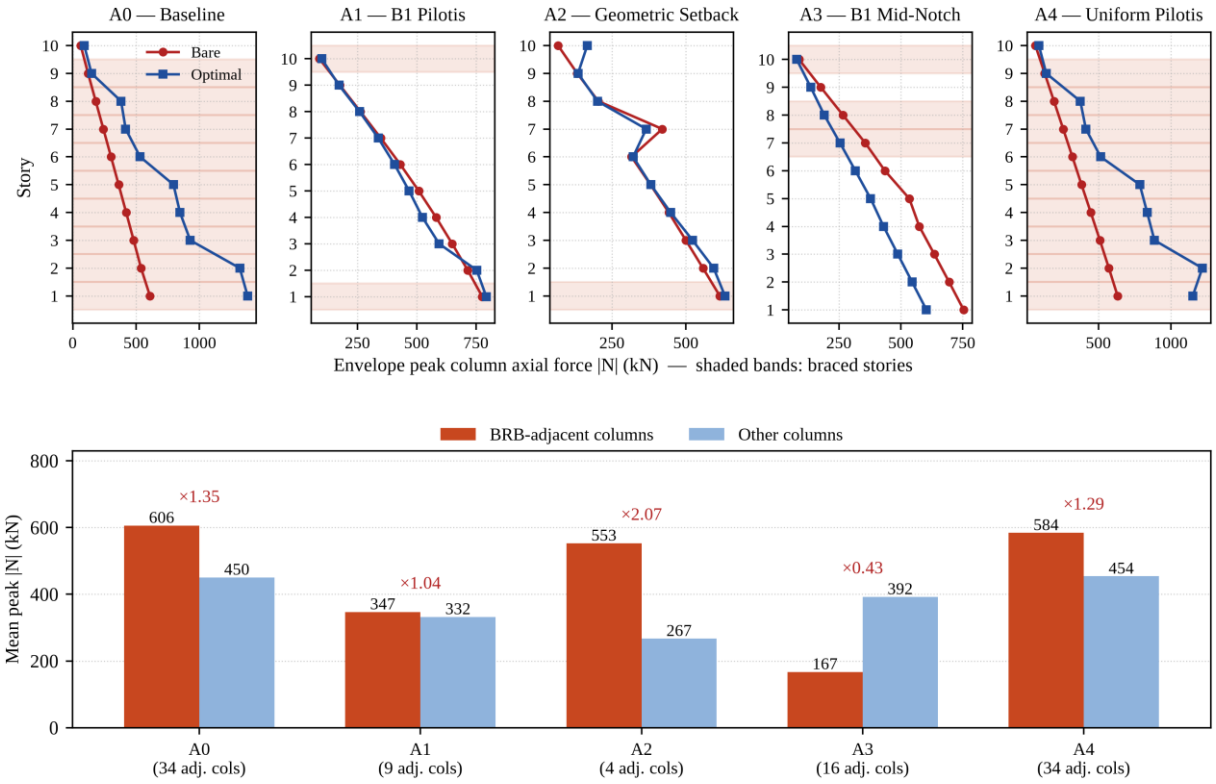

Fig. 4. Column axial force envelopes and the BRB-adjacent versus other column comparison.

Because adding braces shortens the period and therefore raises the record scale factors, each optimal design was additionally re-analysed with records scaled to the bare-frame period (Table 7). This confound does not change the conclusions: the archetypes whose drift improves under own-period scaling improve under common-period scaling as well, and the joint deficiencies exist already in the bare frames at bare-frame scaling.

Table 7. Common-period diagnostic (both models at the bare T_1).

Archetype	Reference T_1 (s)	Bare IDR (%)	Optimal IDR (%)	Δ (%)
A0 — Baseline	1.624	3.51	1.17	-2.34
A1 — B1 Pilotis	2.003	3.16	3.32	0.17
A4 — Uniform Pilotis	1.764	4.03	1.16	-2.87
A2 — Geometric Setback	1.381	2.41	2.96	0.55
A3 — B1 Mid-Notch	1.666	3.76	3.64	-0.12

3.7 Beam-column joint shear

Comparing the sec.7.5.2 joint fields of the bare and retrofitted frames answers whether braces relieve or aggravate joint shear: they are essentially neutral. The peak demand-capacity ratio changes by +3.0%, +1.3%, +2.3%, -0.2% and -0.8% for A0, A1, A4, A2 and A3 respectively (Table 8), and the count of over-capacity joints is identical in the bare and optimal state of every archetype. The ratio is set mainly by the shear area of the 300×300 mm column joints rather than by brace placement: the three archetypes containing them exceed capacity in both states (1.31-1.37), the two with constant 400×400 mm columns stay below it (0.77-0.79). The changes are small and of mixed sign because the beam-bar term of Eq. 7.11 is fixed by the section: only the column shear subtracted from it varies with the brace layout. Joint deficiency is therefore a pre-existing, retrofit-independent brittle failure mode: joints over capacity in the bare frame require local strengthening, such as jacketing, regardless of the brace layout, exactly as the dominance of the joint penalty in the objective already signals to the optimizer. Applied as a hard constraint (DCR ≤ 1), the check would leave no feasible design in A1, A2 and A3 (lowest Pareto peak 1.31-1.36) and would never bind in A0 and A4 (0.76-0.81); at an interior 300×300 mm joint it needs a column shear of at least 158 kN, against the roughly 13-

45 kN implied by the analyses (back-calculated from the DCRs). BRBs alone are therefore not sufficient in these frames: joint strengthening must be designed together with the braces.

Table 8. Joint shear comparison, bare versus optimal.

Archetype	Max DCR bare	#DCR ≥ 1 bare	Max DCR optimal	#DCR ≥ 1 optimal	Change (%)	Net effect
A0 — Baseline	0.766	0	0.789	0	+3.0	higher
A1 — B1 Pilotis	1.356	3	1.374	3	+1.3	higher
A4 — Uniform Pilotis	0.771	0	0.789	0	+2.3	higher
A2 — Geometric Setback	1.360	4	1.358	4	-0.2	neutral
A3 — B1 Mid-Notch	1.324	3	1.314	3	-0.8	lower

4 Conclusions

A multi-objective GA-NRHA framework was applied to the BRB retrofit of five 10-story RC archetypes representative of the pre-2000 Turkish stock, with member-level performance evaluated strictly per TBDY 2018. The principal conclusions are as follows.

First, seismic benefit from optimally placed BRBs does not require a code-recognized irregularity. The gravity-consistent pilotis A4 satisfies both TBDY Table 3.6 checks (max η_{ki} = 1.571) yet its bare frame reaches Collapse and its optimized retrofit removes collapse-level column damage. Code irregularity is a valid screening flag but not a necessary condition for retrofit candidacy.

Second, drift alone is not a valid retrofit-optimization objective: minimizing inter-story drift reduced drift while increasing collapse-level column hinges, because a story-level metric cannot separate ductile beam yielding from brittle column failure. A member-level damage index assembled from sec.15.3.2 hinge classification and sec.7.5.2 joint checks gives the optimizer a signal aligned with the code damage hierarchy.

Third, braces and column confinement act in synergy, not in sum. For A0 neither intervention alone changes the collapse-zone count (5 → 5) while the pair eliminates it (5 → 0); for A4 braces alone are harmful (5 → 7) and confinement alone neutral (5 → 5), yet the pair eliminates collapse damage; for A2 the pair reduces col_G from 5 to 2 on the screening suite, a gain the seven-record validation does not confirm. Braces redistribute the deformation demand and the doubled collapse-limit strain absorbs what remains.

Fourth, BRB diagonals impose a large cyclic axial force couple on adjacent columns, amplifying their axial envelopes by up to 2.07 times and introducing net column tension of up to 503 kN; dispersed placements measurably dilute this effect. Fifth, beam-column joint shear deficiency is essentially insensitive to brace placement: the peak DCR changes by at most 3.0% between the bare and optimal states (1.31-1.37 in A1, A2 and A3; 0.77-0.79 in A0 and A4) and the number of over-capacity joints is unchanged, since it is governed by the 300×300 mm column joint geometry under the γ = 1.0 unconfined classification (640.0 kN exterior joint capacity for 400×400 mm columns, 360.0 kN for 300×300 mm).

The results therefore define a three-part rehabilitation strategy in which BRBs provide global drift control, column confinement and local strengthening at brace connections carry the force couple including its tension side, and joint jacketing addresses the joints that exceed capacity before any brace is installed. Extension of the framework to member sizing, with the core area as a design variable, and to three-dimensional models is ongoing work.

Abstract. Squat shear walls constructed from reinforced concrete (RC) with aspect ratios below 1.0 are susceptible to brittle diagonal shear failure under seismic loading. To predict the seismic response of steel plate-reinforced concrete (SPRC) squat walls and to isolate the effects of web reinforcement and centrally embedded S235 steel plates, a nonlinear finite element framework was developed in Python using OpenSeesPy. The analysis employed multi-layer ShellMITC4 elements incorporating a plastic-damage concrete model, smeared reinforcement layers, and J2-plasticity plate layers, all subjected to boundary conditions replicating a quasi-static test setup. Four wall configurations measuring 400×1000×125 mm were examined: plain concrete, plate-only, conventional RC, and SPRC. The unreinforced wall failed by brittle shear at a drift of 0.09%, while all reinforced and composite configurations achieved a drift of 2%. A parametric study of plate thickness (1–10 mm) demonstrated that capacity increased by 1.8 to 5.3 times relative to the RC reference, with diminishing returns as plate thickness increased. For equivalent steel content (approximately 3.15 kg), the embedded plate configuration exhibited 47% greater capacity than conventional rebar. The embedded plate also mitigated mesh-dependent strain localization observed in the RC model, functioning as a physical regularizer. Independent verification was conducted using a nonlinear SAP2000 model for both plain concrete and RC walls. Elastic stiffness values agreed within 10%, and the SAP2000 pushover analysis of the RC wall yielded a peak capacity within the ACI analytical range and exhibited post-peak softening, consistent with the upper-bound response from OpenSeesPy. The reported capacities correspond to the full-composite upper bound. Perforated-plate (perfobond) detailing is proposed as a potential experimental bonding solution. The developed framework provides a pre-experimental design tool for optimizing composite strengthening of squat walls.

Keywords: Squat Shear Wall; Steel Plate Reinforced Concrete; OpenSeesPy; Layered Shell; Seismic Ductility

1 Introduction

Reinforced concrete (RC) squat shear walls with shear span ratios below 1.0 function as primary elements for resisting lateral loads in basement storeys, industrial facilities, and retaining structures. Experimental studies demonstrate that the behaviour of these walls is governed by the shear span ratio. As the ratio decreases, shear strength increases, while deformation capacity and energy dissipation decrease significantly. Failure is more likely to occur through brittle diagonal compression mechanisms [1]. Such brittle shear failure limits the overall ductility of the structure, which necessitates the implementation of composite strengthening methods.

Steel plate reinforced concrete (SPRC) walls, which incorporate steel plates within conventional reinforced concrete (RC) walls, have emerged as an effective composite system, particularly for high-rise buildings in seismically active regions [2, 3]. Cyclic testing of

embedded steel plate–high strength concrete composite walls has demonstrated significantly enhanced load-bearing capacity, deformation ability, and energy dissipation compared to conventional RC walls, provided that the steel ratio and axial load ratio remain within recommended limits [4]. In China, hysteretic models of SPRC walls developed using OpenSees have been validated against experimental results and utilized for parametric design studies, reflecting the widespread application of this system in super-tall buildings [4]. The SPRC concept has also been extended to coupling beams, where the quantity of embedded steel strongly influences strength, while excessive longitudinal reinforcement reduces ductility [5].

Another category of systems positions the steel plate outside or adjacent to the concrete. Examples include composite steel plate shear walls with reinforced concrete (RC) face panels [6], steel plate shear walls with boundary frames [7], dual-plate walls with infilled concrete channels [8], precast fiber-reinforced concrete panel systems [9], single-side concrete-encased plates [10], prefabricated end-plate connections [11], and partially connected infill plates [12]. In these configurations, the concrete restrains the plate from buckling, promoting shear yielding rather than elastic buckling. Advanced smeared-crack formulations, such as the Disturbed Stress Field Model, have been applied to composite wall elements and have demonstrated the ability to reproduce capacity, ductility, and failure sequence [13]. Additionally, three-dimensional continuum models using ANSYS and ABAQUS have quantified the effects of reinforcement ratio, concrete strength, and plate properties on cyclic response [14, 15]. A numerical comparison of four different systems indicated that the wall with a single plate embedded within the concrete core exhibited the best overall seismic performance, absorbing approximately twice the energy of conventional RC and external-plate systems [15].

Reliable composite action is essential for the performance of these systems. Interface solutions identified in the literature include headed studs and tie bars [2, 16], rubber-coated uplift-restrained studs designed to soften the interface and protect the concrete [17], and shear connectors for thin embedded plates [16]. Retrofitting alternatives, such as steel wire mesh combined with polymer mortar, have also demonstrated effectiveness for shear-deficient walls [18].

Although extensive research exists, systematic numerical studies that (i) isolate the individual effects of web reinforcement and embedded plates within the same squat-wall configuration, and (ii) investigate the influence of plate thickness per unit of steel, remain limited. To address this gap, the present study employs an open-source, Python-based OpenSeesPy framework as the initial phase of an integrated numerical and experimental program. The objectives are to: (1) develop and validate a nonlinear multi-layer shell model of a squat wall under boundary conditions consistent with experimental tests; (2) compare four configurations (plain concrete, plate-only, reinforced concrete (RC), and steel plate reinforced concrete (SPRC)) under monotonic pushover loading; (3) conduct a parametric study on embedded plate thickness (ranging from 1 to 10 mm); and (4) evaluate steel efficiency while maintaining constant steel mass. The numerical results are independently verified using a separate nonlinear SAP2000 model and closed-form analytical approximations.

2 Numerical Modeling Methodology

2.1 Geometry, Boundary Conditions, and Loading

The reference wall measures 400 mm in height, 1000 mm in length, and 125 mm in thickness, resulting in an aspect ratio ($\lambda = H/L$) of 0.40. This configuration classifies the specimen as a short wall where shear is the dominant structural action. The wall is discretized using four-node ShellMITC4 multi-layer shell elements. Boundary conditions replicate those of the intended quasi-static test setup (Fig. 1a): the base is fully fixed to represent an anchored foundation

block, while out-of-plane translations and drilling rotations are restrained to simulate lateral bracing. A stiff steel loading beam (HEB200), modeled with elastic beam-column elements, distributes the load along the top of the wall. Loading is applied in two stages. Initially, a constant axial force of 250 kN is imposed at two actuator positions (125 kN at L/4 and 3L/4). Subsequently, a monotonic lateral pushover is performed under displacement control, with increments of 0.02 mm, until a top displacement of 8 mm (corresponding to a 2% drift) is achieved.

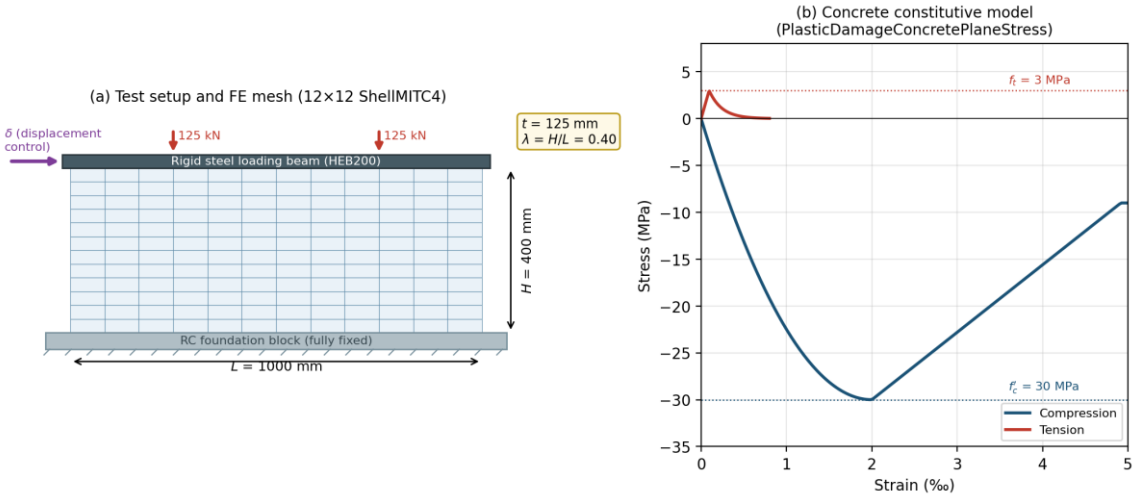

Fig. 1. (a) Test-consistent finite element model and boundary conditions; (b) uniaxial response of the concrete constitutive model.

2.2 Materials and Layered Shell Section

Grade C30 concrete is characterized using a plane-stress plastic-damage model, with a compressive strength (fc′) of 30 MPa and a tensile strength (ft) of 3 MPa. This material is converted into a shell element through a plate-from-plane-stress wrapper, as illustrated in Fig. 1b. The web reinforcement comprises a double layer of Ø8/200 bars in both directions, with a reinforcement ratio (ρ) of 0.40% per direction, utilizing B420C steel with a yield strength (fy) of 420 MPa. These reinforcements are represented by smeared rebar layers exhibiting Steel02 uniaxial material behavior. The embedded S235 plate, possessing a yield strength (fy) of 235 MPa and an ultimate strength (fu) of 360 MPa, is modeled using J2 (von Mises) plasticity, which is appropriate due to the tensile-compressive symmetry of steel. In the initial set of simulations, this model was intentionally excluded for the concrete, as it does not capture cracking behavior. The SPRC section consists of nine layers (see Fig. 2): cover concrete, horizontal and vertical rebar layers, core concrete separated by the centrally embedded plate, and a symmetric mirror sequence. Full composite action between the plate and the concrete is assumed; therefore, the resulting capacities represent theoretical upper bounds [13].

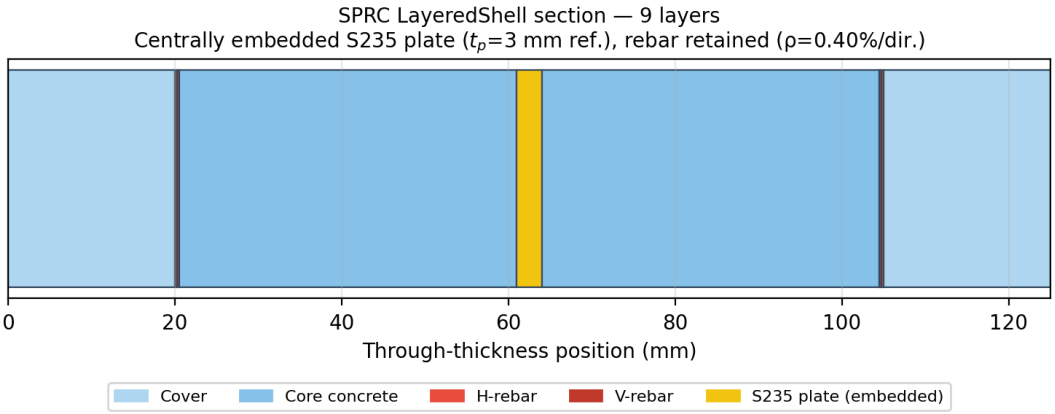

Fig. 2. Nine-layer SPRC layered-shell section with centrally embedded S235 plate (rebar layers exaggerated for visibility).

Model parameters are summarized in Table 1.

Table 1. Principal model parameters.

Parameter	Value	Parameter	Value
Wall H × L × t (mm)	400×1000×125	Rebar (both dir.)	Ø8/200, double curtain
Aspect ratio λ	0.40	Rebar ratio ρ (per dir.)	0.40%
Concrete	C30 (fc′=30, ft=3 MPa)	Rebar steel	B420C (fy=420 MPa)
Ec (MPa)	32 000	Plate steel	S235 (fy=235, fu=360 MPa)
Axial load	2×125 kN (constant)	Plate thickness tp	1 / 3 / 5 / 10 mm
Lateral loading	Displ. control, 0.02 mm	Element / section	ShellMITC4 / layered shell

3 Model Verification

3.1 Mesh Convergence and Failure Mechanism of the Plain Wall

Mesh refinement was conducted on the unreinforced wall, with mesh sizes ranging from 4×4 to 16×16 (see Fig. 3). For the 12×12 and 16×16 meshes, the peak load capacity converged between 634 and 672 kN, which aligns with the analytical upper bound of 0.2fc′Acv = 750 kN. The finer meshes exhibited a sudden loss of equilibrium at a top displacement of approximately 0.25 to 0.34 mm (corresponding to a drift of 0.06 to 0.09 percent), indicating brittle diagonal shear failure of plain concrete rather than a numerical artifact. Consequently, the 12×12 mesh (element size 83×33 mm) was selected as the reference mesh for subsequent analyses.

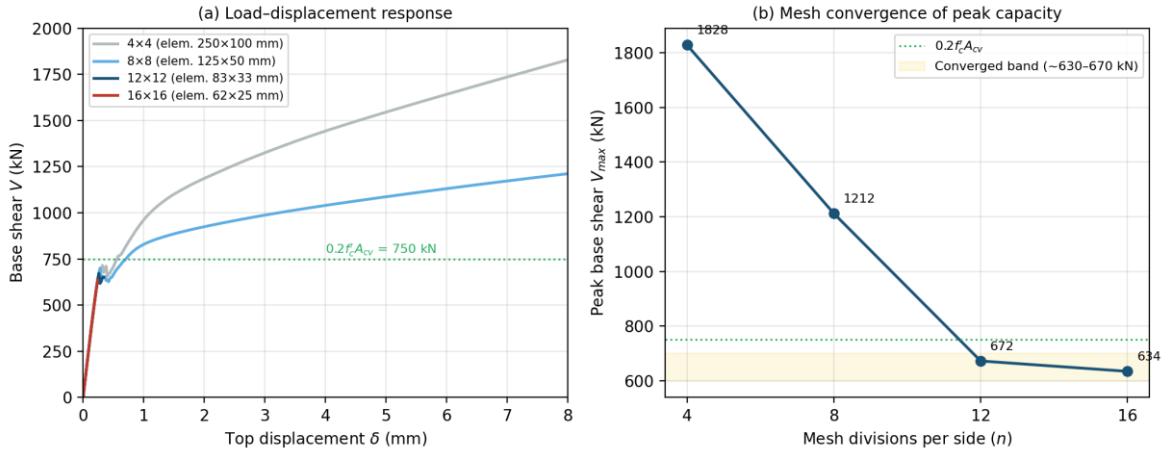

Fig. 3. Mesh convergence of the unreinforced wall: (a) load–displacement response; (b) peak capacity versus mesh density.

3.2 Cross-Platform Verification with SAP2000

To validate the framework, the simple and reinforced concrete (RC) walls were reconstructed in SAP2000 v24 using layered-shell sections with identical geometry, mesh, and material definitions as previously described. This included a user-defined nonlinear C30 stress–strain curve and smeared reinforcement layers with an equivalent thickness of 0.2513 mm per curtain in each direction. A nonlinear gravity stage was implemented to transfer the initial stress state into a displacement-controlled pushover, following the OpenSeesPy protocol.

Within the elastic range, the initial lateral stiffness agreed within 10% across the platforms (see Table 2), confirming the accuracy of the geometry, boundary conditions, and elastic material properties. Following the onset of cracking, the two platforms provided complementary information (Fig. 4 and Table 3). For the plain wall, both models predicted a brittle response terminating below a top displacement of 0.35 mm, corresponding to a drift of less than 0.1%. The SAP2000 solution ceased due to a null-step limit at a load of 189 kN, whereas the OpenSeesPy plastic-damage model redistributed forces up to the diagonal-strut limit at 672 kN. For the reinforced concrete (RC) wall, the SAP2000 pushover reached a maximum load of 404 kN at a displacement of 3.7 mm and exhibited post-peak softening, resulting in approximately a 71% strength loss at 8 mm. In contrast, the OpenSeesPy RC response increased to 2023 kN without any softening. Closed-form estimates indicated that the RC shear capacity ranged between the ACI nominal value ($V_n \approx 326$ kN) and the code upper limit ($0.83\sqrt{f'_c}A_{cv} \approx 568$ kN). The peak load from the SAP2000 RC model fell within the analytically predicted range and included the descending branch characteristic of shear-controlled squat walls. The OpenSeesPy value represented an upper bound consistent with the full-composite, perfect-bond idealization and the absence of compression softening in the current concrete model. Notably, the SAP2000 RC curve displayed a local dip at 0.09 mm, which corresponds to the displacement at which the plain wall fails. Subsequently, the reinforcement bridged the crack and the curve recovered. The RC response thus incorporated the plain-wall response as its initial segment, providing an internally consistent check between the two separate SAP2000 models.

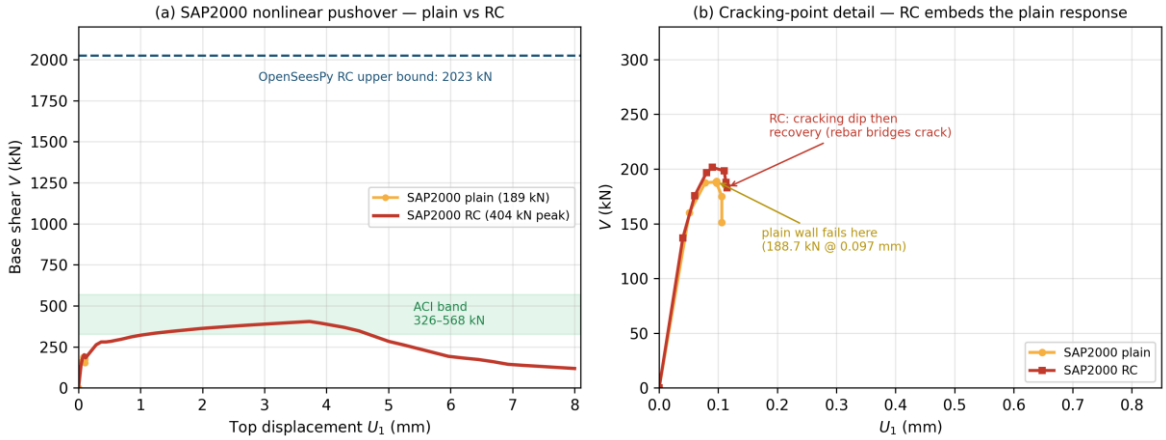

Fig. 4. Independent SAP2000 nonlinear verification: (a) plain and RC pushover curves relative to the OpenSeesPy RC upper bound and the ACI analytical band; (b) cracking-point detail showing that the RC response embeds the plain-wall response.

Table 2. Cross-platform verification of elastic lateral stiffness.

Model	Mesh	K0 (kN/mm)	Difference
SAP2000 v24, linear shell	4×4	3132	—
OpenSeesPy, J2 (pre-cracking)	4×4	2885	7.9%
OpenSeesPy, plastic-damage	4×4	2879	8.1%
OpenSeesPy, plastic-damage	12×12	2826	9.8%

Table 3. Cross-platform nonlinear pushover comparison (plain and RC walls).

Quantity	SAP2000	OpenSeesPy	Analytical (ACI)
Plain wall, peak V (kN)	189	672	0.2fc′Acv = 750
Plain wall, failure	Brittle, <0.11 mm	Brittle, 0.34 mm	Diagonal shear
RC wall, peak V (kN)	404 @ 3.7 mm	2023 (no peak)	Vn = 326–568
RC wall, post-peak	−71% at 8 mm	Not captured	Softening expected
RC/plain capacity ratio	2.14×	3.0×	Same trend

This comparison both reinforces confidence in the model and highlights its limitations. Constitutive uncertainty is greatest for the unreinforced wall and decreases as reinforcement is introduced. Therefore, the quantitative capacities for OpenSeesPy presented below should be considered as complete upper bounds. In contrast, the primary results are the qualitative conclusions, specifically the brittle-to-ductile transition and the relative contributions of the rebar and the plate.

4 Results and Discussion

4.1 Contribution of Reinforcement and Embedded Plate

Four configurations were evaluated using the reference mesh with a plate thickness of 3 mm: (1) plain concrete, (2) concrete with a plate, (3) conventional reinforced concrete, and (4) SPRC, as illustrated in Fig. 5 and detailed in Table 4. The initial stiffness values differ by less than 8%, indicating that both the reinforcement and the plate are largely inactive prior to cracking. Significant changes occur in the post-cracking phase. The plain wall fails by brittle shear at a drift of 0.09%, whereas the walls with the plate, reinforced concrete, and SPRC remain intact up to a drift of 2%. The 3 mm plate alone provides an additional 4957 kN compared to the plain wall, which is 3.7 times the contribution of the rebar (1351 kN). The capacity of the SPRC (6153 kN) is less than the sum of the individual contributions (6980 kN), suggesting that both the plate and the rebar partially fulfill the same crack-bridging function. This behavior aligns with experimental findings that the embedded plate serves as the primary component for carrying lateral loads, while the surrounding concrete secures it in place [2, 3, 15].

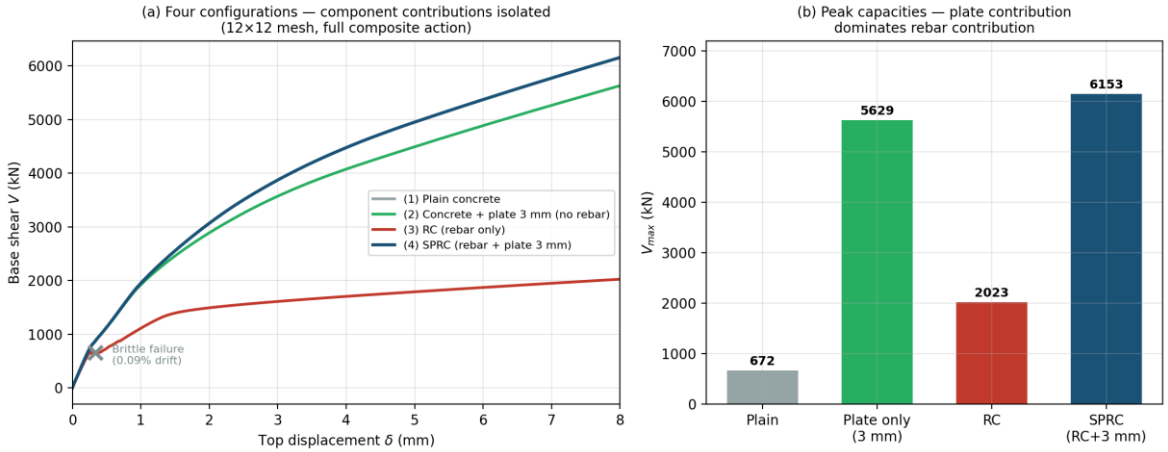

Fig. 5. Four-configuration comparison (12×12 mesh, full composite action): (a) load–displacement curves; (b) peak capacities.

Table 4. Four-configuration results (12×12 mesh; plate tp = 3 mm where present).

Configuration	Vmax (kN)	K0 (kN/mm)	Behavior
(1) Plain concrete	672	2826	Brittle shear, 0.09% drift
(2) Concrete + plate (no rebar)	5629	3059	Ductile, ≥ 2% drift
(3) RC (ρ = 0.40%/dir.)	2023	2826	Ductile, ≥ 2% drift
(4) SPRC (rebar + plate)	6153	3049	Ductile, ≥ 2% drift

4.2 Parametric Study on Plate Thickness

The SPRC configuration was evaluated for embedded plate thicknesses of 1, 3, 5, and 10 mm (see Fig. 6 and Table 5). Structural capacity increased consistently with plate thickness, ranging from 1.8 times that of the RC reference at 1 mm to 5.3 times at 10 mm. However, the marginal gains diminished: the first millimetre of plate resulted in an increase of 1698 kN, while each additional millimetre between 5 and 10 mm contributed only 546 kN. Initial stiffness increased modestly by 3% to 25%, consistent with the limited elastic contribution of the plate to the gross section. All thicknesses exhibited a ductile response up to a drift of 2%. This trend of diminishing returns supports experimental recommendations to maintain the steel ratio in embedded-plate composite walls within an optimal range [4].

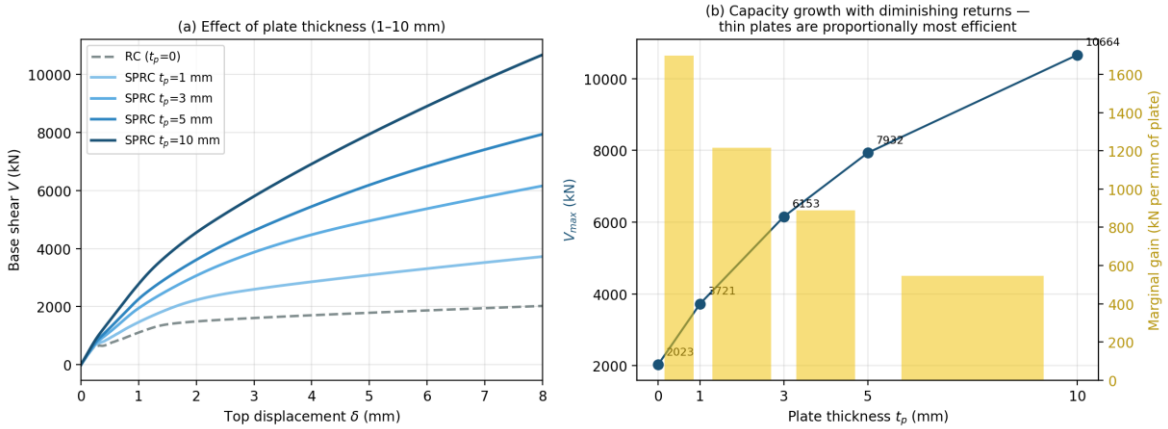

Fig. 6. Effect of embedded plate thickness: (a) load–displacement curves; (b) capacity growth and marginal gain per mm of plate.

Table 5. Parametric results and steel quantities (12×12 mesh).

tp (mm)	Plate steel (kg)	Vmax (kN)	K0 (kN/mm)	Vmax/VRC
0 (RC)	0	2023	2826	1.00
1	3.14	3721	2902	1.84
3	9.42	6153	3049	3.04
5	15.70	7932	3192	3.92
10	31.40	10664	3534	5.27

4.3 Steel Efficiency at Equal Steel Mass

The double-curtain constructed with an Ø8/200 mesh and the 1 mm plate contain nearly identical amounts of steel (3.16 kg and 3.14 kg, respectively), enabling a direct comparison based on steel mass (see Fig. 7). When utilized as an embedded plate, this steel quantity provides a maximum capacity of 2973 kN, whereas its use as rebar results in a capacity of 2023 kN, representing a 47 percent increase. Regarding performance, both configurations exhibit a higher capacity per unit mass of steel compared to a plain wall: the plate configuration achieves 733 kN/kg, while the rebar achieves 428 kN/kg. This enhancement arises because the plate resists in-plane tension and shear in all directions, while the bars resist loads only along their axes. These values assume full composite action; however, actual efficiency will depend on the interface details addressed in the following section.

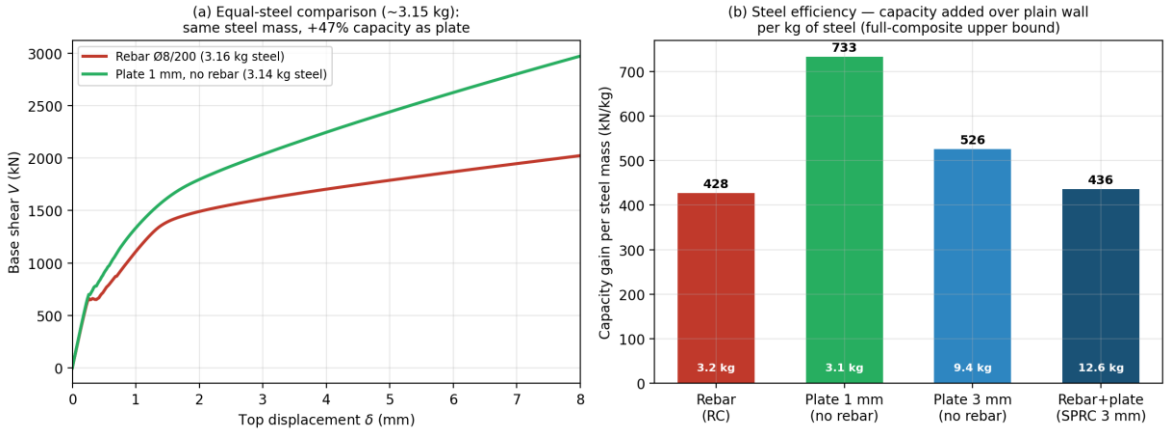

Fig. 7. Steel efficiency: (a) equal-steel comparison (≈3.15 kg); (b) capacity gain over the plain wall per kg of steel.

4.4 Numerical Observations and Practical Considerations

Mesh objectivity. The reinforced concrete (RC) model exhibited typical mesh dependence associated with non-regularized strain-softening, as structural capacity decreased continuously with mesh refinement and premature failure occurred in the finest mesh due to localization within a single element band. The embedded plate approach addressed this issue, with the SPRC meshes converging smoothly (6048–6989 kN, representing a 1.7% change between the two finest meshes). This convergence was achieved because the continuous plate spans cracks across the entire structure, thereby preventing strain localization (Fig. 8). Crack-band (fracture-energy) regularization of concrete softening is planned for the next stage to achieve mesh-objective RC results [13]. The SAP2000 RC model, which simulates post-peak softening within the analytical band, will serve as an independent reference for this calibration.

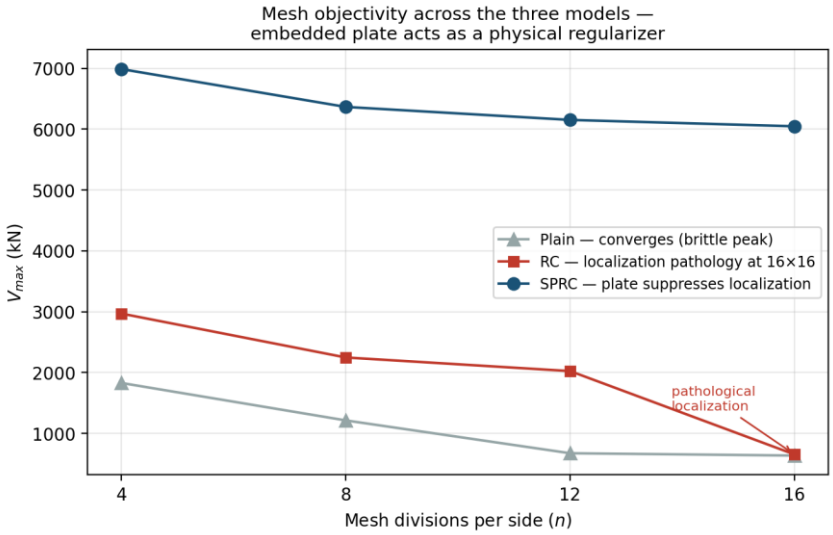

Fig. 8. Mesh behavior of the three models: the embedded plate suppresses the localization observed in the RC model.

Bond and perforated-plate detailing. The assumption of full composite action establishes an upper bound, as interfacial slippage and plate buckling are recognized limitations of the perfect bond approach [13]. During the experimental phase, the use of a perforated embedded plate is proposed. Concrete dowels passing through the perforations, along with optional transverse bars, create a mechanical interlock analogous to that of perfobond (PBL) connectors. The shear resistance in this system arises from the combined effects of interface bonding, concrete-dowel action, and the contribution of transverse bars [16]. In this context, the resulting reduction in net section area can be represented by an effective plate thickness. Alternative solutions that reduce the interface, such as rubber-coated studs [17] and retrofit techniques for existing walls [18], offer additional options tailored to specific applications.

5 Conclusions

A Python-based framework employing multi-layer shell elements was developed and evaluated to predict the seismic behavior of squat steel plate reinforced concrete (SPRC) walls. Validation was performed using a nonlinear SAP2000 model and closed-form analytical calculations. For the configuration studied ($\lambda = 0.40$, C30 concrete, S235 plates, and full composite action), several findings were established. The unreinforced squat wall exhibited brittle diagonal shear failure at a drift of 0.09%, with a capacity of approximately 670 kN, confirming its vulnerability and the necessity for composite strengthening. Conventional web reinforcement and centrally embedded steel plates transformed this brittle response into a ductile one, sustained up to a drift of 2%. The steel plate was identified as the primary contributor; a 3 mm plate increased capacity by 3.7 times compared to the minimum web reinforcement specified in the code. Increasing plate thickness resulted in a consistent rise in capacity (from 1.8 to 5.3 times the reinforced concrete reference as plate thickness increased from 1 to 10 mm), although incremental gains diminished, indicating that thinner plates are proportionally more efficient. With equal steel content, the embedded plate configuration achieved 47% greater capacity than conventional rebar (733 kN/kg versus 428 kN/kg). The embedded plate also served as a physical regularizer, mitigating mesh-dependent strain localization. Cross-platform comparisons revealed that constitutive uncertainty was highest for the unreinforced wall and decreased with reinforcement. The pushover curve from the SAP2000 reinforced concrete model peaked within the ACI band and demonstrated realistic post-peak softening, while the OpenSeesPy response provided a consistent upper bound. The reported capacities represent theoretical upper limits.

Ongoing research addresses fracture-energy regularization, cyclic loading with energy dissipation, interface modeling of perforated plates, and experimental validation using scaled specimens.

Recent Progress in Geopolymer-Based Applications for Bridge Structures: From Material Feasibility to Deployment Readiness

Oğuzhan Çetindemir[1]
[1] 0000-0002-1018-4515, İstanbul Okan University, Department of Motor Vehicles and Transportation Technologies, İstanbul, Türkiye, oguzhan.cetindemir@okan.edu.tr

Abstract. A 2025 review of geopolymer concrete (GPC) in bridge engineering documented a growing portfolio of field applications but also identified limited full-scale evidence, insufficient long-term structural data, and gaps in standardization. This paper provides a focused update on post-review and near-contemporaneous developments published during 2025 through 8 August 2026 and evaluates how the research frontier has shifted toward deployment readiness. Recent studies now include full-scale precast and prestressed alkali-activated concrete (AAC) members, nine-month testing of composite prestressed girders, bridge-deck repair interface models, performance-based chloride testing, fatigue synthesis, anchorage formulations, high-strength engineered geopolymer composites, and embedded ultrasonic monitoring of full-scale prestressed AAC bridge-deck components. The most consequential finding is that demonstrating adequate short-term compressive strength is no longer the sole deployment challenge. Time-dependent deformation, prestress loss, bond and interface deterioration, limit-state-specific design-model accuracy, exposure-specific durability qualification, and production reliability have become increasingly decisive. The new evidence supports a transition from material feasibility toward component-level verification and monitored pilot deployment, but does not yet demonstrate routine use in conventional highway bridges. A deployment-oriented research agenda is therefore proposed, prioritizing long-term prestressed behavior, coupled fatigue-durability testing, code calibration, field monitoring, and performance-based qualification.

Keywords: Bridges; geopolymer concrete; alkali-activated concrete; prestressed concrete; durability; structural health monitoring; deployment readiness.

1 Introduction

Geopolymer concrete (GPC) and related alkali-activated binders have been investigated for bridge applications because they can combine lower Portland-cement demand with favorable mechanical and durability characteristics. The 2025 review by Çetindemir [1] synthesized bridge applications reported up to 2024, including precast panels, bridge decks, prestressed girders, pedestrian and cycle bridges, repair mortars, and circular-bridge concepts. That review also showed that practical implementation remained modest relative to the volume of material-level research. The principal barriers were not simply compressive strength, but the limited amount of long-term field evidence, uncertainty in creep and shrinkage, incomplete code coverage, durability-test compatibility, construction-scale reproducibility, and the absence of mature monitoring and acceptance procedures.

The literature published after that review indicates a notable change in emphasis. Although mixture-dependent strength development and production-scale quality control remain relevant, recent work increasingly addresses the structural, durability, monitoring, and design uncertainties that govern whether bridge owners and designers can deploy AAC/GPC with acceptable risk. Full-scale prestressed members have been produced and tested; time-dependent flexural response has been measured over months; interface constitutive models have been

developed for bridge-deck strengthening; chloride testing has moved toward a RILEM performance-based recommendation; and embedded sensing has been demonstrated on full-scale prestressed AAC bridge elements [2-7]. These developments represent a shift from proof-of-concept research toward deployment-enabling engineering evidence.

Terminology requires care. “Alkali-activated concrete” (AAC) and “alkali-activated materials” (AAMs) are broader categories than geopolymer concrete in the strict chemical sense, and calcium-rich slag systems are not necessarily geopolymers. However, the bridge-related literature published in 2025-2026 increasingly adopts AAC/AAMs terminology. Excluding these studies would omit some of the most relevant new evidence on prestressing, time-dependent response, durability qualification, and monitoring. Accordingly, this paper preserves the terminology used by each source while using “geopolymer-based” as a broad bridge-engineering descriptor when discussing the research field as a whole.

The objective of this paper is therefore not to repeat the bridge case histories already compiled in [1], but to determine what has materially changed since that review. The paper focuses on five questions: whether structural scale has increased; whether time-dependent behavior is being quantified at member level; whether repair and durability assessment are becoming design-oriented; whether standardization is progressing; and whether monitoring can reduce uncertainty during early field deployment. Based on these developments, a concise research agenda for bridge engineering is proposed.

2 Scope and approach

This study is a focused narrative update rather than a new systematic review. Post-review and near-contemporaneous publications appearing during 2025 through 8 August 2026 were screened for direct bridge relevance or for a clear deployment-enabling contribution that was not incorporated into the evidence base of [1]. Priority was given to peer-reviewed journal articles, RILEM outputs, and publisher-verifiable records addressing structural-scale behavior, bridge-deck repair, bond and anchorage, chloride transport, fatigue, high-performance composites, and structural monitoring.

The scope intentionally excludes general mixture-optimization studies that do not materially change bridge design or deployment decisions. Earlier field applications remain important background, but they are referenced through the 2025 review [1] rather than reproduced. The resulting update is therefore organized around engineering readiness rather than chronology alone. Table 1 summarizes the principal post-review developments considered in the synthesis.

Table 1. Main post-review developments relevant to bridge deployment readiness.

Research direction	Representative evidence	Main advance	Readiness and remaining limitation
Prestressed members	Qian et al. [2]; Magnuson et al. [3]	Time-dependent composite-girder testing and full-scale precast/prestressed production	Full-scale feasibility demonstrated; time-dependent prestress, bond and serviceability require longer validation.
Full-scale component SHM / pilot-deployment readiness	Cheng et al. [4]	Embedded ultrasonic indicators validated on prestressed AAC beams and a slab	Full-scale component validation achieved; field thresholds and environmental compensation remain unresolved.
Deck repair interfaces	Li et al. [5]; Zhao et al. [6]	Bond-strength relations, bond-slip behavior, and crack-evolution assessment	Design-oriented bond models emerging; cyclic and environmental interface durability remains uncertain.
Durability qualification	Castel et al. [7]	RILEM 10 V RCPT recommendation validated against bulk diffusion testing	AAC-specific chloride classification available; corrosion thresholds and service-life transfer still require validation.
Fatigue and cyclic demand	Melo et al. [8]	Consolidation of formulation, frequency, fiber, and environmental effects	Evidence base expanding, but standardized S–N/design relationships remain unavailable.
Anchorage and structural design	Rúa-Patiño et al. [9]	Microstructure-informed extension of anchorage mechanics	Mechanistic design framework emerging; calibration range remains too narrow for code use.
High-performance and standardization	Xu et al. [10]; Ye and Dehn [11]; Kar et al. [12]	HS-EGC synthesis and RILEM consolidation/interlaboratory evidence	Reproducibility improving; scale-up, long-term behavior and cost remain barriers.

3 Recent progress toward deployment

3.1 Prestressed members and time-dependent structural response

The clearest advance is the increased attention to prestressed AAC at realistic member scale. Qian et al. [2] investigated composite girders comprising a precast prestressed AAC inverted-T girder and a cast-in-situ AAC topping. Compared with the 28-day reference specimen, the specimen tested at approximately nine months exhibited a 44% lower cracking load. Moreover, the 0.2 mm crack-width criterion was reached at load levels of 160 and 180 kN for the two nine-month specimens, compared with 220 kN for the 28-day specimen. The authors attributed the reduced cracking resistance primarily to pronounced prestress losses associated with ongoing shrinkage and creep, while the larger crack widths may also reflect deterioration of bond between AAC and the prestressing strands.

The time-dependent effects also influenced failure mechanisms and analytical predictions. The nine-month specimen subjected only to self-weight developed anchorage failure, whereas the specimen subjected to additional sustained loading exhibited concrete crushing in the topping, indicating flexural failure. The authors further inferred a possible reduction in strand–AAC bond with time. Analytical models that neglected restrained shrinkage and creep between the precast girder and cast-in-situ topping underestimated prestress loss and consequently overestimated cracking resistance; agreement improved when the restraint level was incorporated. These findings indicate that 28-day structural testing alone is insufficient for

qualification of the AAC system investigated and that time-dependent prestress, bond, restraint, cracking, and anchorage behavior require explicit consideration in structural design [2].

Magnuson et al. [3] provide a complementary production-scale perspective. Full-scale prestressed AAC beams were successfully fabricated using existing precast-plant technology, but transferability of conventional design equations depended on the limit state. Measured flexural capacity was approximately 10% greater than the ACI 318-19 prediction, whereas two of three shear specimens developed capacities approximately 2–4% below the corresponding predictions, making the conventional shear calculation slightly unconservative for those specimens. Production was also sensitive to fresh-state control: unplanned addition of water to improve workability reduced compressive strength by as much as 33%. Although the AAC compressive strength at transfer was only 20.1 MPa, below the specified 24.1 MPa, no strand slip or end cracking was observed during prestress transfer [3]. These results show that deployment requires both limit-state-specific code calibration and controlled production protocols rather than a generic assumption that conventional concrete provisions transfer uniformly to AAC.

3.2 Bridge-deck repair and rehabilitation interfaces

Repair and rehabilitation may offer a lower-risk adoption pathway than complete replacement of conventional bridge concrete. Li et al. [5] investigated GPC for bridge-deck strengthening and showed that substrate treatment governed interface performance: direct-shear bond strength increased from approximately 3.05 MPa for untreated concrete to 3.90 MPa for grooved and 4.55 MPa for roughened surfaces. Hooked steel fibers provided additional mechanical interlocking, but their effectiveness depended strongly on adequate substrate roughness. The study also developed a bond-strength expression and bilinear bond-slip model, moving the evidence toward structural analysis rather than isolated interface tests [5].

Zhao et al. [6] provide an important counterpoint to strength-based optimization. Increasing red-mud content improved compressive and interfacial bond strength, but high red-mud contents reduced flexural strength and increased brittle behavior. Together, these studies show that bridge-repair qualification should consider fracture behavior, compatibility, cyclic degradation, thermal and moisture effects, and long-term bond retention rather than maximizing short-term bond or compressive strength alone [5, 6].

3.3 Durability qualification and standardization

One of the most consequential standardization advances is the RILEM TC 283-CAM recommendation for chloride transport [7]. Because the conventional 60 V ASTM C1202 procedure can cause excessive heating in AAC, the recommendation adopts a 10 V rapid chloride permeability test (RCPT) validated against ASTM C1556 bulk diffusion tests. It proposes three permeability classes: ≤200 C as low, 200–600 C as medium, and >600 C as high. Low-permeability AAC was considered suitable for severe chloride exposure, including tidal conditions, subject to the important assumption that its corrosion-initiation chloride threshold is comparable to that of conventional concrete. Medium-permeability mixtures require additional diffusion-based verification for severe exposure, while high-permeability mixtures cannot be qualified for reinforced chloride environments from the 10 V test alone.

The 2026 RILEM state-of-the-art report [11] and interlaboratory work on fiber-reinforced Ground Granulated Blast-Furnace Slag (GGBFS)-based AAC [12] further indicate that the standardization problem is shifting from absence of evidence toward conversion of experimental knowledge into transferable design provisions, performance classes, and acceptance criteria.

3.4 Fatigue, anchorage, and high-performance composites

Traffic loading makes fatigue a central bridge-specific issue. Melo et al. [8] identified only 33 relevant AAC fatigue studies, of which 83.3% concerned flexural fatigue, 13.3% compressive fatigue, and 3.3% punching shear. Test configurations, loading frequencies, environmental conditions, and mixture formulations remain heterogeneous, and one-third of the studies did not apply statistical analysis despite the intrinsic scatter of fatigue data. Although several studies reported favorable AAC behavior, superiority over Portland-cement concrete cannot be generalized; one reinforced-beam study reported delayed crack initiation but approximately 15% lower fatigue life. Accordingly, the current literature is insufficient to establish transferable AAC-specific S–N relationships or bridge fatigue resistance factors.

At the reinforcement level, Rúa-Patiño et al. [9] proposed a microstructure-informed extension of classical anchorage mechanics in which gel density and interfacial porosity are linked to bond response; gel chemistry explained approximately 93% of the observed variation in 28-day anchorage stiffness within the investigated program. However, calibration was limited to a single Class-F fly-ash AAC system, one bar diameter, two cover depths, and quasi-static loading. Its significance is therefore methodological rather than code-ready: it demonstrates how binder chemistry may eventually be translated into structural design parameters, while broader validation remains necessary for development length, splitting, confinement, sustained loading, and fatigue.

High-strength engineered geopolymer composites (HS-EGC) expand the material design space, but remain at an earlier deployment stage. Xu et al. [10] screened approximately 2500 records yet identified only 44 studies satisfying their strict HS-EGC criteria, despite reported compressive strengths reaching approximately 180 MPa in optimized systems. For bridge engineering, their most credible near-term role is therefore selective use in thin overlays, joints, closure regions, or localized strengthening where tensile ductility and crack control provide disproportionate benefit. Long-term shrinkage, scale-up, activator impacts, fiber cost, and structural validation remain barriers to broader application.

3.5 Structural health monitoring (SHM) as an enabling technology

Cheng et al. [4] validated embedded piezoelectric ultrasonic indicators through full-scale laboratory tests on two prestressed AAC beams and a slab assembled from three beams, providing a basis for subsequent pilot-bridge monitoring. Within the controlled tests, a waveform-coherency coefficient of approximately 0.85 was associated with serviceability-limit-state crack initiation and a relative wave-velocity ratio of approximately 0.90 with more advanced damage; however, these values are material-, geometry-, and loading-specific rather than universal thresholds [4].

The significance of this work lies not only in the sensing technique but in using SHM as part of the qualification strategy for an emerging bridge material. Field interpretation nevertheless remains unresolved because ultrasonic indicators may respond simultaneously to traffic-induced stress, crack opening and closure, creep, shrinkage, temperature, environmental variation, and sensor drift. Project-specific calibration, adaptive baselines, and multi-sensor cross-validation are therefore required before laboratory indicators can function as quantitative bridge-management thresholds.

4 What has changed since the 2025 review?

Compared with the evidence synthesized in the 2025 review [1], the principal advance is not a sudden increase in completed GPC/AAC bridges but a shift in the quality of deployment-enabling evidence. Structural-scale testing now includes prestressed beams, composite girders, and bridge-deck assemblies [2-4]; time-dependent prestress, creep, shrinkage, restraint and strand bond are being addressed as coupled structural problems [2]; bridge-repair research is

progressing toward interface constitutive models [5, 6]; durability assessment now includes an AAC-specific performance-based chloride procedure [7]; and SHM has emerged as an enabling tool for pilot-deployment readiness [4]. Collectively, these developments shift the dominant question from basic material feasibility toward reliability across production, serviceability, durability, monitoring, and code verification. Fig. 1 conceptually summarizes this transition from material feasibility to deployment readiness. The final two stages in Fig. 1 represent the forward deployment pathway rather than the current state; the available evidence is concentrated primarily on component verification, qualification, and preparation for monitored pilot deployment.

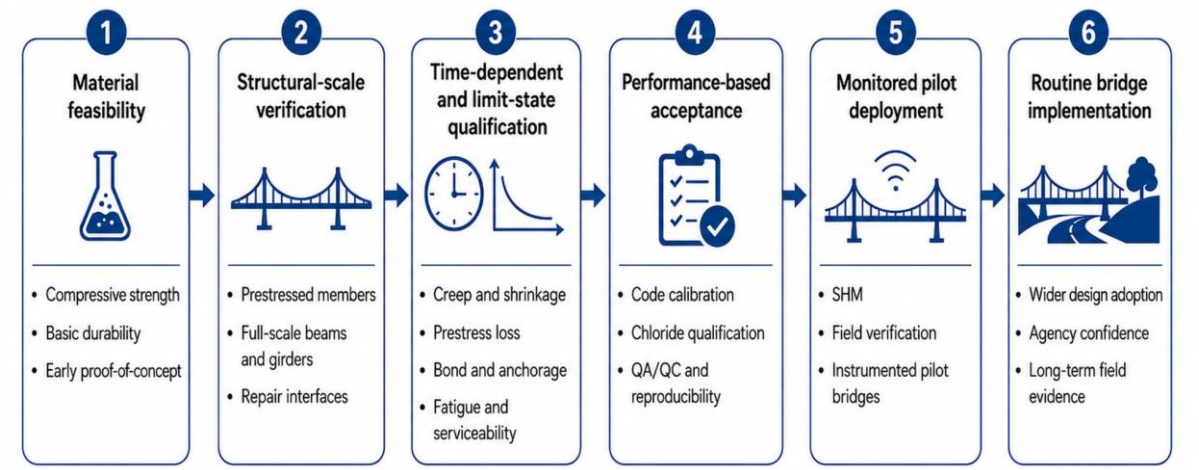

Fig. 1. Evolution of geopolymer-based bridge research from material feasibility to deployment readiness.

Despite this progress, the evidence remains insufficient to support routine deployment in primary highway bridge structures. The recent studies are concentrated in a limited number of material systems and research groups; long-term observations are measured in months or a few years rather than decades; fatigue and environmental effects are rarely coupled; and code calibration remains incomplete. The current stage is best described as preparation for monitored pilot deployment and design-method maturation rather than widespread commercialization for primary highway bridge structures.

5 Priority research needs for bridge engineering

The first priority is long-term prestressed behavior. Multi-year tests are needed to quantify creep, shrinkage, relaxation interaction, strand bond, transfer length, camber, deflection, cracking, and anchorage performance under sustained loading, with particular attention to the large reduction in cracking resistance and altered failure modes observed in [2]. The influence of precast-to-cast-in-situ restraint identified in [2] should be extended to realistic composite deck and girder details, temperature gradients, differential drying, and staged construction.

The second priority is coupled fatigue-durability testing. The current fatigue database is too heterogeneous to define bridge-specific S–N relationships reliably [8]. Bridge decks and girders experience repeated traffic loading while simultaneously being exposed to chlorides, wet-dry cycles, freeze-thaw action, temperature variation, and in some regions deicing salts. Separate fatigue and durability tests cannot fully represent these interactions. A useful bridge-oriented program should measure stiffness degradation, crack growth, residual strength, chloride transport, reinforcement corrosion, and bond deterioration under combined cyclic and environmental exposure. The fatigue synthesis in [8] provides a basis for defining the variables that require standardization.

The third priority is code calibration and performance-based qualification. The 10 V RCPT recommendation [7] is an important model because it adapts the test method to the binder rather than forcing AAC into an unsuitable Ordinary Portland Cement (OPC)-based procedure. Similar efforts are needed for elastic modulus, creep and shrinkage, tensile strength, shear, anchorage, prestress loss, crack-width control, and fatigue. The different flexural and shear prediction trends observed in [3] demonstrate that conventional code equations should be evaluated separately by material family and limit state, with model bias and uncertainty quantified explicitly.

The fourth priority is field-scale verification with transparent monitoring data. Pilot bridges should be instrumented before opening to traffic, with baseline measurements and documented material characterization. Monitoring should capture deformation, strain, temperature, cracking, and where appropriate ultrasonic or acoustic indicators [4, 13, 14]. The work in [4] demonstrates a technically credible starting point. Open or at least well-documented datasets would allow independent validation and accelerate confidence among bridge authorities. Field interpretation should include environmental compensation and adaptive baseline updating rather than direct transfer of laboratory SHM thresholds [4].

Finally, deployment studies should integrate constructability and sustainability. A bridge material is not low-carbon in practice if it depends on impractical curing, highly variable precursors, excessive activator transport, difficult quality control, or premature repair. Future assessments should therefore link structural performance to mixture variability, batching scale, curing demand, local precursor availability, service life, maintenance, and end-of-life scenarios. High-performance geopolymer composites may be most effective when used selectively in components where their properties produce a measurable reduction in material quantity or maintenance demand rather than through indiscriminate full-volume substitution [10].

6 Conclusions

The 2025–2026 evidence confirms measurable progress from material feasibility toward deployment-oriented bridge engineering. Full-scale prestressed AAC members can be produced using conventional precast infrastructure, but structural design transfer is limit-state dependent: available testing found conventional flexural predictions conservative while some shear predictions were slightly unconservative. More importantly, nine-month testing of prestressed composite girders revealed a 44% reduction in cracking load relative to the 28-day reference, increased crack widths, substantial prestress loss, bond deterioration, and age-dependent anchorage behavior. These results establish time-dependent serviceability, bond, and restraint as primary design issues rather than secondary material effects.

Parallel progress has occurred in deployment-enabling technologies. GPC repair studies now provide quantitative interface and bond-slip models; RILEM has introduced an AAC-specific chloride-permeability classification; fatigue research has expanded but remains too heterogeneous for transferable bridge design relationships; and full-scale laboratory bridge components have demonstrated embedded ultrasonic indicators intended for pilot-bridge monitoring. Anchorage and HS-EGC research further indicate movement toward material-specific structural design, although both remain insufficiently validated for routine code application.

Accordingly, short-term compressive strength should no longer be treated as the sole qualification criterion for geopolymer-based bridge materials. The near-term pathway is selective deployment in controlled precast applications, rehabilitation systems, high-value localized components, and monitored pilot bridges, accompanied by long-term prestress and bond characterization, coupled fatigue-durability testing, limit-state-specific code calibration, performance-based durability qualification, and transparent field monitoring. Current evidence supports design-method maturation and preparation for monitored pilot deployment, but not yet

routine substitution of AAC/GPC for conventional concrete in primary highway bridge structures.

Bridge Damage during the 2023 Kahramanmaraş Earthquake Sequence: Failure Mechanisms and Seismic Risk-Reduction Strategies

Oğuzhan Çetindemir[1]
[1] 0000-0002-1018-4515, İstanbul Okan University, Department of Motor Vehicles and Transportation Technologies, İstanbul, Türkiye, oguzhan.cetindemir@okan.edu.tr

Abstract. The 6 February 2023 Kahramanmaraş earthquake sequence produced a rare regional dataset for evaluating the seismic resilience of highway bridges under intense shaking, near-fault effects, and widespread ground failure. This study presents a document-based forensic synthesis of observed bridge damage and translates the observations into a mechanism-based risk-reduction framework. Reconnaissance groups collectively visited 140 bridges, with performance ranging from no damage to total collapse. Recurring damage included abutment cracking and translation, shear-key failure, bearing displacement or dislodgement, girder distress, pier plastic hinging and residual drift, and damage to decks and carried utilities. Representative cases from Hatay, including the Demirköprü, Karasu, Hatay Stadium, D817, Bekir Karabacak, and Utku Acun Street bridges, show that structural damage was frequently coupled with liquefaction, lateral spreading, riverbank instability, approach settlement, and abutment movement. The central finding is that many severe outcomes resulted from a system-level failure chain rather than from one deficient component. Accordingly, the paper proposes an integrated mitigation strategy combining liquefaction and lateral-spreading screening, foundation and abutment strengthening, unseating prevention, displacement-capable bearings and expansion joints, ductile and replaceable shear keys, pier retrofit, appropriately designed isolation or damping devices, fragility-based network prioritization, and structural health monitoring (SHM). The framework is intended to support retrofit decisions for existing bridge inventories in Türkiye and comparable high-seismicity regions.

Keywords: Kahramanmaraş earthquakes; bridge damage; liquefaction; lateral spreading; seismic retrofit; bridge resilience.

1 Introduction

Bridges are not only individual structural assets; after a major earthquake they become part of the emergency-response system. Loss of a bridge can isolate communities, delay rescue and medical access, interrupt utility corridors, and force traffic onto longer or less reliable routes. This system role is why bridge seismic design cannot be judged solely by collapse prevention. The relevant performance objectives also include controlled damage, rapid inspection, continued or quickly recoverable functionality, and network redundancy. These objectives are consistent with the broader resilience concepts of robustness, redundancy, resourcefulness, and rapidity [1].

The 6 February 2023 Kahramanmaraş earthquake sequence provides an unusually important case history. Bas et al. [2] compiled observations from multiple reconnaissance groups that collectively visited 140 bridges; the reported damage spectrum extended from no damage to total collapse. The most common component-level observations included abutment cracking and shifting, failure of pier-cap shear blocks, bearing-pad movement or dislodgement, girder cracking and loss of prestress, plastic hinging and residual drift of piers, and distress to deck

surfaces, handrails, and carried utilities. These observations resemble failure modes documented after earlier destructive earthquakes, including the 1994 Northridge [3] and 2010 Maule [4] events, but the 2023 sequence is particularly instructive because structural demands were repeatedly combined with liquefaction, lateral spreading, approach settlement, and riverbank instability.

The geotechnical contribution is evident in the bridge-specific case histories. Demirköprü Bridge experienced liquefaction-induced failure of its pile foundation and retaining system [5], while the Karasu Bridge approaches developed mapped lateral spreading exceeding 1.5 m and settlements of approximately 0.40-0.55 m [6]. Regional liquefaction reconnaissance further documented extensive soil ejecta and ground deformation, including severe liquefaction-related damage near Demirköprü Bridge [7]. Detailed GEER surveys of four concrete bridges in Antakya recorded large deck translations, abutment rotations, pile cracking and spalling, shear-key damage, retaining-wall failures, and slope movements adjacent to river crossings [8].

The principal engineering question therefore extends beyond documenting what failed: which interventions could have interrupted the observed failure chains, and how should limited retrofit resources be prioritized? Seismic fragility research has established probabilistic methods for linking ground-motion intensity, component demand, damage state, and system performance [9-14]. Retrofit studies show that relative displacement, unseating potential, and isolation performance can be modified substantially through targeted devices and component upgrades [14-16]. Soil-pile-structure interaction (SPSI) research likewise demonstrates that foundation response and kinematic soil demands must be represented explicitly when bridge behavior depends on deforming ground [17].

This work critically synthesizes the 2023 bridge observations with these established seismic assessment and retrofit concepts. Its contribution is a mechanism-to-intervention framework that links the observed damage to practical risk-reduction measures at the ground, foundation, abutment, bearing, superstructure, pier, and network levels.

2 Evidence Base and Analytical Framework

2.1 Selection and use of sources

The evidence base comprises 20 references selected to balance event-specific observations with established studies on bridge seismic performance, fragility, retrofit, SPSI, resilience, and structural health monitoring (SHM). Priority was given to (i) peer-reviewed studies and reconnaissance reports directly addressing the 2023 earthquake sequence and (ii) widely cited foundational studies providing the analytical and mitigation basis for interpreting the observed damage. The seven event-specific sources [2, 5-8, 18, 19] provide the observed evidence; the remaining sources [1, 3, 4, 9-17, 20] provide the analytical and mitigation basis used to interpret that evidence. Table 1 summarizes these evidence classes, their primary roles in the present study, and the corresponding references.

Table 1. Evidence classes used in the mechanism-based synthesis.

Evidence class	Primary role in this study	References
Regional bridge reconnaissance	Regional damage spectrum and recurring component failure modes	[2, 8]
Liquefaction-related bridge case histories	Ground deformation, abutment/foundation response, and serviceability loss	[5-7]
Monitored bridge and expansion-joint performance	Observed dynamic response, joint/device demand, and monitoring value	[18, 19]
Empirical and analytical fragility	Component/system vulnerability and retrofit prioritization	[3, 9-13]

Evidence class	Primary role in this study	References
Retrofit, SPSI, and historical bridge evidence	Restraining, isolation, foundation interaction, and transferable failure lessons	[4, 15-17]
Resilience and SHM	Network-level objectives and rapid post-event decision support	[1, 20]

2.2 Failure-chain interpretation

For each case, the observed damage is interpreted through six linked stages: hazard and ground deformation; foundation/abutment response; component response; substructure response; system-level failure; and operational consequence. A corresponding intervention is then assigned to the earliest feasible point in the failure chain. This is important because strengthening a downstream component can simply transfer demand elsewhere. For example, a stronger shear key does not solve liquefaction-induced abutment translation, and a high-capacity bearing does not eliminate unseating risk if seat width and residual ground displacement are inadequate. The proposed measures should therefore be understood as coordinated design checks rather than isolated products. The resulting system-level failure chain and the corresponding intervention points are schematically illustrated in Fig. 1.

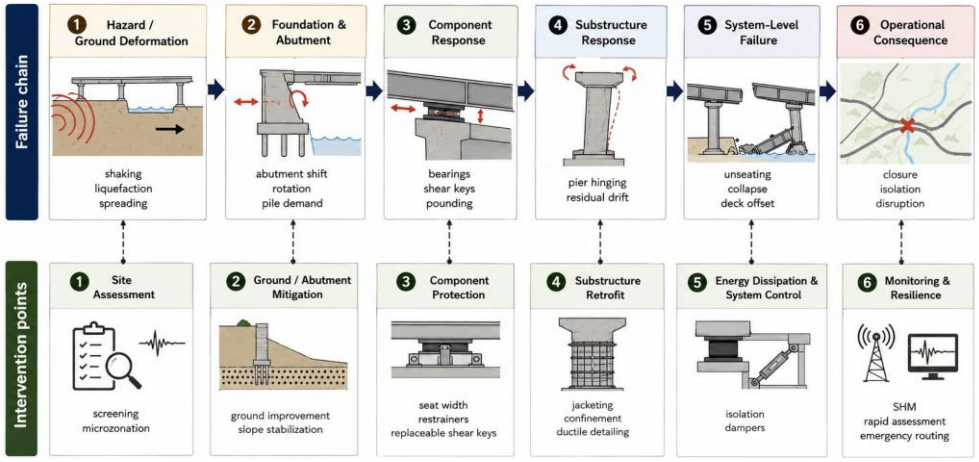

Fig. 1. Conceptual system-level failure chain for earthquake-induced bridge damage and corresponding intervention points.

3 Observed Bridge Damage and Dominant Failure Mechanisms

3.1 Regional pattern

Regional observations show recurring damage to bearings, shear blocks, abutments, deck interfaces, girders, and piers [2], consistent with system-fragility studies showing that multiple components can jointly control bridge vulnerability [12, 13]. Even without collapse, failure of bearings, joints, shear keys, approaches, or utility crossings could control functionality. At river crossings, structural and geotechnical response were inseparable: liquefaction, slope movement, and permanent ground displacement imposed kinematic demands and residual offsets on abutments and piles, as illustrated by Demirköprü, Karasu, and the GEER Antakya surveys [5-8].

3.2 Representative case histories

Representative bridge case histories were examined to identify how site-specific geotechnical conditions and structural vulnerabilities interacted during the earthquake sequence. Table 2 summarizes representative bridge cases illustrating interactions between site-specific ground deformation, support movement, and structural vulnerability, with damage ranging from localized distress to partial span collapse.

Table 2. Representative bridge observations from the 2023 Kahramanmaraş earthquake sequence, dominant interpreted mechanisms, and operational implications.

Bridge / location	Key observed damage	Dominant mechanism	Operational implication / source
Demirköprü Bridge, Hatay	Severe bridge damage associated with liquefaction; pile-foundation and retaining-system failure documented.	Liquefaction-induced permanent ground deformation and foundation/abutment demand.	Loss of operability / severe damage [5, 7].
Karasu Bridge, Hatay	Lateral spreading >1.5 m; mapped approach settlements about 0.40-0.55 m.	Liquefaction of silty sands; lateral spreading and differential settlement at approaches.	Major deformation threatening approach/bridge functionality [6].
Hatay Stadium Bridge	Deck transverse offsets about 17-21 cm at east abutment; south deck translation about 59-63 cm at west; shear-key and girder damage; local slope failure.	Pounding/sliding combined with approach settlement and riverbank instability.	Heavily damaged and closed to regular traffic during reconnaissance [8].
D817 Bridge, Antakya	Abutment/deck compression and separation; pile cracking/spalling; abutment tilt; riverbank offsets locally up to about 0.8 m.	Bank/slope movement imposed abutment rotation and pile kinematic demand, with deck pounding.	Remained open, but with distributed structural/geotechnical damage [8].
Bekir Karabacak Bridge	South deck uplift about 0.37 m; pavement compression up to about 0.50 m; deck cracking; all four wingwall/retaining-wall corners failed.	Large relative longitudinal deformation and retaining-fill/abutment system failure.	Only the north twin bridge remained open during reconnaissance [8].
Utku Acun Street Bridge	Approach-deck gaps about 0.10-0.16 m; north deck shifted about 0.17 m; girder cracking, shear-key damage, bearing relative movement.	Lateral movement toward river plus abutment rotation and deck/bearing displacement.	Open to traffic despite localized damage [8].
Old bridge south of Hatay Hospital	Three easternmost deck spans collapsed; local bank slumping was observed nearby.	Local collapse associated with severe support/ground movement environment; detailed causal attribution requires bridge-specific investigation.	Partial span collapse [8].

3.3 System-level interpretation

Across the cases, ground movement altered foundation or abutment geometry, generating relative displacement at deck supports and demand on bearings, shear keys, girders, and piers. Consequently, post-earthquake functionality was often governed by displacement compatibility rather than member strength alone [3, 4, 11-13].

Monitoring of the Nissibi, Ağın, and Kömürhan bridges further demonstrated the value of recorded response for rapid condition assessment [18], while expansion-joint observations confirmed that special devices remain vulnerable when displacement capacity is incompatible with near-fault and permanent-deformation demands [19].

4 How Could the Observed Damage Have Been Reduced?

The principal damage mechanisms identified from the 2023 observations and the corresponding risk-reduction measures are schematically summarized in Fig. 2. The figure emphasizes that seismic mitigation should address the bridge as a coupled ground–foundation–substructure–superstructure system rather than as a collection of isolated components.

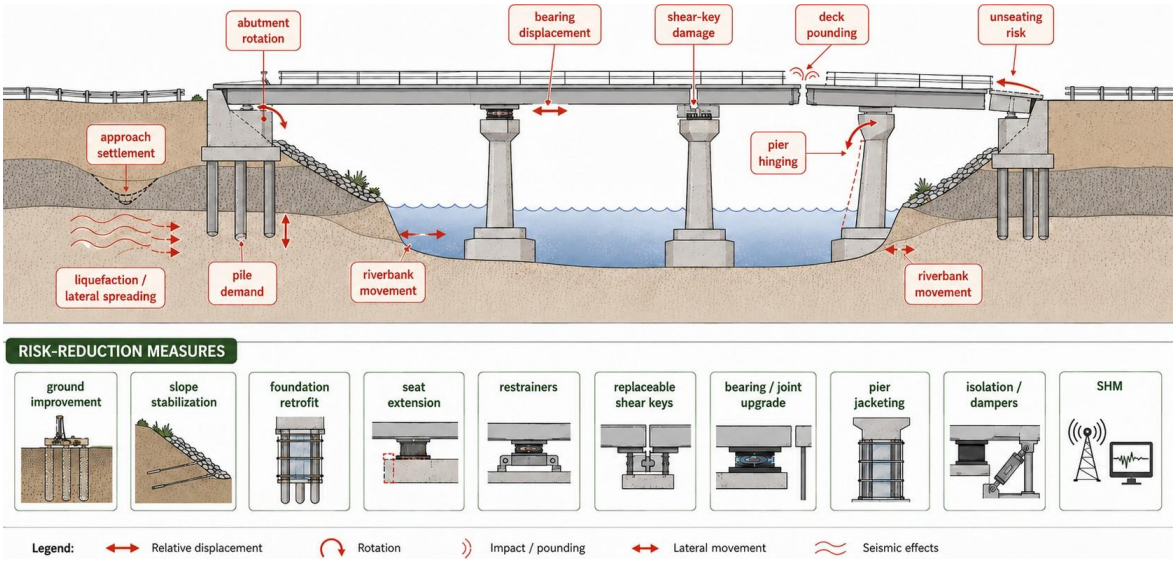

Fig. 2. Major bridge damage mechanisms identified from the 2023 Kahramanmaraş earthquake observations and corresponding seismic risk-reduction measures.

4.1 Geotechnical screening, ground improvement, and foundation design

The highest-priority intervention for river crossings on young alluvium is to quantify permanent ground-deformation demand before selecting a structural retrofit. The Demirköprü and Karasu cases [5-7] show that liquefaction and lateral spreading can generate displacement demands far larger than those implied by inertial analysis alone. A screening program should therefore identify saturated loose or medium-dense granular layers, susceptible silty mixtures, free faces, riverbanks, approach fills, retaining systems, and evidence of historical or current lateral movement. Where screening indicates significant risk, bridge-specific investigations should evaluate liquefaction triggering, post-liquefaction strength, lateral-spreading displacement, settlement, and the kinematic loading imposed on piles and abutments.

Mitigation can then be selected at the source or at the structure. Source-oriented measures include densification, drainage, deep mixing, stone columns or other ground-improvement systems where constructability and environmental constraints permit; slope stabilization and retaining-system strengthening may be equally important near channels. Structural measures include piles and pile groups designed for combined inertial and kinematic actions, adequate ductility where yielding is permitted, and abutment details capable of accommodating predicted permanent ground displacement without brittle loss of support. The dynamic soil-pile-structure experiments of Boulanger et al. [17] underscore the need to represent nonlinear soil response and pile-soil interaction explicitly. For existing bridges, the key principle is not to "strengthen the pier first," but to determine whether the ground and foundation will impose the controlling deformation.

4.2 Unseating prevention, bearings, shear keys, and expansion joints

Several 2023 cases were dominated by large relative deck-to-support movements [2, 8, 19]. The first line of defense should therefore be a positive unseating-prevention system: sufficient seat width, seat extensions where necessary, longitudinal and transverse restrainers, and details that maintain a viable load path after bearing displacement. Restrainer systems can substantially reduce relative movement; superelastic shape-memory-alloy (SMA) restrainers, for example, were shown by DesRoches and Delemont [15] to provide large recoverable deformation capacity in simply supported bridge retrofit applications. The specific restrainer type should be chosen from demand, durability, inspection, and replaceability requirements rather than from device novelty.

Bearings, shear keys, and expansion joints should be designed as a compatible system. Shear keys can act as sacrificial, replaceable fuses, but their protected components and post-yield load path must be explicitly defined. Bearing travel, uplift resistance where relevant, keeper geometry, and joint opening/closing capacity should be checked against bidirectional displacement histories and residual offsets, not only peak force demand. The Hatay Stadium and Utku Acun observations [8] illustrate the consequences of large transverse translation and shear-key/bearing movement, while Bayraktar et al. [19] demonstrate that near-fault pulse and permanent-deformation effects can produce severe joint and device demands. A practical retrofit therefore combines seat capacity, restraining, replaceable fuses, and sufficient joint/bearing travel rather than relying on one component.

4.3 Pier ductility and capacity-protected load paths

Pier plastic hinging and residual drift were among the regional damage modes reported by Bas et al. [2]. Where assessment identifies deficient confinement, inadequate lap-splice behavior, low shear margin, or poor displacement capacity, column retrofit should target stable cyclic ductility and an intentional hierarchy of strength. The objective is to prevent brittle shear or connection failure while allowing controlled flexural response in inspectable regions. Fragility-based retrofit studies [9, 14] are useful because they quantify whether a proposed intervention actually reduces bridge-system failure probability rather than merely increasing the capacity of one member. Particular attention is required when stronger piers or shear keys may transfer larger forces into foundations, caps, or bearings.

4.4 Isolation and damping under near-fault displacement demand

Seismic isolation can reduce force demand and fragility when the isolation system is properly selected and proportioned. Zhang and Huo [16] showed that isolation effectiveness and optimal properties can be evaluated directly through fragility functions. However, the 2023 sequence cautions against treating isolation or damping as a universal solution. Near-fault velocity pulses, large displacement demand, pounding, and permanent tectonic or ground offsets can govern performance [19]. Isolation bearings and dampers should therefore be checked for maximum and residual displacement, stroke, velocity, stability, temperature and aging effects, uplift or rotation where applicable, and the consequences of exceeding design travel. Supplemental damping is most effective when it is embedded within a displacement-compatible system that also provides adequate seats, joints, and restrainers.

4.5 Structural health monitoring and rapid post-earthquake assessment

A resilient bridge network must support fast decisions after shaking stops. Permanent monitoring cannot replace inspection, but it can identify changes in vibration characteristics, unusually large displacements, residual offsets, bearing/joint demand, or cable response and thereby prioritize field resources. The SHM framework summarized by Farrar and Worden [20] provides the general basis for data-driven condition assessment, while the 2023 monitored cable-stayed bridge study [18] demonstrates its direct value during a real earthquake sequence. For strategically important bridges, a minimum instrumentation package can include strong-motion accelerometers, displacement or joint sensors at selected supports, and environmental measurements needed to distinguish earthquake-induced changes from normal variability.

The most useful output is not a large volume of raw data but a pre-agreed decision protocol. Thresholds should be tied to inspection actions: immediate closure, restricted use, priority inspection, or continued operation subject to verification. Post-event measurements should also update analytical models and fragility estimates. In this way, monitoring becomes part of emergency management rather than a stand-alone research system. Based on the preceding observations and mitigation considerations, Table 3 synthesizes the principal vulnerabilities,

recommended intervention sequences, performance objectives, and supporting evidence into a mechanism-to-intervention framework.

Table 3. Mechanism-to-intervention matrix proposed from the 2023 observations.

Observed vulnerability	Preferred intervention sequence	Primary performance objective	Evidence
Liquefaction / lateral spreading	Screen site → quantify permanent deformation → improve ground or stabilize slope → design/retrofit piles and abutments for kinematic demand	Prevent loss of support and excessive residual deformation	[5-8, 17]
Short seats / unseating risk	Increase seat width → add longitudinal/transverse restrainers → verify residual support after bearing movement	Maintain gravity load path after large relative displacement	[2, 4, 15]
Bearing / shear-key damage	Define fuse hierarchy → provide replaceable shear keys/keepers → verify bearing travel and uplift/rotation demand	Control damage location and preserve inspectable/repairable support	[2, 8, 12-14, 19]
Expansion-joint pounding / opening	Displacement-based joint design → compatible bearings/restrainers → check near-fault pulse and residual offset	Maintain deck continuity and post-event serviceability	[8, 16, 19]
Pier hinging / residual drift	Assess ductility and shear → retrofit deficient regions → capacity-protect caps/foundations/bearings	Avoid brittle failure and excessive residual drift	[2, 9, 14]
Critical-route uncertainty after event	Install targeted SHM → define alarm/inspection thresholds → update fragility and emergency routing	Reduce closure uncertainty and inspection time	[2, 18, 20]

5 Proposed Risk-Reduction Framework for Bridge Networks in Türkiye

5.1 Screening and prioritization

A network-scale retrofit program should begin with consequences as well as fragility. Bridges carrying emergency routes, providing the only access across a river or valley, or supporting utilities should receive higher priority because their loss produces disproportionate system consequences [1]. Within that critical set, vulnerability screening should flag bridges with liquefiable foundations, riverbank free faces, large or skewed deck discontinuities, short seats, older or deteriorated bearings, unrestrained simply supported spans, deficient pier detailing, and high near-fault displacement demand. Component-based fragility methods [9-14] can then rank the probability of reaching operationally relevant damage states rather than relying only on qualitative condition scores.

5.2 A practical three-tier intervention hierarchy

For limited budgets, the recommended sequence is three-tiered. Tier 1 addresses collapse and access-loss mechanisms with high consequence: liquefaction/lateral-spreading hazards, inadequate seat width, missing restrainers, unstable abutment or retaining systems, and critical foundation deficiencies. Tier 2 targets repairability and downtime through bearing/joint replacement, ductile and replaceable shear keys, pier ductility upgrades, and protection of carried utilities. Tier 3 enhances rapid recovery through optimized isolation or damping where justified, strategic monitoring, digital bridge inventories, pre-defined inspection thresholds, and fragility-informed emergency routing. The tiers are cumulative; a sophisticated monitoring system should not substitute for a known unseating or foundation vulnerability.

This hierarchy also clarifies what “damage reduction” means. The objective is not necessarily to eliminate every crack or replaceable-device failure during an extreme event. A resilient design may deliberately concentrate damage in accessible fuses while preserving

foundation stability, gravity support, deck continuity, and emergency functionality. Fragility analysis is valuable precisely because it can compare alternative retrofit packages in terms of the probability of exceeding these system-level performance states [9, 13, 14]. The proposed three-tier intervention hierarchy and its progression from collapse prevention to rapid recovery are summarized in Fig. 3.

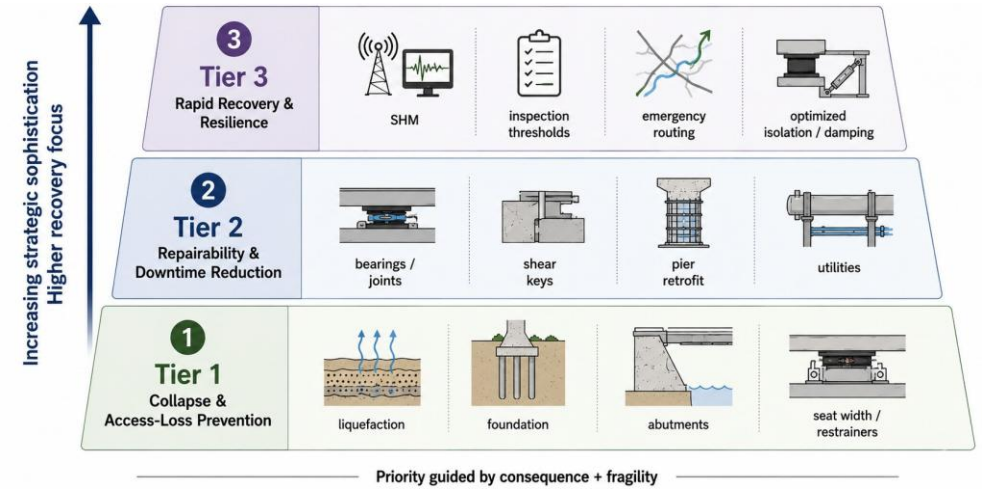

Fig. 3. Proposed three-tier hierarchy for seismic risk reduction and retrofit prioritization of bridge networks.

6 Conclusions

The 2023 Kahramanmaraş earthquake sequence showed that bridge performance was governed by coupled structural and geotechnical mechanisms. Across 140 bridges visited during post-earthquake reconnaissance, the damage spectrum ranged from no damage to total collapse, with recurring distress at abutments, shear blocks, bearings, girders, piers, decks, and utilities. Detailed Hatay case histories further showed that liquefaction, lateral spreading, approach settlement, riverbank instability, and retaining-system movement can initiate or amplify structural damage.

The most important risk-reduction lesson is therefore system compatibility. Ground, piles, abutments, bearings, shear keys, joints, decks, and piers must be checked as one displacement-sensitive load path. The highest-value interventions are: (1) site-specific liquefaction and permanent-ground-deformation assessment; (2) foundation and abutment measures that tolerate or reduce kinematic demand; (3) positive unseating prevention through seat capacity and restrainers; (4) bearings, shear keys, and joints designed as compatible and preferably replaceable components; (5) ductile, capacity-protected pier response; and (6) isolation or damping devices proportioned for near-fault displacement and residual offset rather than force reduction alone.

At network level, fragility-based prioritization and SHM can reduce both physical risk and post-event decision time. The proposed mechanism-to-intervention matrix should be treated as a screening framework: each bridge still requires site-specific geotechnical characterization, structural analysis, detailing review, and constructability assessment. The 2023 evidence nevertheless indicates that many severe consequences could be reduced by intervening earlier in the failure chain, before ground movement or support displacement is allowed to propagate into loss of deck support and network functionality.

Abstract. This study evaluates the performance of twenty contemporary metaheuristic algorithms in the minimum cost optimization of precast reinforced concrete segmental tunnel linings. The optimization model aims to minimize costs by determining the optimal joint locations, lining thickness, and principal reinforcement amount across a six-segment lining system. The problem is formulated using twelve discrete design variables, with design viability governed by eight structural and geometric constraints. Structural analyses are conducted employing a computationally efficient analytical method tailored for optimization processes. The research investigates the impacts of geometry and soil quality on the optimal design by systematically varying the tunnel radius (2.5 to 4.5 m) and the subgrade reaction coefficient of the surrounding soil (5,000 to 20,000 kN/m³). To ensure a rigorous and fair comparison, the algorithmic simulations are assessed using standard statistical metrics alongside non-parametric Friedman and Wilcoxon tests. Furthermore, stability analyses are executed for the top three competitive algorithms. The findings indicate that the vertical displacement limit at the tunnel crown acts as the primary active constraint dictating the design, particularly under weak soil conditions. Furthermore, concrete expenses constitute a significantly larger share of the total cost compared to reinforcement expenses. Through rigorous statistical and stability analyses, the Cuckoo Search (CS) and Stochastic Fractal Search (SFS) algorithms are identified as the most robust and highest-performing methods. Consequently, these algorithms are highly recommended as effective computational tools for similar structural optimization problems in the literature.

Keywords: Optimization; Segmental Tunnel Lining; Cost; Metaheuristic Search Algorithms

1 Introduction

Escalating costs and limited resources necessitate that modern engineering projects satisfy strength and safety criteria at a minimum cost. In solving complex, non-linear optimization problems, heuristic algorithms are frequently preferred due to the implementation flexibility they provide. In Türkiye, the length of highway tunnels constructed over the past two decades has reached 753 km, and metro lines, which predominantly consist of circular precast concrete segmental linings, have reached 231 km. This rapid expansion indicates that optimization-oriented designs in such high-budget projects play a critical role in the national economy.

The literature encompasses various studies on the analytical modeling of segmental tunnel linings [1–6], the impact of the number of segments on structural behavior [7], machine learning-based prediction models [8], and the optimization of specific parameters using heuristic algorithms [9–11]. However, there is a lack of comprehensive research that simultaneously optimizes joint locations, lining thickness, and reinforcement quantities to

directly minimize lining costs. The primary reason for this gap is that the high computational cost associated with structural analyses significantly restricts iterative optimization processes.

Aiming to address this deficiency, the present study establishes a suitable foundation for the optimization process by employing an analytical structural analysis method [5] that features low computational complexity and proven accuracy. The main objective of this research is to determine the optimal design variables that minimize lining costs under various subgrade reaction coefficients and tunnel diameters, utilizing twenty different metaheuristic algorithms widely adopted in the literature. Algorithm performances are evaluated using non-parametric Friedman [12] and Wilcoxon [13] tests in accordance with standard experimental procedures, and stability analyses are conducted for the competitive algorithms. The paper is structured as follows: problem definition, discussion of the simulation findings, and presentation of the obtained results.

2 Problem Definition

In this section, an optimization problem related to the design of a segmented tunnel lining has been formulated. In this problem, the objective function consists of the cost per unit length of the tunnel lining. This objective function is given in Eq. 1.

$$min\ f(x) = V_c C_c + W_s C_s \tag{1}$$

Here, V_c represents the volume per unit length of the tunnel lining, C_c represents the unit cost of concrete, W_s represents the weight of reinforcement used per unit length of the tunnel lining, and C_s represents the unit cost of reinforcement. The optimization problem involves a total of 12 design variables, which are shown in Fig. 1.

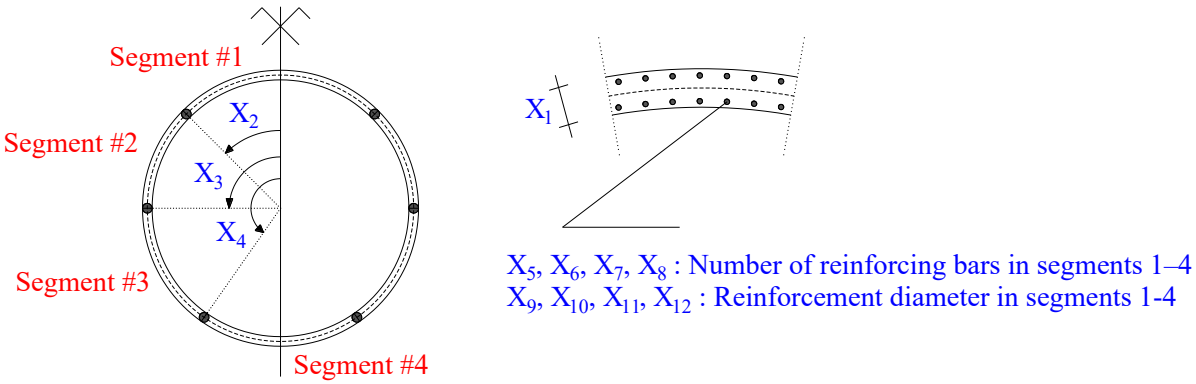

Fig. 1. Design variables of the problem.

While searching for the lowest-cost design during the optimization process, various constraints must be defined to ensure that the designs meet the necessary limit states in terms of strength and durability. The constraints presented here have been formulated in accordance with the conditions set forth in published international guidelines on segmental tunnel linings [14,15]. The first of these constraints involves verifying the moment-carrying capacity of the segment cross-sections. Since the segment cross-sections are subjected to combined bending effects, the condition $M_r \geq M_d$ is checked for the moment-carrying capacities calculated from the interaction diagrams created for the cross-sections, assuming $N_r = N_d$ in the cross-section under consideration. The normalized constraint in Eq. 2 was used for this check.

$$g_1(x) = \frac{M_d}{M_r} - 1 \leq 0 \tag{2}$$

For each member cross-section, the condition $V_r \geq V_d$ must be verified to ensure that the shear force-carrying capacity is met. Here, the shear force-carrying capacity (V_r) of the cross-section

is considered to be the shear force carried by the concrete in the member cross-section. The normalized constraint in Eq. 3 below is used for the shear force control.

$$g_2\,(x) = \frac{V_d}{V_r} - 1 \leq 0 \tag{3}$$

An analytical method with relatively low computational complexity was chosen to determine the design section effects (Nd, Md, Vd) in tunnel segments [5]. In this method, the force method is used for the structural analysis of a segmentally lined circular tunnel. In the relevant reference, the authors demonstrated the accuracy of the proposed method by comparing the internal forces obtained using this method with findings from model tests. In the method, the loading condition shown in Fig. 2 was established by taking into account the effects of soil and hydrostatic pressures on the tunnel. The guidelines of the International Tunneling Association [14] were used in the calculation of these loads.

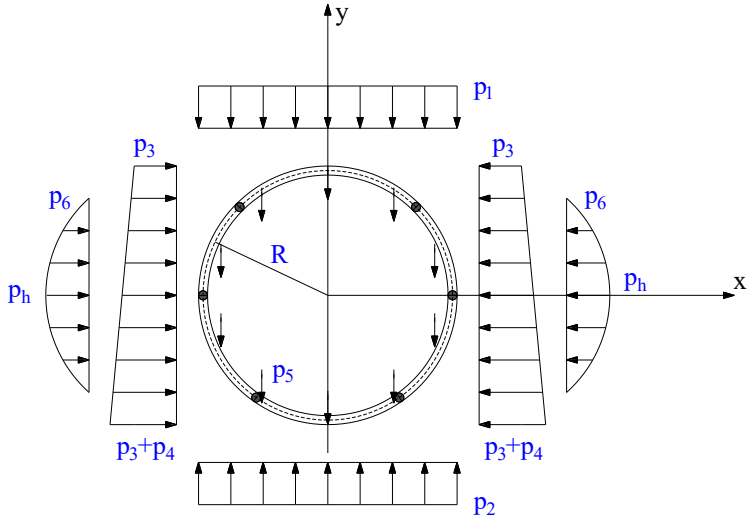

Fig. 2. Load condition considered for the tunnel [5].

The load combination given in Eq. 4 is used to determine the design section effects.

$$1{,}25(w + WA_p\,) + 1{,}35\,(EH + EV) + 1{,}5\,ES \tag{4}$$

Here, w represents the self-weight, WA_p represents groundwater pressure, EH represents horizontal soil pressure, EV represents vertical soil pressure, and ES represents surcharge load. The horizontal soil reaction, denoted by p6 in the loading condition shown in Fig. 2, is calculated using Eq. 5 based on the tunnel's horizontal displacement and the coefficient of soil reaction.

$$\mathrm{p_6} = \mathrm{p_h}(1 - 2\cos^2\varphi) \quad \rightarrow \quad \mathrm{p_h} = \mathrm{K_s} \cdot \Delta_\mathrm{h} \tag{5}$$

Here, p_h represents the soil resistance developing along the tunnel's centerline, φ is the angle measured vertically around the tunnel, K_s is the coefficient of soil reaction, and Δ_h is the horizontal displacement along the tunnel's centerline. For more detailed information on the calculation of cross-sectional effects, see references [5,16].

Another condition that must be monitored during the optimization process is the control of tunnel displacements. Regarding displacement limits, the literature recommends that the maximum displacement at the tunnel roof ($\Delta_{v,max}$) be 15 mm and the maximum displacement at the wall ($\Delta_{h,max}$) be 35 mm [17]. The normalized constraints in Eq. 6–7 were used for these checks.

$$g_3\,(x) = \Delta_v/\Delta_{v,max}\; - 1 \leq 0 \tag{6}$$

$$g_4\,(x) = \Delta_h/\Delta_{h,max}\; - 1 \le 0 \tag{7}$$

In addition, the reinforcement ratio limits in the designed cross-sections (segments) are also checked. In the design, the reinforcement ratio limits were set at ρ_{min} = 0.002 and ρ_{max} = 0.035 [18]. Let ρ denote the reinforcement ratio in the cross-section; for these checks, the normalized constraints in Eq. 8–9 were used.

$$g_5\,(x) = \frac{\rho_{min}}{\rho} - 1 \le 0 \tag{8}$$

$$g_6\,(x) = \frac{\rho}{\rho_{max}}\; - 1 \le 0 \tag{9}$$

The reinforcement spacing to be used in cross-sections must be a maximum (s_{max}) of 150 mm [18] and a minimum (s_{min}) of 25 mm [19]. These checks are performed using the following normalized constraints.

$$g_7\,(x) = \frac{s_{min}}{s} - 1 \le 0 \tag{10}$$

$$g_8\,(x) = \frac{s}{s_{max}} - 1 \le 0 \tag{11}$$

The design variables for circular tunnel design were shown in Figure 1. The lower and upper limits of the 12 design variables to be used in this study are presented in Table 1. To evaluate the optimal design for different tunnel diameters and coefficient of soil reaction a problem set consisting of the 9 problems listed in Table 2 was created.

The design parameters kept constant across all problem sets are presented in Table 3 below. The unit costs presented in Table 3 are taken from the 2026 construction and installation unit prices of the Ministry of Environment, Urbanization, and Climate Change of the Republic of Türkiye.

Table 1. Design variables for applications: lower and upper limits, increments

Design Variables	Lower Bound	Upper Bound	Increment
X_1	0,15 m	1 m	0,01

X_{11}	{10 12 14 16 18 20 22 24} mm		
X_{12}	{10 12 14 16 18 20 22 24} mm		

Table 2. Problem sets prepared for the evaluation of the optimal design for different tunnel diameters and coefficient of soil reaction

Problem Number	P1	P2	P3	P4	P5	P6	P7	P8	P9
Tunnel Radius	2,5 m	2,5 m	2,5 m	3,5 m	3,5 m	3,5 m	4,5 m	4,5 m	4,5 m
Subgrade Coefficient (kN/m^3)	5000	10000	20000	5000	10000	20000	5000	10000	20000

3 Results and Discussions

In this study, 20 meta-heuristic algorithms were used to investigate the optimal designs of segmented tunnel linings. These algorithms, listed in alphabetical order, as follows: Artificial Bee Colony (ABC), Big Bang–Big Crunch (BBBC), Child Drawing Development Optimization (CDDO), Coyote Optimization (COA), Cuckoo Search (CS), Differential Evolution (DE), Flower Pollination (FPA), Genetic Algorithm (GA), Gaining-Sharing Knowledge-Based (GSK), Grey Wolf Optimizer (GWO), Harmony Search (HS), JAYA, Particle Swarm Optimization (PSO), Simulated Annealing (SA), Stochastic Fractal Search (SFS), Snake Optimizer (SO), Symbiotic Organisms Search (SOS), Teaching Learning Based Optimization (TLBO), Transit Search (TS), and Whale Optimization (WOA). It is clear that performance comparisons of these algorithms will be influenced by their parameter settings. Therefore, to ensure a fair comparison, the parameter settings recommended by the developers of the meta-heuristic algorithms were used. Other conditions considered to objectively compare the search performance of the algorithms used are listed below.

- The maximum number of function evaluations (maxFEs) was used as the algorithm's termination criterion, and maxFEs was set to 10,000xD. Here, D represents the number of design variables.
- For each problem, 25 independent simulations were performed using each algorithm.
- All experimental studies were conducted in a laboratory equipped with an Intel® Core™ i5-144000F CPU @ 2.50 GHz Intel® X64 processor and 16 GB of RAM, using MATLAB R2026a.

Table 3. Design parameters to be kept constant across all problem sets

Design Parameter	Value	Unit
Relative stiffness ratio of the joint	0,1	-
Embedded depth	30	m
Concrete Grade	C30	-
Steel Grade	B420C	-
Young's modulus	35000	MPa
Segment width	1000	mm
Net concrete cover	50	mm
Soil horizontal pressure coefficient	0,50	-
Overcharge load	30	kN/m^2
Unit cost of steel (B420C)	44681.18	₺/ton
Unit cost of concrete (C30)	3836.85	₺/m3

3.1 Investigation of the Optimal Solution

In this subsection, the best solutions obtained by the algorithms used in this study for the nine problems formulated for the optimal design of segmented tunnel linings are investigated. The best solutions obtained are presented in Table 4.

Table 4 summarizes the best solution values obtained for a problem set (P1–P9) consisting of nine different problems with varying tunnel diameters and coefficient of soil reaction, along with the design variables derived for these solutions. Upon analyzing the table, it is observed that in all problems, the total concrete cost accounts for a much larger share of the budget compared to the total steel cost. In problems P1, P4, and P7, which represent weak soil conditions with a coefficient of soil reaction of 5000 kN/m^3, the vertical displacements at the tunnel crown reached 14.99 mm, 14.95 mm, and 14.89 mm, respectively. This demonstrates that the 15 mm displacement limit is an active and design-constraining factor in scenarios with low soil quality. As the tunnel radius increases from 2.5 meters to 4.5 meters, it was found that both the amount of reinforcement used and the segment thicknesses increase significantly, thereby notably driving up the total cost.

Table 4. Details of the best solutions obtained

3.2 Identification of Competitive Algorithms

For each problem in the problem set, the Friedman scores of the competing algorithms were calculated using the Friedman test [12], taking into account the obtained solutions. Based on these scores, the top three algorithms for each problem were identified as competing algorithms. The Friedman scores of the algorithms for each problem are presented in Table 5.

In this table, the green, blue, and orange colors in each problem's column represent the first, second, and third algorithms, respectively. According to this explanation, 12 of the 20 algorithms used in the experimental studies ranked among the top three for at least one problem, thereby qualifying as competing algorithms. An examination of the average Friedman scores in the table reveals that the CS algorithm is the most successful among the twenty algorithms.

A Wilcoxon signed-rank test was conducted to evaluate the relative performance of the CS algorithm, which was the most successful algorithm based on the Friedman mean score, compared to other competing algorithms. The results of this analysis are presented in Table 6.

Upon analyzing Table 6, it is evident that for problems P1, P2, P4, P5, P8, and P9, the CS algorithm achieved a statistically significant advantage over the vast majority of other algorithms. In particular, for problem P9, the CS algorithm outperformed 18 of its 19 competitors statistically, demonstrating its most dominant performance. The only problem in which the CS algorithm statistically performed worse than its competitors was P7. In this problem, the FPA and GSK algorithms produced better solutions than the CS algorithm. This indicates that, within the solution space created by the combination of a large tunnel diameter (4.5 m) and poor soil quality, the search strategies of FPA and GSK performed more consistently. In the P3 and P6 problems, where the coefficient of soil reaction is high, the CS algorithm showed statistically similar performance to 10 different algorithms and was able to outperform only 9 of them.

Table 5. Friedman scores of algorithms for the problems investigated

Algorithm	Friedman Score

3.3 Algorithm Stability Analysis

The purpose of the stability analysis conducted in this subsection is to examine the stability of the competing algorithms identified for specific problems and the time required to obtain these solutions. This allows for a comparison of algorithms that exhibit statistically similar performance in finding optimal solutions in terms of success rates, and facilitates the selection of the most effective algorithm for optimizing the problems [20]. To this end, the stability of 12 competitive algorithms was analyzed for all problems. The success rates obtained from the analysis are presented in Table 7. The last column of Table 7 shows the average success rates of the algorithms.

Table 7. Stability analysis results of competing algorithms for the problems investigated

	Success Rate (%)									
Algorithm	P1	P2	P3	P4	P5	P6	P7	P8	P9	Mean SR
CS	100	100	100	20	100	100	8	52	100	76
SFS	100	100	100	40	76	100	4	16	92	70
FPA	88	100	100	8	84	100	4	4	84	64
JAYA	88	100	100	4	64	100	4	12	92	63
COA	96	100	100	4	100	100	0	4	44	61
GSK	100	100	100	4	96	96	4	0	44	60
ABC	84	92	100	0	96	84	0	0	4	51
GWO	60	100	100	0	24	100	0	4	52	49
SOS	60	100	92	8	40	96	0	8	20	47
HS	24	100	100	0	20	96	0	0	76	46
PSO	44	80	84	0	60	88	0	4	4	40
TS	0	100	100	0	12	76	0	0	20	34

An examination of the mean success rate (Mean SR) data in Table 7 reveals that the Cuckoo Search (CS) algorithm achieved a success rate of 76%, while the Stochastic Fractal Search (SFS) algorithm achieved a success rate of 70% both of which are quite high. These rates demonstrate that these algorithms possess a strong global search capability even in a challenging engineering problem with many variables and constraints, such as fragmented tunnel lining. It is noteworthy that the CS and SFS algorithms achieved a 100% success rate in problems P1, P2, P3, P6, and P9. This indicates that these algorithms provide robustness in finding the optimal design across various combinations of soil types and tunnel diameters and can achieve the same successful outcome in all independent simulations.

In summary, the stability analysis in Table 7 documents that the Cuckoo Search (CS) and SFS algorithms are stable and highly successful analytical tools capable of replacing traditional trial and error methods in structural optimization processes.

4 Conclusion

Within the scope of this study, the performance of twenty different state-of-the-art meta-heuristic algorithms was evaluated for the optimization of precast reinforced concrete segmental tunnel linings at minimum cost. In the developed optimization model, lining thickness, optimal joint locations, and primary reinforcement quantities were defined as design variables, and the structural and geometric adequacy of the system was verified using eight different constraints. As a result of analyses conducted on nine different problem sets (P1–P9), generated by systematically varying the tunnel radius and coefficient of soil reaction, the following key findings were obtained:

- In all design configurations, it was found that concrete costs account for a much larger share of the total cost compared to steel (reinforcement) costs. In problems P1, P4, and P7, which represent weak soil conditions with a coefficient of soil reaction of 5000 kN/m^3, the vertical displacement values at the tunnel crown reached the limit value of 15 mm (14.99 mm, 14.95 mm, and 14.89 mm, respectively). This demonstrates that, in scenarios with low soil quality, the vertical displacement limit is the primary active constraint guiding the design. As the tunnel radius increased (from 2.5 meters to 4.5 meters), it was observed that the amounts of reinforcement and segment thicknesses increased significantly to accommodate the rising internal forces, thereby markedly raising the system cost.
- The search performance of meta-heuristic algorithms was compared using non-parametric Friedman and Wilcoxon tests, in addition to standard statistical data. Considering the average Friedman scores, the Cuckoo Search (CS) algorithm emerged as the most successful among the other nineteen algorithms in the pool. Wilcoxon analyses also confirmed that the CS algorithm achieved a statistically significant advantage over the vast majority of other algorithms in problems P1, P2, P4, P5, P8, and P9. When stability analyses were evaluated, the CS algorithm emerged as the most stable method with an average success rate of 76%, followed by Stochastic Fractal Search (SFS) with a success rate of 70%.

In summary, the findings demonstrate that the meta-heuristic algorithms evaluated, particularly Cuckoo Search (CS) and Stochastic Fractal Search (SFS) are reliable and effective tools specifically for the problems addressed in this study. These algorithms have the potential to generate safe and economically viable optimization solutions in tunnel engineering and are recommended for similar structural problems in the literature.

Abstract. Historical masonry minarets are slender heritage structures for which repeated sensor installation and direct access to critical regions can be difficult. This study presents a multi-camera vision-based approach for non-contact anomaly detection and regional damage-sensitive assessment of masonry minarets. Structural displacements are obtained by tracking selected surface regions using the Pyramidal Lucas–Kanade optical-flow algorithm and converting the resulting pixel motions into physical units. A one-dimensional convolutional autoencoder trained exclusively on healthy-reference measurements is then used to calculate reconstruction-error-based anomaly scores, while relation-based analysis provides spatial inspection-priority information. The approach is first validated using a laboratory masonry minaret model subjected to controlled shaking-table excitations. Camera-derived dominant frequencies showed close agreement with accelerometer measurements, with differences below 2.1%. Following the excitations, the identified modal frequencies decreased by approximately 13.9–17.9%, visible cracking developed mainly in the shaft and transition regions, and reconstruction errors increased markedly toward the advanced damage state. The method is subsequently demonstrated on İskenderpaşa Mosque Minaret in Trabzon, where persistent anomaly exceedances were accompanied by higher regional inspection priorities around the balcony and transition zones. Visible cracking observed in these regions provided qualitative support for the spatial assessment. The results demonstrate the potential of vision-derived displacement measurements and healthy-reference anomaly analysis for non-contact monitoring and targeted inspection of masonry minarets.

Keywords: onry minarets; Vision-based monitoring; Structural health monitoring; Unsupervised anomaly detection; Convolutional autoencoder.

1 Introduction

Historical masonry structures require effective monitoring strategies to support their preservation and structural assessment. Masonry minarets are particularly vulnerable because of their slender geometry, high aspect ratio, and exposure to seismic and environmental actions [1–3]. Damage may develop through cracking, joint separation, material degradation, or stiffness loss, some of which may not be readily identified by visual inspection alone. Periodic monitoring can therefore help detect changes in structural behavior and guide detailed inspection. Conventional structural health monitoring (SHM) commonly relies on contact

sensors such as accelerometers, displacement transducers, and strain gauges [4–6]. Although accurate, their use in historical and tall structures may be limited by installation, cabling, accessibility, maintenance, and conservation requirements. Vision-based techniques offer a non-contact alternative by tracking structural motion remotely and providing displacement time histories suitable for dynamic and damage-sensitive assessment [7–9].

A key challenge is interpreting these measurements because labeled data representing different damage states are generally unavailable for historical structures. Unsupervised learning addresses this limitation by establishing a baseline from assumed healthy measurements. Autoencoders trained on healthy-reference data typically produce low reconstruction errors for baseline-like responses, while structural changes may increase these errors [10–11]. Such errors should be interpreted as indicators of deviation from reference behavior rather than direct measures of physical damage.

Recent studies have also demonstrated the potential of vision-based and data-driven approaches for the structural assessment of masonry minarets [12,13]. This study presents a vision-based framework combining non-contact displacement measurement, healthy-reference reconstruction-error analysis, and regional damage-sensitive mapping. The methodology is first validated on a laboratory masonry minaret subjected to controlled shaking-table excitations, with camera-derived dynamic responses compared against accelerometer measurements. It is then demonstrated on İskenderpaşa Mosque Minaret as a representative field application, where reconstruction-error trends and relation-based regional mapping are used to identify persistent deviations and prioritize regions for inspection.

2 Vision-Based Monitoring and Anomaly Assessment

2.1 Multi-Camera Vision-Based Measurement

The proposed monitoring system uses four synchronized high-speed monochrome CoaXPress cameras for non-contact displacement measurement: two VICTOREM 16B276MCX cameras (1456×1088 pixels at 276 fps) and two VICTOREM 32B216MCX cameras (2064×1544 pixels at 216 fps). All cameras have a 3.45×3.45 μm² pixel size and 75 mm C-mount lenses. Video acquisition was performed using an IO Industries DVR Express Core 2 unit and controlled through CoreView software, enabling simultaneous monitoring of different structural elevations. Structural motion was extracted from the recorded image sequences using the Pyramidal Lucas–Kanade optical-flow algorithm. For each camera, predefined target regions were selected on the structural surface and tracked frame by frame. The resulting pixel trajectories were converted into physical displacement histories using a scale factor obtained from a known reference length within the measurement plane. The conversion can be expressed as

$$s = \frac{L_{\mathrm{ref}}}{L_{\mathrm{px}}}, \qquad d_{\mathrm{phys}} = s\, d_{\mathrm{px}} \tag{1}$$

where (L_{ref}) is the known physical reference length, (L_{px}) is its corresponding length in pixels, and (d_{px}) and (d_{phys}) denote the measured displacement in pixel and physical units, respectively. The resulting multi-point displacement histories formed the input for dynamic-response evaluation and data-driven anomaly assessment. For the laboratory validation, the displacement records were additionally analyzed in the frequency domain and compared with

accelerometer measurements.

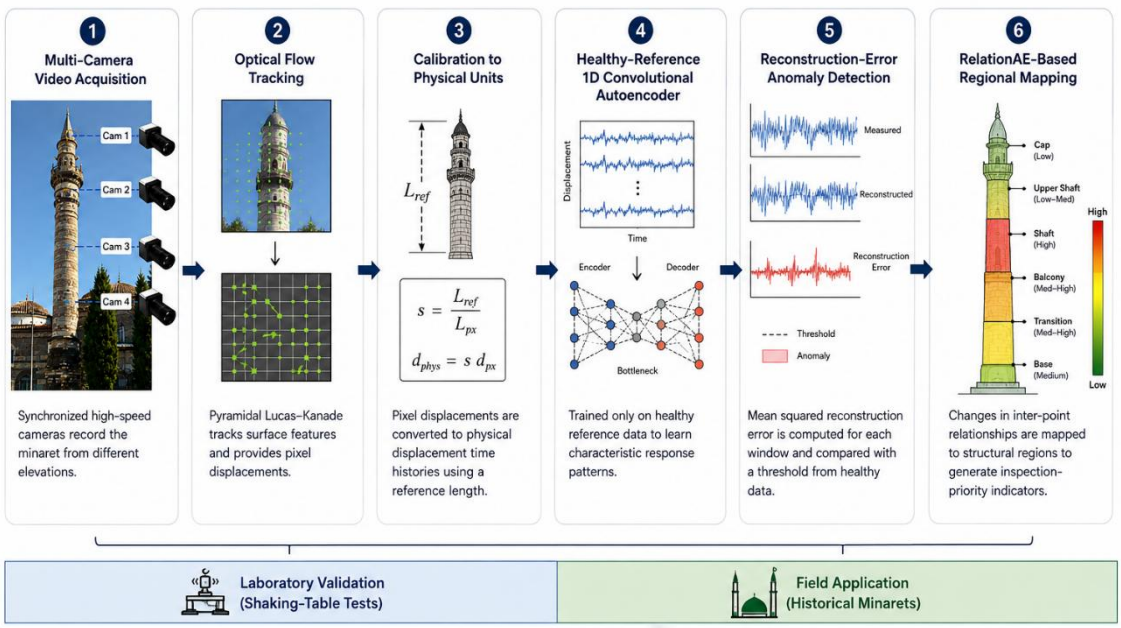

Fig. 1. Overview of the proposed multi-camera vision-based monitoring and unsupervised anomaly assessment framework.

2.2 Reconstruction-Error and Regional Anomaly Assessment

An unsupervised one-dimensional convolutional autoencoder (1D CAE) was used to identify deviations from the healthy-reference response. The multi-channel displacement records were divided into normalized temporal windows, and the model was trained exclusively on healthy data. The encoder compressed each window into a latent representation, while the decoder reconstructed the input. The deviation between the measured and reconstructed responses was quantified using the mean squared reconstruction error:

$$\left[RE_i = \frac{1}{WC}\sum_{c=1}^{C}\sum_{t=1}^{W}\left(x_{i,c,t} - \hat{x}_{i,c,t}\right)^2\right] \tag{2}$$

where W is the window length, C is the number of measurement channels, $x_{i,c,t}$ is the normalized measured response, and $\hat{x}_{i,c,t}$ is the reconstructed response. Four displacement channels were used. The anomaly threshold was derived solely from the healthy training-error distribution, and threshold exceedances were interpreted as deviations from the learned reference behavior rather than direct measures of physical damage. To provide spatial interpretation, a relation-based autoencoder (RelationAE) was additionally applied to healthy-reference relationships between monitored-point pairs. Pair-specific anomaly scores were mapped to predefined structural regions to generate relative inspection-priority maps. Thus, reconstruction error identifies when the response departs from the healthy baseline, whereas RelationAE indicates where the strongest deviations are concentrated.

3 3 Laboratory Validation

3.1 Laboratory Model and Shaking-Table Testing

The proposed approach was first evaluated on a laboratory masonry minaret model constructed in the Structural Health Monitoring Laboratory of Karadeniz Technical University. The model,

representing the main structural regions of a typical masonry minaret, was built using clinker bricks and hydraulic lime-based mortar and installed on a uniaxial shaking table. Four cameras positioned approximately 4.5 m from the model were used for simultaneous displacement measurements, while six accelerometers at three elevations provided reference data for validation. Before excitation, the undamaged model was monitored for 20 days using 2-min synchronized video recordings to establish the healthy-reference dataset. The minaret was then subjected to sinusoidal excitations of 10, 20, and 30 mm at 1 Hz for five cycles. Visible cracking developed during the final 30-mm excitation, mainly along masonry interfaces in the shaft and transition-zone regions, providing physical evidence of structural change for comparison with the anomaly indicators.

Fig. 2. Laboratory validation setup: (a) masonry minaret model and multi-camera measurement configuration, (b) shaking-table installation, and (c) representative cracking observed after the final excitation.

3.2 Dynamic Validation and Reconstruction-Error Response

The reliability of the vision-based displacement measurements was first assessed through frequency-domain comparison with accelerometer records. In the healthy condition, the first dominant frequency was identified as 9.364 Hz from the accelerometers and 9.322 Hz from the camera response, corresponding to a difference of 0.45%. The second dominant frequency was 47.536 and 47.131 Hz, respectively, with a difference of 0.85%. After the shaking-table tests, the corresponding frequencies were 7.692 and 7.755 Hz for the first mode and 39.750 and 40.577 Hz for the second mode, with differences remaining below 2.1%. Compared with the healthy state, the modal frequencies decreased by approximately 13.9–17.9%, confirming that the vision-based system captured the principal dynamic changes of the model. The four-channel displacement data were then evaluated using the reconstruction-error-based anomaly framework. The 1D CAE was trained only on healthy-reference windows, and the anomaly threshold was derived exclusively from the training reconstruction-error distribution.

As shown in Fig. 3, anomaly scores remained generally low and stable during the training and test periods. In Damage 1, reconstruction-error variability increased and threshold exceedances became more frequent. In Damage 2, the anomaly scores increased markedly and remained above the healthy-reference threshold for extended periods, indicating a progressively stronger departure from the learned healthy behavior.

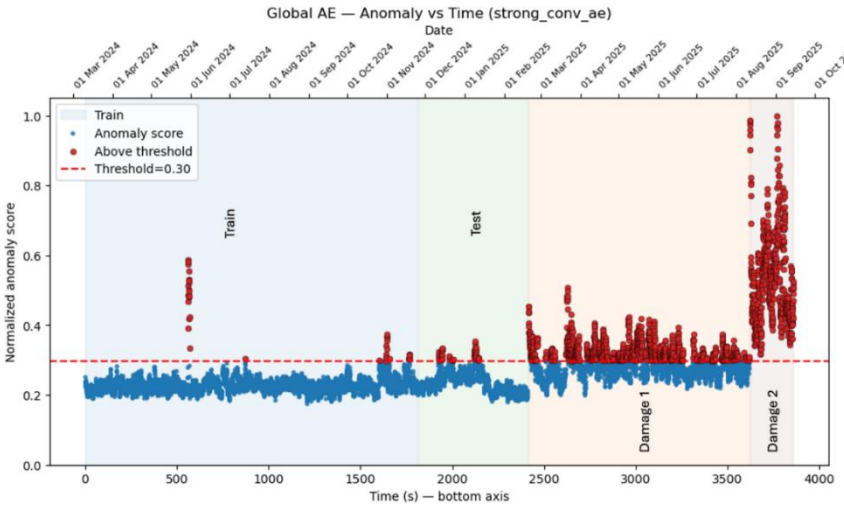

Fig. 3. Normalized reconstruction-error-based anomaly scores of the laboratory minaret model for the training, test, Damage 1, and Damage 2 measurement periods.

The discrimination capability of the reconstruction-error scores was also examined retrospectively using receiver operating characteristic and precision–recall analyses. Under the controlled laboratory conditions, the model achieved an ROC–AUC of 0.916 and an average precision of 0.856. These values support the observed separation between the healthy-reference and damaged-state responses; however, they represent classification performance under controlled experimental conditions rather than a quantitative measure of physical damage severity.

3.3 Regional Damage-Sensitive Assessment

The RelationAE analysis was used to investigate whether the experimentally induced structural changes also altered the relationships between responses measured at different locations. Pairwise anomaly scores remained generally stable during the training and test periods, while intermittent deviations emerged in Damage 1. In Damage 2, pronounced and sustained threshold exceedances occurred across all evaluated measurement-point pairs. The Point 2–Point 4 relationship exhibited the largest deviation, while Point 1–Point 4 and Point 2–Point 3 also showed substantial changes. To obtain a spatially interpretable representation, the pairwise anomaly contributions were mapped to the corresponding structural regions. The resulting inspection-priority map is presented in Fig. 4. The upper shaft was identified as the highest-priority region. The balcony, lower shaft, and transition zone were classified as medium-priority regions, whereas the base and cap were assigned low priority. The high priority attributed to the upper shaft was consistent with the visible cracking observed in the shaft region after the shaking-table tests. The transition zone, where additional cracking was also observed, received a medium-priority classification, indicating that the relation-based assessment captured a notable response change in this region, although at a lower level than in the upper shaft.

The spatial distribution should nevertheless be interpreted with caution because the resulting regional scores depend on the number and location of the monitored points, the relationships represented by each point pair, and the assignment of these measurements to predefined structural regions. Accordingly, the map should be considered a relative damage-sensitive inspection-priority indicator rather than a direct or complete representation of the physical crack distribution. Overall, the laboratory results provided complementary evidence at different assessment levels. The modal-frequency reductions indicated a global change in dynamic behavior, the reconstruction-error analysis identified the temporal progression of deviations

from the healthy reference, and the RelationAE assessment provided a regional interpretation of the detected changes.

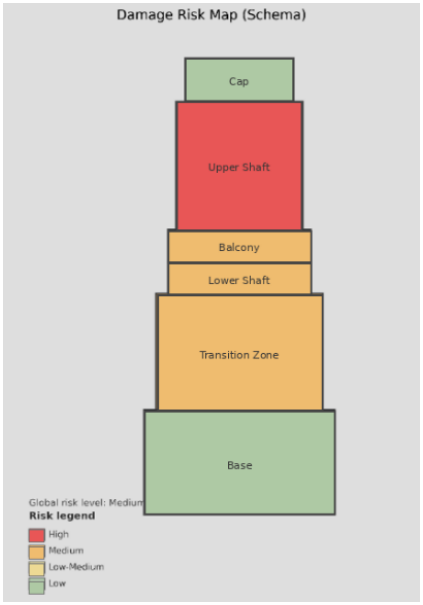

Fig. 4. RelationAE-based regional inspection-priority map of the laboratory minaret model.

4 Field Application: İskenderpaşa Mosque Minaret

4.1 Field Monitoring and Reconstruction-Error Assessment

Following the laboratory validation, the vision-based monitoring framework was applied to eight historical masonry minarets in Trabzon under different structural and environmental conditions. Because each structure had a different geometry, camera configuration, visibility condition, and surrounding environment, the displacement responses were evaluated relative to structure-specific reference measurements rather than using a common threshold. Among the monitored structures, İskenderpaşa Mosque Minaret exhibited the most persistent reconstruction-error exceedances and was therefore selected as the representative field case for detailed regional assessment. İskenderpaşa Mosque Minaret was monitored at approximately monthly intervals. Its courtyard provided a suitable location for repeatable installation of the multi-camera system despite the surrounding urban environment. Four target regions distributed along different elevations of the minaret were monitored using the same vision-based measurement system described in Section 2. Natural masonry features and clearly identifiable surface details were used as tracking targets, while the camera geometry was documented to improve repeatability between successive monitoring campaigns.

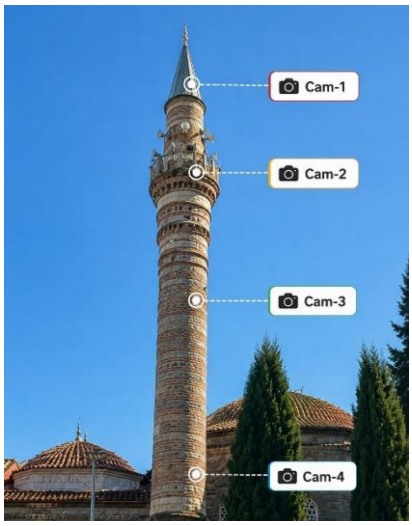

Fig. 5. İskenderpaşa Mosque Minaret and the selected camera-based monitoring regions.

The measured displacement histories were processed using the same healthy-reference anomaly framework employed in the laboratory study. A 1D CAE was trained using the reference portion of the field measurements, and reconstruction errors obtained from subsequent monitoring windows were compared with the threshold derived exclusively from the training-error distribution. As shown in Fig. 6, İskenderpaşa Mosque Minaret exhibited a more pronounced anomaly pattern than the other monitored structures. A substantial proportion of the test windows exceeded the training-calibrated threshold, and the exceedances were relatively dense and persistent throughout the evaluated monitoring period. Although individual threshold exceedances cannot independently be interpreted as evidence of physical damage, their persistence indicated a systematic departure from the response patterns represented by the reference measurements and justified a more detailed local assessment.

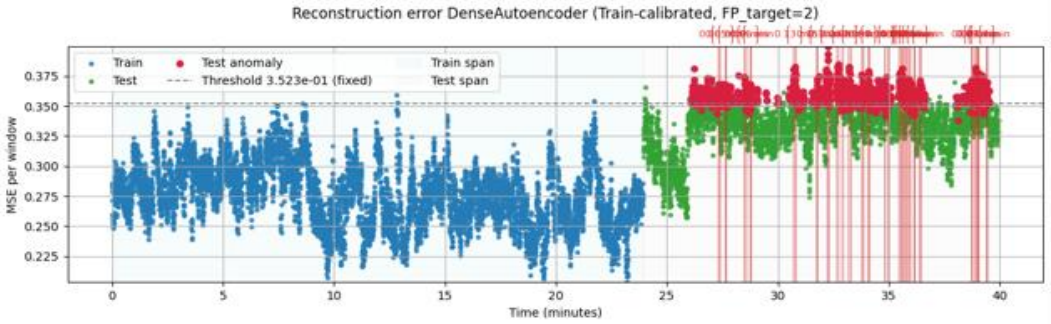

Fig. 6. Reconstruction-error-based anomaly assessment of İskenderpaşa Mosque Minaret.

4.2 Regional Anomaly Mapping and Visual Corroboration

A RelationAE-based analysis was subsequently performed to investigate whether the detected field anomalies were associated with particular relationships between the monitored regions. The anomaly pattern was distributed across several sensor pairs rather than being concentrated in a single relationship. The S1–S4 pair showed the largest number of anomalous segments, followed by S2–S4 and S1–S2, while the remaining sensor combinations also exhibited threshold exceedances. The sensor-level anomaly contributions were then mapped onto the structural regions of the minaret to provide a spatial interpretation of the detected deviations. The resulting regional inspection-priority map identified the balcony and transition zones as the highest-priority regions. The lower shaft and base were classified as medium priority, while the upper shaft showed a low-to-medium priority level and the cap remained in the low-priority

category. The distribution indicates that the detected deviations were more strongly associated with the middle and lower monitored regions than with the upper part of the minaret.

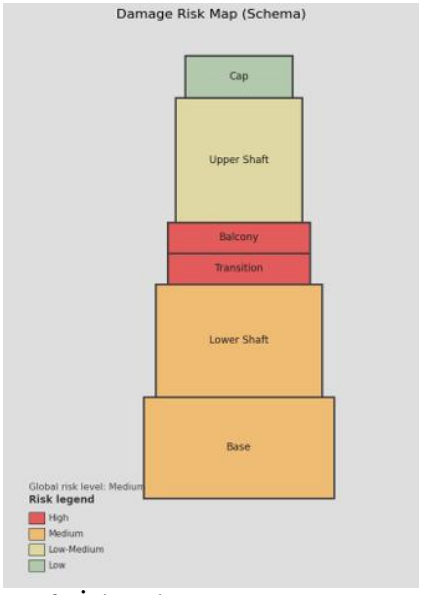

Fig. 7. Regional assessment of İskenderpaşa Mosque Minaret: (a) RelationAE-based inspection-priority map and

5 Discussion

The laboratory and field applications demonstrate the complementary roles of vision-based displacement measurement, reconstruction-error analysis, and relation-based regional assessment. In the laboratory tests, the close agreement between camera- and accelerometer-derived dominant frequencies confirmed the reliability of the optical-flow measurements. Following the shaking-table excitations, modal frequencies decreased by approximately 13.9–17.9%, accompanied by visible cracking in the shaft and transition regions. Reconstruction-error analysis captured the progression from stable healthy and test responses to more frequent exceedances in Damage 1 and persistent anomalies in Damage 2. RelationAE further provided spatial information, identifying the upper shaft as the highest-priority region; the balcony, lower shaft, and transition zone as medium priority; and the base and cap as low priority. The field application demonstrated the extension of the framework to a full-scale historical structure under more variable environmental and operational conditions. İskenderpaşa Mosque Minaret exhibited the most persistent reconstruction-error exceedances among the monitored structures, while RelationAE concentrated the highest inspection priorities around the balcony and transition regions. These findings indicate that frequency-based assessment, reconstruction error, and regional mapping provide complementary global, temporal, and spatial indicators of structural change.

The proposed framework should be interpreted as an inspection-support tool rather than a direct damage-quantification method. Anomaly scores indicate deviations from learned reference behavior but do not directly quantify physical damage severity. Their interpretation may also be affected by camera motion, illumination, viewing geometry, environmental variability, tracking uncertainty, and measurement-point distribution. Therefore, persistent anomalies and regional maps should be evaluated together with repeated monitoring, visual inspection, and complementary structural assessment.

6 Conclusions

This study presented a multi-camera vision-based framework for non-contact anomaly detection and regional damage-sensitive assessment of masonry minarets. The method combines Pyramidal Lucas–Kanade optical-flow displacement measurements with healthy-reference 1D CAE reconstruction error and RelationAE-based regional interpretation. Laboratory validation showed close agreement between camera- and accelerometer-derived dominant frequencies, while the 13.9–17.9% frequency reductions and visible cracking after shaking-table excitation confirmed structural change. Reconstruction-error scores progressively increased from the healthy and test periods to Damage 1 and Damage 2. The framework was also demonstrated on İskenderpaşa Mosque Minaret, where persistent reconstruction-error exceedances indicated deviation from the reference response and RelationAE identified the balcony and transition as the highest-priority regions.

Overall, the approach provides a minimally invasive tool for detecting structural-response changes and supporting inspection prioritization. The anomaly indicators should not be interpreted as direct measures of physical damage and should be evaluated together with repeated monitoring, visual inspection, and complementary non-destructive assessment. Future work should consider longer monitoring periods, environmental variability, and denser multi-view measurements.

Abstract. Post-earthquake visual inspection is time-sensitive, yet unstable components, debris, and restricted access may expose engineers to avoidable risk. This paper presents the architecture, implementation, and controlled experimental assessment of a human-supervised quadrupedal platform for preliminary crack-related inspection. The system combines a Unitree Go2 EDU robot, an Intel RealSense D435i RGB-D camera, a Unitree 4D LiDAR L1, external computing hardware, YOLOv8x crack-candidate detection, aligned-depth distance association, and ROS 2 communication. Annotated images, cropped candidate regions, approximate camera-to-target distances, system states, and control-related messages are integrated within an operator-supervised workflow. The platform was evaluated in a controlled indoor course containing eight prepared crack models using four fixed camera-pitch configurations. The −15°, 0°, +15°, and +30° configurations produced observed coverage of 1/8, 3/8, 7/8, and 7/8 targets, respectively, indicating a strong practical influence of camera viewpoint on crack-candidate visibility. These observations represent scenario-level system evaluation rather than statistical detector validation. The platform is intended as an inspection-support tool and does not determine crack geometry, structural severity, or building safety.

Keywords: Post-earthquake inspection; quadrupedal robot; structural crack detection; RGB-D sensing; ROS 2; YOLOv8x

1 Introduction

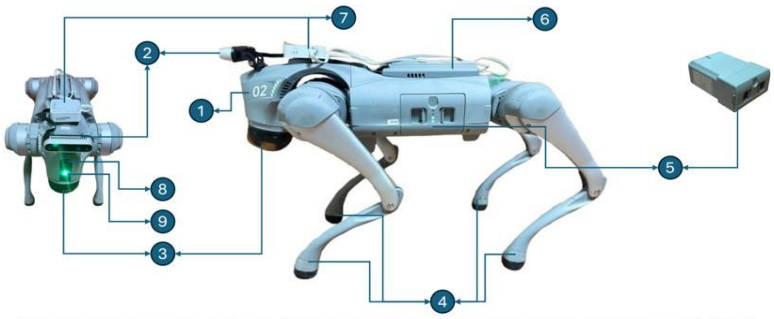
Post-earthquake assessment requires the rapid documentation of visible damage while preserving the engineering judgement needed to distinguish superficial cracking from potentially significant distress. Established safety procedures place trained personnel at the centre of occupancy and intervention decisions [1–3]. Applying these procedures, however, may require entry into buildings affected by unstable finishes, falling hazards, damaged stairs, debris, poor lighting, and uncertain floor conditions. Robotic inspection is therefore most defensible as a means of collecting preliminary evidence before, or alongside, direct professional assessment rather than as an automated substitute for it.

Mobile robotic systems can extend visual access and improve the traceability of inspection records, although their usefulness depends on mobility, sensing quality, communication, and operator control [4]. Quadrupedal platforms are relevant to built environments because legged locomotion can negotiate thresholds and irregular surfaces that may constrain conventional wheeled bases. Field studies with legged robots have demonstrated inspection in industrial and sewer environments, while also identifying practical limits associated with payload, power, sensing geometry, and environmental variability [5, 6]. These constraints are particularly important after earthquakes, when irregular access or an unsuitable viewpoint may result in a missed or ambiguous observation.

Computer vision provides a complementary means of screening inspection imagery. Convolutional approaches have been developed for crack detection and the recognition of multiple visual damage types in civil infrastructure [7–9]. One-stage object detectors provide bounding-box outputs that can be incorporated into mobile sensing workflows [10, 11], whereas segmentation methods produce richer pixel-level representations [12, 13]. Neither output removes the need for scale, calibration, contextual evidence, and engineering interpretation. A crack-related visual indication must therefore be connected to sensing context, evidence storage, and a controllable robotic platform.

ROS 2 provides the middleware needed to connect distributed sensing, perception, robot-state, and operator-facing processes [14, 15]. Related work has also demonstrated real-time structural crack inspection using a quadrupedal robotic platform [16]. In the present system, ROS 2 connects RGB-D sensing, crack-candidate detection, aligned-depth distance context, environmental sensing, evidence recording, platform communication, and human supervision.

The contribution of this work is the implementation and controlled system-level assessment of a human-supervised quadrupedal inspection platform integrating RGB-D sensing, deep-learning crack-candidate detection, approximate distance association, ROS 2 communication, environmental sensing, evidence recording, and operator control. The integrated workflow is evaluated using prepared crack targets under four camera-pitch configurations to examine the practical influence of viewpoint on observed detection coverage. The study does not claim structural diagnosis, crack-severity classification, exact crack measurement, complete three-dimensional localisation, certified safety operation, or unrestricted autonomous building inspection.



2 System Design and Architecture

2.1 Quadrupedal robotic platform

The mobile base is a Unitree Go2 EDU quadrupedal robot [17], which serves as the carrier for the inspection sensors and provides mobility for collecting visual and spatial evidence. Its legged configuration is relevant to built environments where thresholds and surface irregularities may constrain conventional wheeled platforms. Robot-state and command-related communication are separated from the perception layer so that crack-candidate processing remains independent of structural interpretation while the operator retains supervisory control.

2.2 Sensor and computing configuration

The platform carries a front-mounted Intel RealSense D435i for RGB-D inspection sensing and a Unitree 4D LiDAR L1 for surrounding-geometry information. RGB images from the D435i support crack-candidate detection, while aligned depth provides approximate distance context. An Orin NX 8 GB expansion module is installed on the robot; however, during the reported implementation, YOLOv8x inference and the principal ROS 2 monitoring processes were executed on an external Lenovo L340 equipped with an Intel Core i7 processor, 16 GB RAM, and an NVIDIA GTX 1650 GPU.

Table 1. System components and their implementation roles.

Component	**Function**	**Data or communication role**
Unitree Go2 EDU	Mobile sensor carrier	Robot state and command-related communication
Intel RealSense D435i	RGB-D inspection sensing	RGB images and aligned-depth images
Unitree 4D LiDAR L1	Environmental sensing	Surrounding-geometry data for operator awareness
Expansion Dock Orin NX 8 GB module	Robot-mounted expansion computing	Installed hardware; not documented as the YOLO inference device
Lenovo L340 with GTX 1650	External processing computer	YOLOv8x inference, ROS 2 processes, monitoring, and logging
ROS 2 and Go2 SDK	Middleware and robot interface	Sensor, state, log, and control-related message exchange

2.3 ROS 2 communication architecture

ROS 2 forms the communication backbone between the robot interface, sensing processes, perception node, monitoring tools, and control-related messages. Robot data exchange uses WebRTC-based communication and the go2_ros2_sdk framework, including its go2_robot_sdk package [18]. The driver exposes robot state and sensor information to ROS 2 and accepts command-related messages. Unitree SDK Python provides high-level control access when direct operator intervention or perception-related behaviour is required.

The RealSense interface publishes colour and aligned-depth images. A single-frame RGB queue replaces an older waiting frame when a newer image arrives, thereby limiting the accumulation of stale imagery. The latest aligned-depth frame is retained separately and queried when the crack-processing node produces a candidate region. This division keeps semantic processing in the RGB branch and uses depth selectively for geometric context.

The perception node publishes annotated evidence and damage-related messages, while the operator interface presents module states and logs. The topics /yolo/stop_trigger and /yolo/stop_state communicate perception-related stop conditions to other processes. These messages are software communication mechanisms, not certified safety functions. Figure 2 summarises the sensing, perception, communication, evidence, and supervision paths.

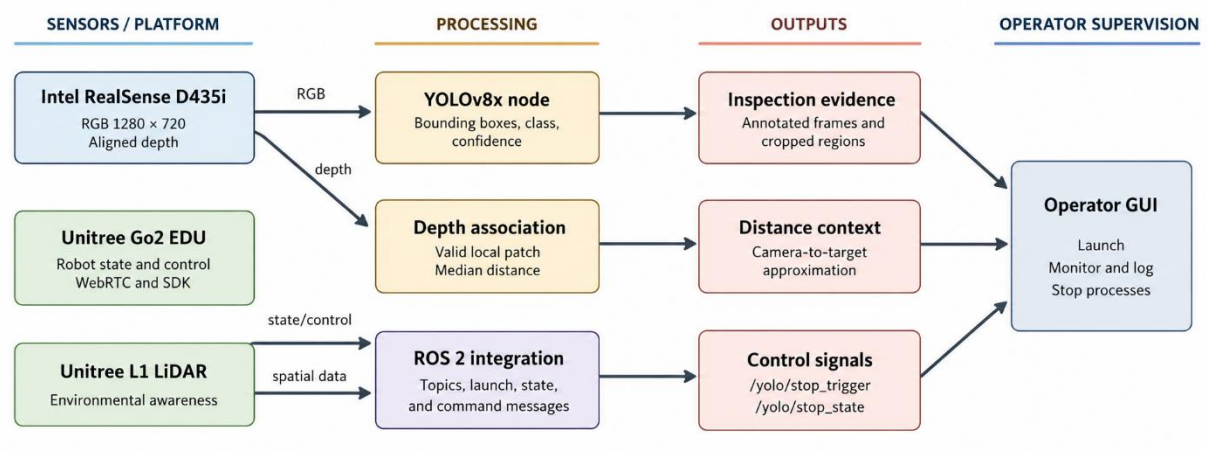

Fig. 2. ROS 2-based data flow for crack-candidate detection, aligned-depth association, evidence generation, control signals, and operator supervision.

3 Crack-Inspection Methodology

3.1 RGB image acquisition and YOLOv8x processing

The visual-processing module uses the Ultralytics YOLOv8x object-detection architecture, initialised from pretrained yolov8x.pt weights with Ultralytics version 8.2.92 [19]. The model was adapted to a single class, crack, using labelled crack images and bounding-box annotations from the SurfaceCrackDetection dataset on Roboflow Universe [20]. The present paper focuses on system architecture and implementation; dataset statistics and model-development outcomes are therefore outside its scope.

The RealSense colour stream is configured at 1280 × 720 pixels and 30 frames/s. Incoming frames are converted into the representation expected by the YOLO node, after which configurable confidence filtering and non-maximum suppression remove unsuitable or overlapping candidate boxes. For each retained candidate, the node records the bounding-box coordinates, class identifier, confidence value, and annotated RGB image. A cropped image of the candidate region may also be generated for later review.

The term crack candidate is used deliberately throughout this paper. A bounding box directs attention to an image region but does not provide a segmentation mask or determine crack length, width, orientation, physical depth, mechanism, or structural significance.

3.2 RGB-depth alignment

The RealSense interface aligns the depth image to the RGB image so that a pixel coordinate produced by the visual detector can be queried in the corresponding depth frame. RGB and depth remain separate data products: the RGB image supplies the appearance information used by YOLOv8x, whereas the aligned-depth image supplies local range information. The

architecture retains the latest depth frame and associates it with a candidate only when the required aligned data are available.

Alignment supports pixel-level correspondence between the two streams, but correspondence alone does not establish a calibrated position in the robot or building coordinate system. Such a transformation would require camera intrinsics, camera-to-robot extrinsics, time synchronisation, and appropriate coordinate-frame transformations.

3.3 Local median-depth association

Depth association begins at the centre pixel of the detected bounding box. Because a single depth sample can be invalid near edges, reflective regions, or occlusion boundaries, the implementation extracts a local patch around that centre. Values outside the accepted depth limits are removed, and the median of the remaining samples is converted to metres when the depth image is represented in millimetres:

$$d = median\{D(u,v) \mid d_{min} < D(u,v) < d_{max}\} \quad (1)$$

Here, $D(u, v)$ is the aligned-depth value at image coordinate (u, v), and $d$min and $d$max define the accepted depth interval. The resulting quantity is an approximate camera-to-target distance associated with the candidate region. Median filtering limits the influence of isolated invalid samples, but it does not provide exact crack depth, crack width, three-dimensional crack localisation, structural severity, or a calibrated structural measurement.

3.4 Evidence recording and damage-related messages

The perception process combines visual and distance information within a common evidence record. Annotated frames retain the bounding box and confidence value in the surrounding scene, while candidate crops and the available approximate distance can be saved for subsequent review. The node also publishes /yolo/stop_trigger and /yolo/stop_state messages to communicate configured crack-candidate conditions to downstream processes. These outputs support operator supervision and evidence review rather than structural or safety decisions.

4 Operator Interface and System Workflow

The graphical user interface provides a common entry point for launching and monitoring the robot interface, camera, perception, and supporting ROS 2 processes. Module states and textual logs allow the operator to identify active processes, communication faults, missing sensor data, and node termination without changing applications. Visual evidence and perception-related information are presented together with the relevant system state to support traceable inspection review.

The operator can stop individual process groups or terminate active processes when intervention is required. Perception-related stop messages provide an additional software mechanism for holding robot activity when a candidate region requires attention. Because visual candidates and local depth values do not independently establish structural significance, the operator remains responsible for reviewing the evidence and deciding how the platform should proceed.

5 Experimental Test Course and Procedure

The integrated robotic workflow was evaluated in a controlled indoor inspection course using eight prepared visual crack models positioned at different heights. The targets were used as repeatable crack-related visual features rather than representations of the full variability or structural significance of earthquake-induced cracking. Models 1–8 were positioned at heights of 90, 50, 100, 45, 90, 70, 30, and 90 cm from the ground, respectively. Their distribution provided targets across different portions of the robot-mounted camera's vertical field of view.

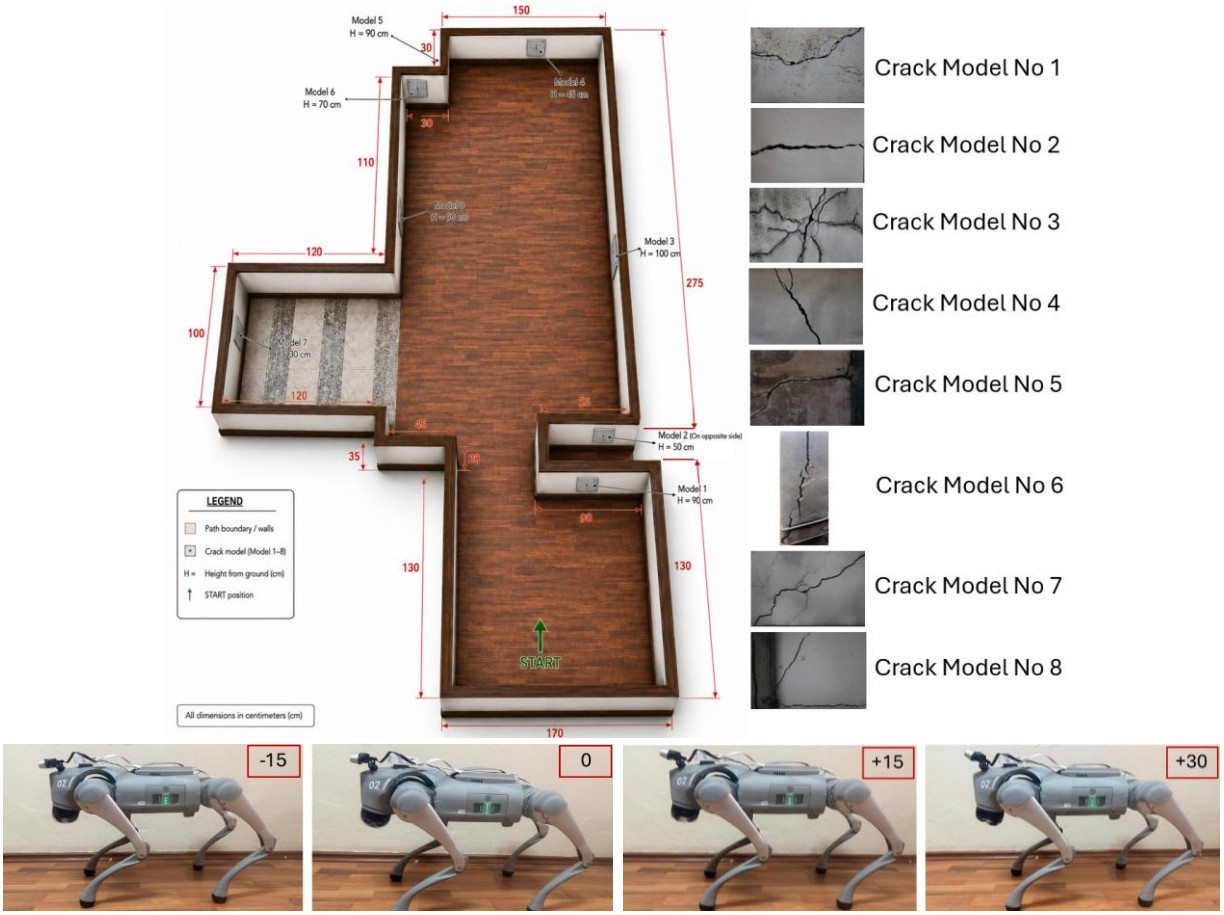

Fig. 3. Controlled indoor inspection test course used for the integrated robotic experiments.

Four experimental scenarios were defined by changing the fixed pitch of the Intel RealSense D435i while maintaining the same inspection course and prepared targets. Scenario 1 used −15°, Scenario 2 used 0°, Scenario 3 used +15°, and Scenario 4 used +30°. Each configuration was represented by one documented integrated run. The scenarios were intended to examine how camera orientation and the viewpoints produced during robotic inspection affected crack-candidate visibility. Consequently, the runs are treated as controlled scenario observations rather than repeated statistical trials or detector-validation measurements.

6 Experimental Results and Discussion

The observed detection coverage varied substantially among the four camera-pitch configurations. At −15°, only Model 7 was observed, corresponding to 1 of the 8 prepared targets. At 0°, Models 2, 4, and 7 were observed, increasing coverage to 3 of 8. The +15° configuration produced substantially broader coverage, with Models 2, 3, 4, 5, 6, 7, and 8 observed and only Model 1 missed. The +30° configuration also produced 7-of-8 coverage, detecting Models 1, 2, 3, 4, 5, 6, and 8 while Model 7 was not observed.

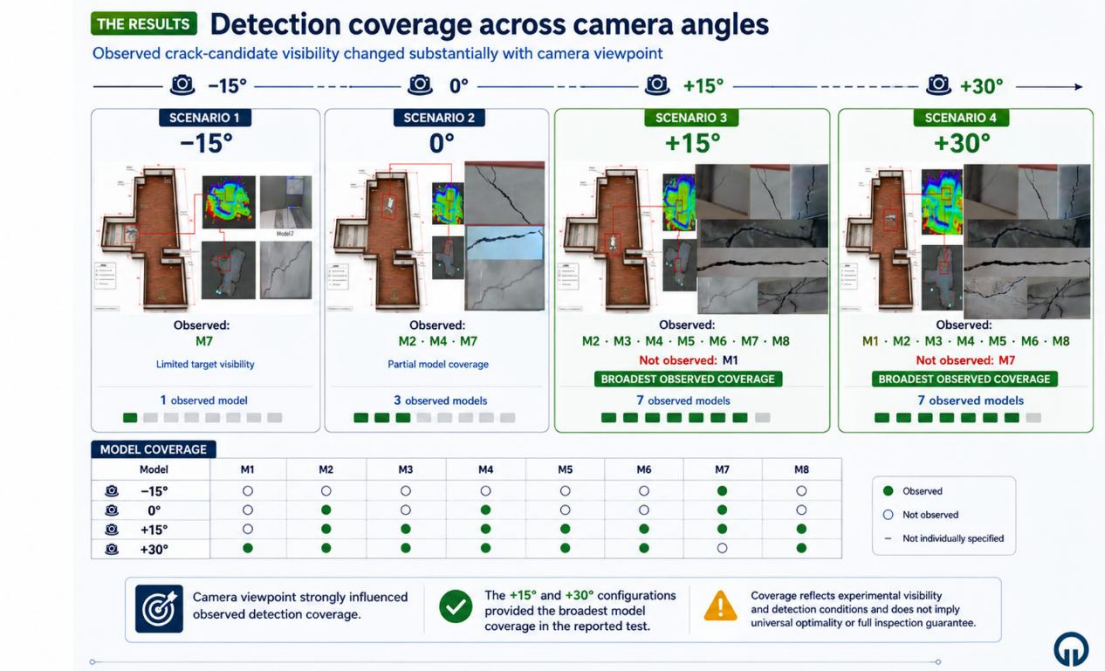

Fig. 4. Detection coverage across the four tested camera-pitch configurations, showing representative scenario outputs and the observed model coverage for the prepared crack targets.

The results indicate that the downward −15° configuration favoured the lowest target, Model 7 at 30 cm, but provided limited useful visibility of higher targets. The horizontal configuration remained biased toward lower-to-medium targets under the achieved viewpoints. Both positive-pitch configurations produced the broadest observed coverage. The +15° configuration retained visibility of the 30 cm target while also detecting Model 3 at 100 cm, whereas +30° favoured medium and higher targets but did not observe the lowest model. No single tested camera pitch independently produced observations of all eight targets.

These findings should not be interpreted as evidence of a universally optimal camera angle. Crack-candidate visibility in the integrated robotic workflow depended on the interaction of camera pitch, field of view, target height, standoff distance, robot pose, surface approach geometry, target scale, and image quality. In addition, each camera configuration was represented by only one documented integrated run, and the experiments used prepared visual crack models in a controlled indoor environment. The results therefore demonstrate scenario-based system behaviour and the practical importance of viewpoint selection rather than statistical repeatability, structural-damage classification, or field performance in earthquake-damaged buildings.

7 Experimental Results and Discussion

This paper presented the architecture, implementation, and controlled experimental assessment of a human-supervised quadrupedal platform for post-earthquake crack inspection. The system integrates a Unitree Go2 EDU, RealSense D435i RGB-D sensing, Unitree 4D LiDAR L1 environmental sensing, external computing, YOLOv8x crack-candidate processing, local median-depth association, ROS 2 communication, evidence recording, and operator supervision. Controlled inspection-course observations showed that camera viewpoint had a strong practical influence on crack-candidate coverage. The −15°, 0°, +15°, and +30° configurations produced observed coverage of 1/8, 3/8, 7/8, and 7/8 prepared targets, respectively, while the two positive-pitch configurations missed different targets. The findings show that useful robotic inspection depends on the interaction between perception and achieved

viewpoint rather than on visual detection alone. The platform remains an inspection-support system and does not determine crack geometry, structural severity, structural condition, or building safety. Further assessment should include repeated trials, calibrated spatial association, more diverse damage conditions, and representative field environments.

Abstract. In recent years, glass-bottomed observation platforms built along cliff edges have become prominent architectural landmarks for tourism. Despite their aesthetic appeal, ensuring the seismic safety of these structures poses a major engineering challenge. Their massive viewing decks, coupled with highly flexible steel supports and low natural damping, amplify their sensitivity to seismic ground motions. In this study, the optimization and seismic performance evaluation of a steel observation platform using a Tuned Mass Damper (TMD) as a passive control strategy are investigated. To design an efficient control system, the optimal parameters of the damper (including damping ratio, and tuning frequency) were determined considering the objective function of minimizing the peak displacement response of the structure. Following the development of the 3D structural model, its seismic response was evaluated under 4 benchmark earthquake records using time-history analyses. The performance evaluation indices in this research include the reduction of Peak and Root Mean Square (RMS) values for both displacement and acceleration responses. The analysis results indicate that the optimized tuned mass damper exhibited excellent performance in mitigating seismic responses under all investigated records. Implementing this control system not only leads to a significant reduction in displacement and acceleration demands in the main structure but also improves the deformation distribution in the deck. These findings demonstrate that utilizing optimized TMD systems serves as an efficient and practical methodology for enhancing the seismic performance of slender steel observation platforms.

Keywords: Glass observation platform; Tuned mass damper (TMD); Optimization; Seismic performance evaluation.

1 Introduction

The twenty-first century has witnessed a remarkable transformation in the philosophy of tourism-oriented structural engineering [1, 2]. Observation platforms, once regarded as simple viewpoints for appreciating natural landscapes, have evolved into internationally recognized architectural landmarks that symbolize technological innovation, engineering excellence, and regional identity [3]. Enabled by rapid advances in structural steel, laminated glass technology, digital fabrication, and computational mechanics, modern glass observation platforms are becoming increasingly slender, transparent, and architecturally ambitious. Their dramatic cantilevered forms, often extending beyond steep cliffs or mountainous terrain, provide visitors with the extraordinary sensation of walking in mid-air while maintaining uninterrupted panoramic views [4-6].

Among countries actively investing in such landmark infrastructure, Türkiye has emerged as one of the world's most dynamic tourism destinations. Beyond its exceptional cultural

heritage and natural landscapes, recent years have witnessed substantial investments in panoramic viewing terraces, glass observation decks, skywalks, and other iconic tourism-oriented structures located in mountainous and coastal regions [5].

This architectural evolution reflects a broader trend in structural engineering toward maximizing structural efficiency while minimizing visual obstruction. Similar developments have historically transformed the design philosophy of long-span bridges, where advances in structural analysis enabled engineers to move beyond purely strength-based designs toward significantly more slender and elegant structural systems while maintaining satisfactory safety and serviceability [7-10]. Observation platforms follow the same philosophy. Unlike conventional buildings, whose structural members are generally hidden within architectural finishes, the supporting system of an observation platform remains continuously exposed to public view.

From a structural engineering perspective, glass observation platforms constitute a unique class of flexible cantilevered structures. Their structural systems typically consist of a relatively massive viewing deck supported by slender steel trusses possessing low inherent damping and limited lateral stiffness. Such configurations produce dynamic characteristics that differ substantially from those of conventional buildings. The combination of concentrated deck mass, significant cantilever action, geometric irregularity, and relatively small structural damping increases their susceptibility to earthquakes, strong wind events, and pedestrian-induced vibrations [3, 9-11].

Mitigating structural vibrations has remained one of the central research topics in structural dynamics for more than a century [12-14]. Since Frahm first introduced the concept of an auxiliary oscillating mass in 1909, passive vibration control systems have continuously evolved through the pioneering contributions of Lanchester and Den Hartog into the classical Tuned Mass Damper (TMD), which remains one of the simplest, most reliable, and most widely implemented structural control devices [15, 16]. Owing to its mechanical simplicity, robustness, and independence from external power sources, the TMD has been successfully employed in numerous skyscrapers, communication towers, long-span bridges, stadium roofs, offshore platforms, and industrial facilities subjected to dynamic loading. Nevertheless, the overwhelming majority of these investigations have focused on conventional buildings and bridge structures, while applications to cantilevered tourist observation platforms remain remarkably scarce [17].

Interestingly, vibration control devices themselves have also become part of modern architectural expression [18]. One of the best-known examples is the 660-ton TMD installed in the Taipei 101, which, unlike conventional practice, was intentionally left visible to visitors rather than concealed within the structure. Such a philosophy is particularly relevant for modern observation platforms, where engineering innovation increasingly forms part of the attraction itself [17].

Despite the growing number of observation platforms constructed worldwide, research on their seismic vibration control remains extremely limited. Existing studies have primarily addressed architectural design, visitor perception, tourism development, structural safety assessment, and pedestrian serviceability, whereas the application of optimized passive vibration control systems has received little attention. Furthermore, because observation platforms differ fundamentally from conventional buildings through their dominant cantilever action, localized flexibility, concentrated deck mass, and unique performance requirements, design methodologies developed for ordinary structures cannot be directly generalized without careful verification [5].

Motivated by these observations, this study investigates the seismic retrofit of a slender steel observation platform using an optimally designed Tuned Mass Damper. A detailed three-dimensional finite element model is developed, and the optimal TMD parameters—including

frequency ratio, and damping ratio—are determined through numerical optimization. The seismic performance of the controlled structure is subsequently evaluated using linear time-history analyses under four representative earthquake records [19].

2. Materials and Methods

The Oylat Glass Observation Platform (GOP) recently constructed as a tourism landmark, located in Hilmiye Village, İnegöl district, Bursa Province, in northwestern Türkiye, was selected as the numerical case study. *Fig.* 1 (left) illustrates the general configuration of the investigated observation platform together with the proposed location of the Tuned Mass Damper (TMD). A detailed three-dimensional finite element model of the observation platform was developed using the commercial finite-element software SAP2000 v26 [20], as shown in *Fig.* 1 (right). The structural members were modeled using three-dimensional frame elements capable of accurately representing both flexural and axial deformation characteristics. The self-weight of all structural components, permanent gravity loads associated with the glass flooring system, and other dead loads were incorporated according to the original design specifications.

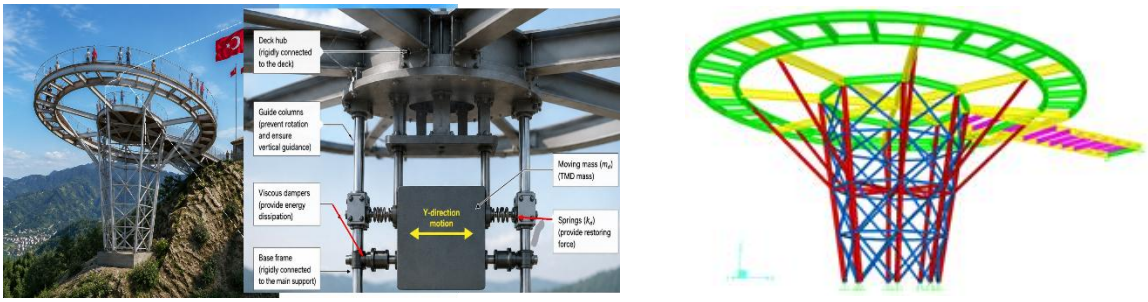

Fig. 1. The Oylat GOP and the position of TMD attached under the deck center joint (left), 3D model of the GOP (right)

The structure consists of a circular cantilevered viewing deck supported by a conical three-dimensional steel truss system anchored directly to the rock foundation. Owing to its lightweight steel configuration, long cantilever span, and relatively low inherent damping, the platform exhibits pronounced flexibility, making it potentially vulnerable to dynamic excitations induced by earthquakes and other transient loading conditions.

The supporting foundation was assumed to be rigidly connected to the underlying rock formation, resulting in fixed boundary conditions at the base of the supporting steel tower. Geometric properties, member connectivity, and material characteristics were adopted directly from the original structural design model provided by the project engineers.

The supporting foundation was assumed to be rigidly connected to the underlying rock formation, resulting in fixed boundary conditions at the base of the supporting steel tower. Geometric properties, member connectivity, and material characteristics were adopted directly from the original structural design model provided by the project engineers.

To improve the dynamic performance of the structure, an optimally tuned passive vibration control device was incorporated into the numerical model. The proposed TMD was installed near the central node of the upper deck support system, where modal participation and structural deformation indicated the highest control effectiveness. Within SAP2000, the TMD was represented by an auxiliary concentrated mass connected to the main structure through linear spring and viscous dashpot elements, enabling simultaneous simulation of inertia, stiffness, and energy dissipation mechanisms.

The TMD was designed according to the classical passive vibration control concept using a fixed auxiliary mass of 5 tons, corresponding to approximately 5% of the effective mass of the

GOP. Since the auxiliary mass was predefined, the optimization problem involved only two design variables, namely the frequency ratio and the damping ratio of the TMD. These parameters were optimized through an iterative numerical procedure coupled with linear time-history analyses in SAP2000. The objective function was defined as the minimization of the maximum deck displacement under the El Centro earthquake record. After obtaining the optimum nondimensional parameters, the corresponding spring stiffness and viscous damping coefficient were calculated and assigned to the numerical model for subsequent seismic performance evaluation.

The seismic performance of the uncontrolled and TMD-controlled observation platform was evaluated using linear time-history analyses under four benchmark earthquake records. To investigate the influence of different seismic characteristics, two far-field earthquakes (El Centro 1940 and Hachinohe 1968) together with two pulse-like near-fault earthquakes (Northridge 1994 and Kobe 1995) were selected. These benchmark records have been widely employed in previous structural control studies, allowing meaningful comparison with existing literature. The benchmark earthquake ground motions adopted in this study are illustrated in *Fig. 2*.

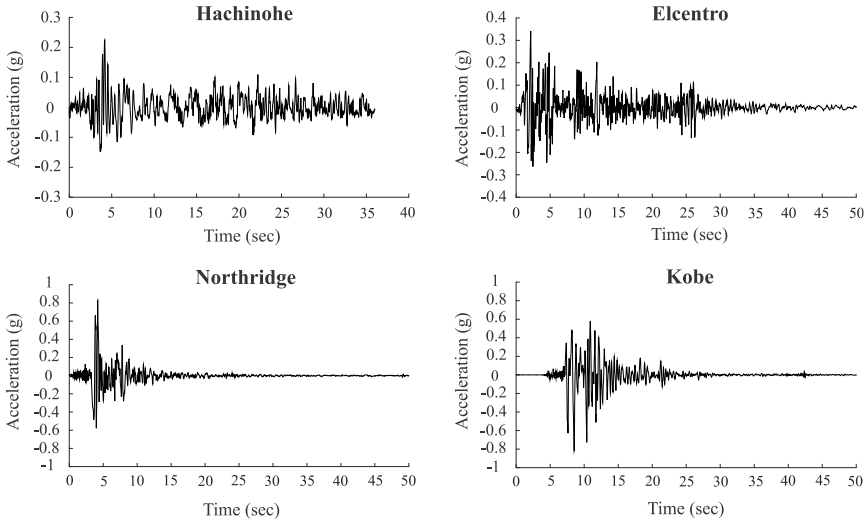

Fig. 2. Time history of benchmark ground motions

Each benchmark earthquake record was applied simultaneously along the two horizontal global directions (U1 and U2) of the three-dimensional structural model by assigning the same single-component ground motion to both directions. The dynamic analyses were carried out using Nonlinear Direct Integration Time History Analysis in SAP2000 with the Hilber–Hughes–Taylor (HHT) integration algorithm and an output time step of 0.01 s. Geometric nonlinearity was neglected, and a proportional damping model corresponding to an inherent structural damping ratio of 0.5% was adopted to represent the low intrinsic damping of the lightweight steel observation platform. Throughout the analyses, relative deck displacements were used to evaluate the effectiveness of the TMD, whereas absolute deck accelerations were employed to assess vibration comfort and seismic acceleration demands.

The effectiveness of the proposed vibration control strategy was assessed by comparing the seismic responses of the uncontrolled and controlled structural models. Two complementary response indices were adopted. The first group consists of conventional peak responses, including the maximum deck displacement and peak acceleration, which represent the maximum structural demand during earthquake excitation and are commonly employed in performance-based seismic design. The second group comprises the Root Mean Square (RMS) values of displacement and acceleration responses. Unlike peak responses, RMS indices

characterize the overall intensity of structural vibrations throughout the entire duration of the earthquake and therefore provide a more comprehensive assessment of the sustained dynamic response. Since observation platforms are continuously occupied by visitors, RMS responses are particularly relevant because they better reflect vibration serviceability, occupant comfort, and the overall effectiveness of the passive control system in suppressing structural vibrations during seismic excitation.

3. Optimum Design of Tuned Mass Damper

A preliminary modal analysis was performed to identify the dominant dynamic characteristics of the uncontrolled observation platform prior to the TMD design. The first vibration mode is primarily torsional, with a natural period of 1.28 s (0.78 Hz) and a rotational modal participation ratio of 82.3% about the vertical axis. Since the objective of the present study is to mitigate the lateral vibration of the observation deck rather than its torsional response, the TMD was tuned to the third vibration mode, which governs the translational response in the global Y-direction. This mode has a natural period of 0.55 s, corresponding to a natural frequency of 1.83 Hz, and exhibits a translational modal participation ratio of approximately 77.3% in the Y-direction. It should be noted that the observation platform is connected to the surrounding terrain through a relatively stiff access walkway aligned with the global X-direction. This structural configuration considerably increases the lateral stiffness of the system in the X-direction, resulting in relatively small translational responses and lower modal participation in that direction. Consequently, the global Y-direction governs the lateral dynamic behavior of the platform and was therefore selected as the target mode for TMD tuning.

If the (ω_d) and (ω_s) represents damper frequency and structural frequency, the frequency and damping ratios could be defined by Eq. (1). These parameters are considered as TMD free parameters, and the optimum values of these parameters are determined such that the structural response is minimized.

$$f = \frac{\omega_d}{\omega_s},\ \zeta_d = \frac{c_d}{2m_d\omega_d} \tag{1}$$

In Eq. (1), the frequency ratio (f) is defined as the auxiliary mass frequency to main mass frequency, and the damping ratio (ζ_d) is defined for the damper with the ratio of its damping to the critical damping. In the latter equation, c_d and m_d are the damping and the mass of damper, respectively.

General steps of the TMD optimum parameters calculation for this equivalent structure are as follows:

1. A frequency analysis is performed and natural frequencies, and modal shapes are realized.
2. Dynamical properties of the first mode (mass, stiffness and damping) are determined, and an equivalent SDOF structure is constructed.
3. Optimization algorithm is employed to find the TMD optimum parameters. In this procedure, the minimization of the maximum deck center displacement is selected as the objective function, and the frequency and damping ratios are applied as the design variables.
4. For the optimum design, a 5-ton TMD (corresponding to approximately 5.4% of the platform mass) was obtained with an optimum frequency ratio of f = 0.95 and an optimum damping ratio of ζ_d = 0.027. The uncontrolled platform exhibits a first natural frequency of 1.83 Hz, resulting in an optimum TMD frequency of 1.74 Hz. The corresponding spring stiffness and viscous damping coefficient were calculated as approximately 600 kN/m and 3000 N·s/m, respectively, and subsequently assigned to the numerical model.

4. Seismic Performance of Optimum TMD

The seismic performance of the optimized TMD was evaluated through linear time-history analyses under four benchmark earthquake records, including two far-field motions (El Centro and Hachinohe) and two near-fault motions (Kobe and Northridge). The dynamic responses were assessed in terms of deck-center displacement, deck-center acceleration, and TMD stroke histories. Both peak and root-mean-square (RMS) response indices were considered to evaluate not only the maximum structural demand but also the overall vibration energy throughout the excitation duration.

Fig. 3 compares the displacement time histories of the uncontrolled and TMD-controlled platform. For all earthquake records, the optimized TMD effectively suppresses the vibration amplitude immediately after the onset of strong shaking and accelerates the decay of free vibration after the principal excitation. Although the effectiveness varies depending on the frequency content and duration of each earthquake, the controlled responses consistently remain below those of the uncontrolled structure. The most pronounced improvement is observed under the El Centro earthquake, where the peak deck displacement decreases by approximately 38%. The Kobe record also exhibits a substantial reduction of about 34%, while reductions of approximately 21% and 17% are obtained for the Hachinohe and Northridge records, respectively. These results demonstrate that the optimized TMD remains effective under both pulse-like near-fault and conventional far-field ground motions despite their significantly different dynamic characteristics.

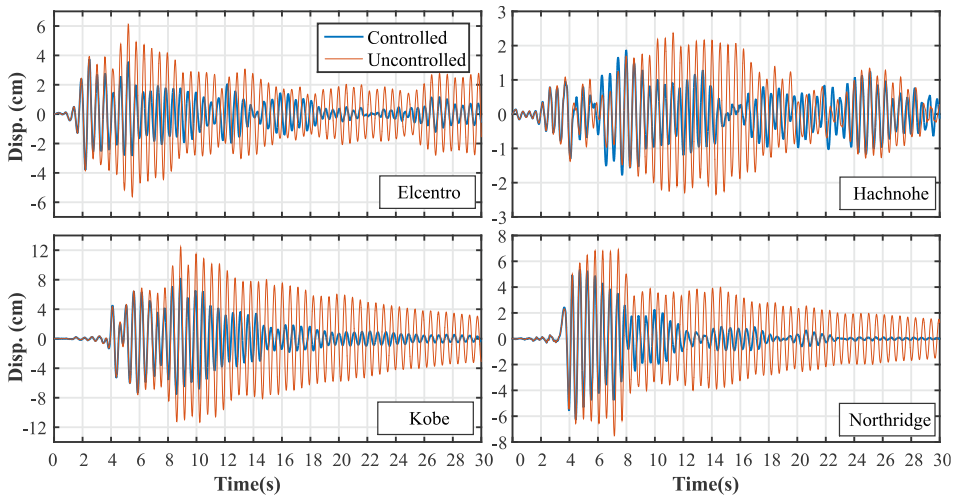

Fig. 3. Deck center displacement history of uncontrolled and controlled platform under four different earthquake.

The acceleration responses shown in *Fig.* 4 exhibit similar trends. Since acceleration is directly associated with occupant comfort and serviceability of observation platforms, its mitigation is particularly important for tourism-oriented structures. The optimized TMD substantially reduces the acceleration amplitudes during the strong-motion phase while also shortening the vibration decay period. Again, the highest improvement is achieved under the Kobe earthquake, where the peak acceleration decreases by approximately 34%, whereas reductions of about 25%, 16%, and 18% are obtained for El Centro, Hachinohe, and Northridge, respectively. These observations confirm that the TMD efficiently dissipates the seismic input energy over a broad range of excitation characteristics.

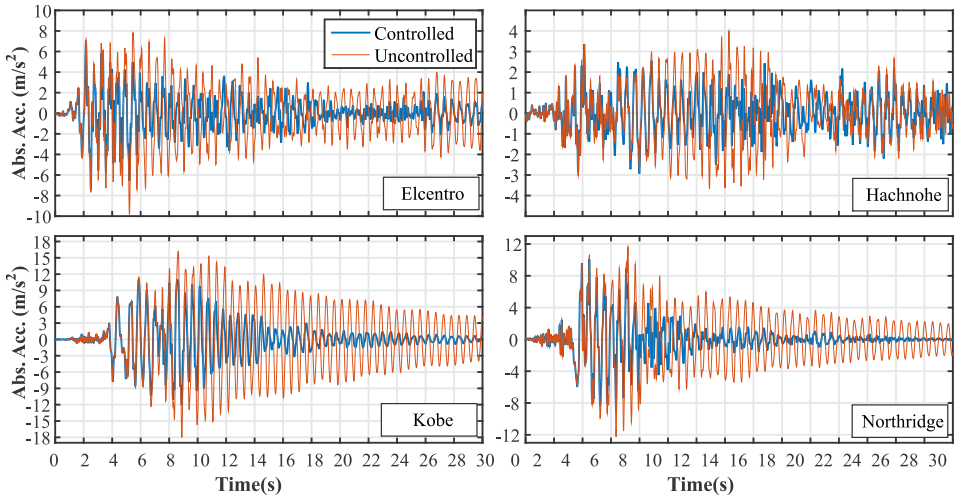

Fig. 4. Deck center Acceleration history of uncontrolled and controlled platform under four different earthquake.

A more comprehensive comparison is presented in Tables 1 and 2. Besides the reduction in maximum responses, the RMS values reveal an even more significant improvement. The RMS displacement decreases by approximately 49%, 35%, 51%, and 44% for El Centro, Hachinohe, Kobe, and Northridge earthquakes, respectively. Likewise, the RMS acceleration is reduced by approximately 43%, 30%, 47%, and 40%, respectively. The consistently larger reductions in RMS responses compared with peak responses indicate that the TMD not only limits the maximum structural demand but also dissipates vibration energy efficiently throughout the entire earthquake duration. This finding is particularly important because RMS represents the cumulative dynamic response of the structure and therefore better reflects vibration mitigation performance, fatigue-related demands, and post-earthquake serviceability than peak values alone.

Table 1. The maximum uncontrolled vs controlled responses at the deck level for different earthquakes

Response	Structure	Far field Earthquakes		Near Field Earthquakes	
		Elcentro	Hachinohe	Kobe	Northridge
Max Disp. (cm)	Uncontrolled	6.11	2.37	12.44	7.52
	Controlled	3.79	1.87	8.16	6.26
Reduction Max Disp. (%)		**37.93**	21.11	34.35	**16.78**
Max Acc. (m/s^2)	Uncontrolled	9.83	3.99	18.04	12.26
	Controlled	7.44	3.36	12.06	10.08
Reduction Max Acc. (%)		24.26	**15.8**	**33.16**	17.77

Table 2. The RMS of uncontrolled vs controlled responses at the deck level for different earthquakes

Response	Structure	Far field Earthquakes		Near Field Earthquakes	
		Elcentro	Hachinohe	Kobe	Northridge
RMS Disp. (cm)	Uncontrolled	1.96	0.93	4.46	2.41
	Controlled	1.00	0.60	2.23	1.35
Reduction RMS Disp. (%)		49.16	**35.21**	**50.12**	44.18
RMS Acc. (m/s^2)	Uncontrolled	2.71	1.34	6.00	3.29
	Controlled	1.56	0.95	3.18	1.95
Reduction RMS Acc. (%)		42.42	**28.89**	**46.91**	40.64

Another interesting observation is that the earthquake producing the largest peak reduction is not necessarily associated with the highest RMS reduction, suggesting a trade-off between instantaneous peak suppression and long-term energy dissipation. Consequently, evaluating only maximum responses may not provide a complete picture of control effectiveness. Simultaneous consideration of both peak and RMS indices offers a more comprehensive assessment of the overall seismic performance of passive control systems.

The displacement histories of the TMD mass relative to the deck are illustrated in *Fig.* 5. As expected, the largest TMD stroke occurs in the dominant vibration direction (Y-direction), while considerably smaller relative motions develop along the orthogonal direction. The maximum stroke reaches approximately ±50 cm under the Kobe record, whereas significantly smaller values are observed for the remaining earthquakes. More importantly, the displacement histories remain smooth without abrupt impacts or unstable oscillations, indicating that the selected tuning frequency and damping ratio enable stable energy exchange between the main structure and the auxiliary mass. The maximum relative displacement obtained in this study may serve as a preliminary design parameter for sizing the available TMD travel and clearance in future practical implementations.

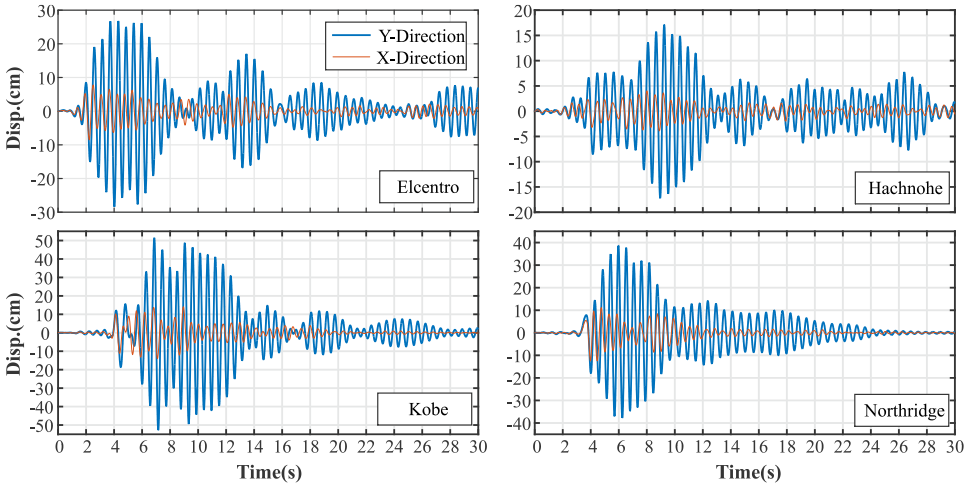

Fig. 5. TMD stroke history in X and Y-direction under four different earthquake.

Overall, the numerical results demonstrate that the optimized TMD provides a reliable passive vibration control solution for slender observation platforms subjected to different seismic scenarios. Besides reducing peak structural demands, the considerable reduction in RMS responses indicates a substantial improvement in global vibration mitigation efficiency, making the proposed system particularly attractive for landmark tourist structures where both structural safety and visitor comfort are of primary importance.

5. Conclusion

This study presented the seismic performance evaluation of a slender steel observation platform equipped with an optimized tuned mass damper (TMD). The TMD parameters were optimized by minimizing the peak deck displacement, and the effectiveness of the proposed passive control strategy was assessed through linear time-history analyses under two far-field and two near-fault earthquake records.

The numerical results demonstrated that the optimized TMD effectively mitigates both displacement and acceleration responses for all investigated earthquakes. Peak deck displacement and acceleration were reduced by up to approximately 38% and 34%, respectively, while the RMS responses exhibited even greater reductions, reaching approximately 51% for displacement and 47% for acceleration. These results indicate that the

proposed TMD effectively suppresses both the peak and sustained dynamic responses of the observation platform throughout the earthquake duration.

The results also highlight that the vibration mitigation performance is highly sensitive to the tuning frequency of the TMD. Therefore, careful optimization of the frequency ratio, which directly governs the equivalent stiffness of the damper, is essential for achieving efficient seismic response reduction.

The computed TMD stroke histories remained stable under all considered earthquake records, providing useful information for the preliminary sizing of the TMD travel during the conceptual design stage.

Overall, the proposed optimized TMD provides an efficient, practical, and economical passive vibration control solution for slender observation platforms. The presented methodology can be readily extended to other lightweight landmark structures, including panoramic viewing decks, skywalks, elevated pedestrian platforms, and similar flexible steel systems where structural safety and visitor comfort are both critical design objectives.

Abstract. In modern structural engineering, composite materials are widely used, but varying coefficients of thermal expansion (CTE) among components generate complex internal stresses under high temperature differences. These thermal stresses can lead to interfacial stress concentrations, microcracks, and delamination. While these mechanisms are extensively studied using numerical methods in the literature, there remains a significant need for experimental validation under complex boundary conditions. The primary objective of this study is to experimentally investigate thermal stresses in composite systems using the photoelasticity method. Before advancing to multi-component tests, this preliminary study aims to simulate targeted thermal behavior using the mechanical modeling principle and validate the obtained photoelastic data.

In the experimental phase, the stress-freezing technique was employed. A specifically designed specimen was heated to its viscoelastic temperature, subjected to a mechanical tensile load to reflect uniform thermal deformations, and then cooled to room temperature under a controlled regime to freeze the deformations.

The pre-strained components obtained from this specimen were subsequently bonded to initially unloaded components containing a geometric discontinuity. A second thermal cycle was then applied to release the frozen deformations and generate a self-equilibrated stress field resulting from the strain incompatibility between the bonded components. Stress measurements were subsequently performed at designated points using a polariscope. To verify the optical results, both experimental stages were modeled using ABAQUS finite element analysis, while analytical solutions based on the wedge problem and an axisymmetric thermoelastic model were employed for the corresponding stages.

The experimental optical data, numerical finite element analysis, and analytical solutions demonstrated a reasonable agreement, following the expected stress attenuation trend. This convergence indicates that the stress-freezing technique can be used to simulate thermal stress behaviors in composites. Overall, this validated experimental approach provides a basis for analyzing more complex composite models in subsequent research stages.

Keywords: Photoelasticity; Thermal stress; Composite materials; Mechanical modeling

1 Introduction

The design of contemporary load-bearing systems extends beyond mere mechanical strength and capacity; thermomechanical stability under environmental variations is an equally critical criterion [1]. While composite materials offer substantial advantages such as high strength-to-

weight ratios and corrosion resistance—making them ideal for civil infrastructure and aerospace applications—their heterogeneous nature presents unique challenges. When exposed to significant thermal gradients, the mismatch in the coefficients of thermal expansion (CTE) among different constituents induces unbalanced internal forces [2, 3]. Such thermal mismatches are known to cause cracking in the concrete surrounding FRP reinforcement [1], pose pressurized thermal shock (PTS) threats in nuclear facilities [2], and affect the mechanical response of composite laminates under repeated impact loading [5].

In the current literature, the assessment of these complex thermal interactions heavily relies on computational and analytical frameworks. Extensive research has been dedicated to estimating thermal loads in steel-concrete girders, predicting the thermal buckling of functionally graded (FGM) plates, and solving 1D and 3D heat conduction problems in multilayered shells [3, 6-11]. Analytical formulations have also been established for axisymmetric configurations, including elastic matrices reinforced with fiber rods and cylinders exhibiting radially dependent properties [8, 9]. Concurrently, numerical simulations have been utilized to evaluate the stress fields in multi-bolt aircraft hybrid panels subjected to extreme thermal environments [14].

Although numerical and analytical models provide useful information on thermomechanical behavior, verifying these theoretical predictions through physical experiments is essential, especially for structures with intricate interfaces and varying boundary conditions [3, 4]. Optical techniques, particularly photoelasticity, address this gap by exploiting the birefringence of certain transparent polymers to capture full-field stress distributions [15]. Digital photoelasticity has been successfully implemented to quantify strain intensity factors near inclusions, assess stress concentrations around stiffeners, and observe thermal stress fields in graded materials [4, 12, 13]. Such optical measurements are crucial for calibrating finite element models and correcting assumptions related to boundary constraints.

Based on this need, the current study presents an experimental methodology to simulate temperature-induced stresses in composite structures via the "mechanical modeling" concept, utilizing the stress-freezing technique. Rather than applying direct thermal gradients, a specially manufactured variable cross-section polymer specimen was utilized. The process involved heating the material in a temperature-controlled oven at a rate of 7°C/h until it reached its viscoelastic state (155°C). A predefined mechanical tensile load was then introduced to mimic the targeted thermal expansion. By systematically cooling the specimen back to ambient conditions while maintaining the load, the induced deformations were permanently locked into the molecular structure. The stress-frozen specimen was then sectioned into radial components, which were bonded to initially unloaded components containing a geometric discontinuity. During a second thermal cycle, the recovery tendency of the pre-strained components was restrained by the bonded components, thereby generating a self-equilibrated stress field that mechanically represents thermally induced strain incompatibility. The radial stress fields acquired from polariscope readings were subsequently correlated with a corresponding ABAQUS finite element model and Timoshenko's analytical solutions for a wedge subjected to a concentrated load [16]. The strong correlation between the optical, numerical, and theoretical findings confirms the reliability of the stress freezing procedure, thereby providing an experimental basis for the future analysis of multi-phase composite geometries.

2 Experimental Methodology

2.1 Photoelastic Material Characterization

Initially, the material for fabricating the experimental specimens was determined. Epoxy resin was selected for this purpose due to its high light transmittance and known stress-optic coefficient.

Since the subsequent mechanical modeling stages require both the critical temperature at which the material exhibits linear elastic behavior and its modulus of elasticity at this specific temperature, corresponding tests were conducted to evaluate these properties.

To determine the critical temperature and the thermomechanical behavior of the selected epoxy resin, test specimens were manufactured and subjected to a single-cantilever bending test using a DMA Q800 (Dynamic Mechanical Analyzer). This test facilitated the precise determination of the glass transition and critical temperature values. This identified critical temperature represents the exact thermal state required to successfully freeze the induced deformations and stresses within the material.

As observed in Figure 1, the critical temperature was determined to be 155°C by considering the region where the values stabilize. Tensile test specimens were fabricated from the selected epoxy resin, heated to 155°C in the DMA, and subjected to tensile testing at this elevated temperature. The results of these tests facilitated the determination of the modulus of elasticity and the overall mechanical behavior of the epoxy resin at the specified thermal state. An examination of the resulting plot in Figure 1 confirms that the material explicitly exhibits linear elastic behavior at this temperature.

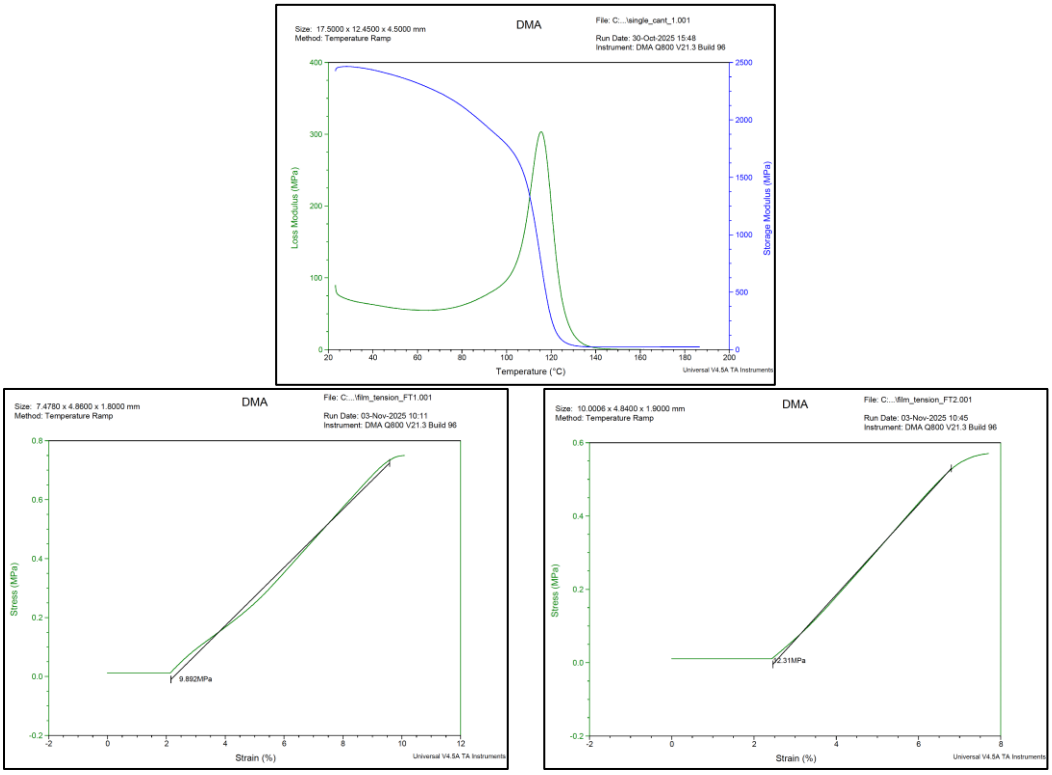

Fig. 1. Epoxy Resin Flexural Test Results and Tensile Test Results

2.2 Mechanical Simulation of Thermal Strain

Following the characterization of the material's mechanical properties, the experimental procedure advanced to the fabrication of the specimen required to simulate the thermal induced deformations via mechanical loading. In this phase, a tensile test specimen featuring a variable cross-section was designed to generate radial stresses. A CNC machine was utilized to achieve high dimensional accuracy and precision during the fabrication process. The resulting tensile specimen is depicted in Figure 2.

Fig. 2. CNC Cutting and Tensile Test Specimen

The specimen was heated in a controlled manner to the previously determined critical temperature so that the radial stresses and strains induced in the specimen could be permanently retained using the stress-freezing technique. To obtain a temperature distribution as uniform as possible within the specimen and to minimize undesirable residual stresses that could arise during heating, the temperature was increased at a rate of approximately 7°C/h until 155°C was reached. The specimen was held at this temperature for approximately two hours to ensure that the entire cross-section reached the target temperature. This temperature corresponds to the viscoelastic state of the epoxy resin suitable for the stress-freezing process, as determined from the DMA tests.

Following thermal equilibration, an axial tensile load was applied to the specimen. Owing to the variable cross-section geometry, the applied axial load generated a radially varying stress and strain field in the body region of the specimen. Thus, without directly applying a thermal gradient, a radial strain distribution intended to represent the target thermal expansion behavior was mechanically generated. The strain state obtained under loading was subsequently used as the initial strain state in the bonded model prepared in the following stage.

While the applied load was maintained, the specimen was subjected to a controlled cooling program, and the temperature was reduced to room temperature at approximately 4°C/h. Cooling under load enabled the strains generated at the elevated temperature to be frozen within the specimen. As a result, the stress field produced by mechanical loading and representing the targeted thermal strain state was retained in the specimen even after the external load was removed.

Before and after the stress-freezing process, the specimen was examined under a polariscope. The isochromatic fringe pattern observed after loading clearly demonstrates the stress field generated by mechanical loading in the variable cross-section region in Figure 3. The resulting stress distribution was also related to the analytical solution based on the wedge problem, which was used to evaluate the theoretical behavior of the variable cross-section specimen.

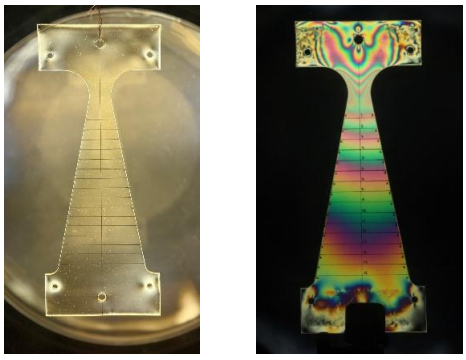

Fig. 3. Photoelastic fringe patterns of the variable cross-section specimen before and after stress-freezing

2.3 Preparation of the Bonded Composite Model

After completion of the stress-freezing process, photoelastic readings were taken at selected points on the specimen using a polarizing microscope. Subsequently, radial strips were cut from the variable cross-section specimen by CNC machining in order to transfer the mechanically generated and frozen strains into a bonded model. Thus, each strip retained the frozen strain state corresponding to the radial position it occupied during mechanical loading.

A second group of specimens with the same geometric characteristics but without prior mechanical loading was prepared to correspond to the pre-strained strips obtained above. Geometric discontinuities were also introduced into these specimens to investigate local stress concentrations. By bonding the stress-frozen strips to their initially unloaded counterparts, a composite experimental model consisting of two components with different initial strain states was obtained.

An epoxy-based adhesive was used for the bonding process. The adhesive and hardener were heated to approximately 55–60°C and mixed at a ratio of 1.5 g hardener per 10 g epoxy resin. The prepared mixture was applied to the contact surfaces, and the specimens were mechanically clamped to prevent gaps at the interface. Additional weights were placed on the specimens to limit relative sliding between the components during bonding. The bonded specimens were first kept at room temperature for 48 h and were then placed in an oven at 50°C for 24 h to complete the bonding process.

After bonding was completed, the composite specimen was subjected to a second thermal cycle. The model was again heated in a controlled manner to the critical temperature of 155°C and held at this temperature for approximately one hour. Upon reaching the critical temperature, the frozen stresses in the strips that had been pre-strained during the first mechanical loading and stress-freezing stage began to relax. The tendency of the pre-strained strips to recover their free deformation state was restrained by the initially unloaded component to which they had been bonded. As a result of this strain incompatibility, internal force transfer occurred between the two components, generating a self-equilibrated stress field in the composite model without the application of an external mechanical load. This procedure mechanically simulates the thermal stress mechanism that develops when components with different thermal expansion behavior restrain one another during a temperature change.

After completion of the second thermal cycle and cooling of the specimen back to room temperature, the bonded model was examined under a polariscope. The stress field produced by the strain incompatibility between the pre-strained and initially unloaded components was observed through the development of isochromatic fringes. In particular, the increase in fringe density around the geometric discontinuity, as shown in Figure 4, clearly indicated a local stress concentration in this region.

To quantify the stress values, measurements were performed using a polarizing microscope at selected distances from the geometric discontinuity and in regions where the stress distribution became more regular. The experimental values obtained were subsequently compared with the finite element analysis and analytical solution results.

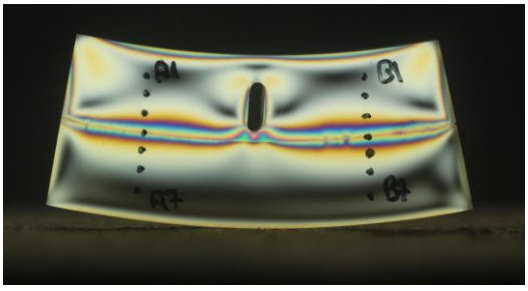

Fig. 4. Stress distribution developed in the bonded model after the second thermal cycle

3 Analytical Model

A two-stage analytical approach was adopted to theoretically evaluate the stress and strain distributions generated at different stages of the experimental study. In the first stage, the behavior of the variable cross-section specimen produced for mechanical modeling was examined under tensile loading; in the second stage, the self-equilibrated stress distribution arising after bonding the stress-frozen and initially unloaded components was evaluated analytically. Thus, both the generation of the initial strain state and its transformation into stresses within the bonded model due to strain incompatibility were considered separately.

The variable cross-section specimen used for mechanical modeling was designed so that the applied axial tensile load produced a radially varying stress and strain distribution in the body region. The behavior of this specimen under mechanical loading was evaluated using the classical wedge problem in elasticity under a concentrated load. This solution established the relationship between the applied tensile force and the radial stresses generated at different radial positions of the specimen. The radial stress equation used is expressed as follows:

$$\sigma_r = -\frac{P\cos\theta}{r\left(\alpha + \frac{\sin(2\alpha)}{2}\right)} \tag{1}$$

Using this equation, the radial stresses and corresponding strain values at different radial positions were determined. Accordingly, the initial strain distribution carried by the radial strips after stress-freezing was theoretically defined, providing an analytical reference for evaluating the photoelastic results obtained during the mechanical modeling stage.

To determine the self-equilibrated stresses developed in the bonded experimental model, the system was idealized as an axisymmetric annular section. The inner and outer radii were denoted by a and b, respectively, while the radius c represented the boundary between regions having different initial strain states (Figure 5). The problem was considered under plane-stress conditions, and all mechanical quantities were assumed to depend only on the radial coordinate. The mechanically generated initial strain incompatibility was represented in the analytical model by an equivalent radially varying temperature effect, T(r).

In the region $a \le r \le c$, the equivalent temperature effect was taken as zero, whereas T=T(r) was defined for $c \le r \le b$. Since the inner and outer surfaces were traction-free, the boundary conditions were applied as $\sigma_r(a)=0$ and $\sigma_r(b)=0$.

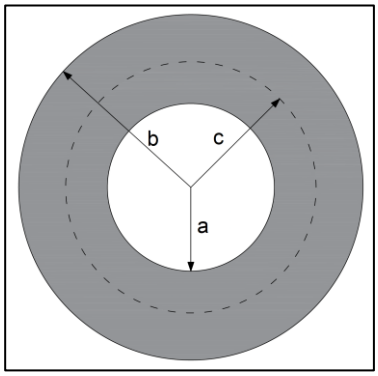

Fig. 5. Problem definition

Before substituting the obtained constants into the displacement expression, the integral terms were represented by symbols to simplify the subsequent expressions. The first integral extends

from the inner radius a to an arbitrary radius r, whereas the second extends from radius c to the outer radius b and also appears in the previously obtained constants.

$$\int_a^r (\alpha T) r dr = I \quad , \quad \int_c^b (\alpha T) r dr = \bar{I} \tag{2}$$

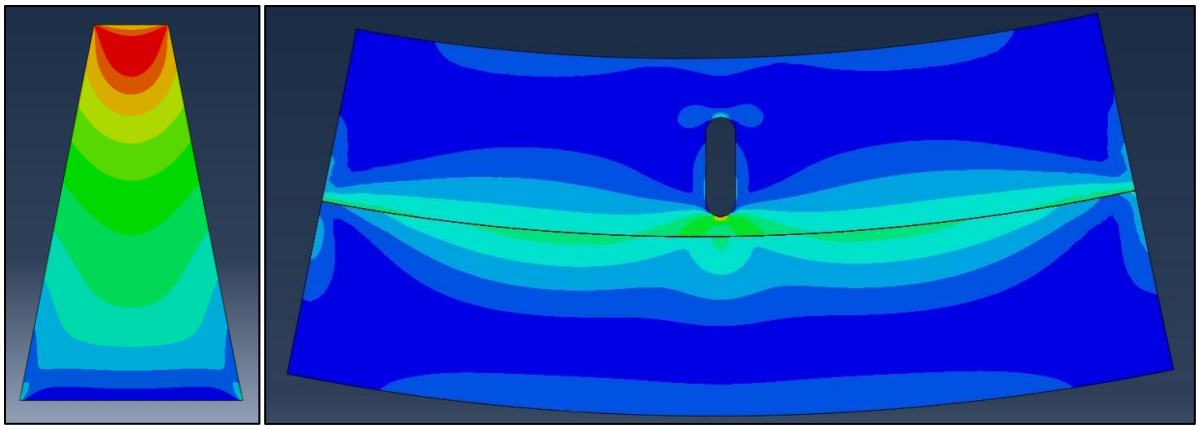
Substitution of these expressions into the displacement and stress relations yields the final equations.

$$\sigma_r = -\frac{E}{r^2}(I) + \frac{E(\bar{I})}{b^2 - a^2}\left(1 - \frac{a^2}{r^2}\right) = \frac{E}{r^2}\left(-(I) + \frac{(\bar{I})}{b^2 - a^2}\left(r^2 - a^2\right)\right) \tag{3}$$

$$\sigma_\theta = \frac{E}{r^2}\left((I) - \alpha T r^2 + (\bar{I})\left(\frac{r^2 + a^2}{b^2 - a^2}\right)\right) \tag{4}$$

The analytical results obtained in this manner were directly compared with the photoelastic measurements on the bonded specimen and the finite element analysis results.

4 Finite Element Analysis



To numerically evaluate the results obtained from the experimental and analytical studies, two separate models were developed in ABAQUS. The first model represented the variable cross-section specimen used in the mechanical modeling stage, whereas the second represented the final experimental specimen obtained by bonding the stress-frozen and initially unloaded components. Thus, both stages of the experimental procedure were investigated numerically.

The first finite element model was developed to determine the behavior of the variable cross-section tensile specimen under mechanical loading. The model was defined using a two-dimensional planar shell representation consistent with the experimental specimen geometry, and the mechanical loading conditions applied in the experiment were transferred to the model. The radial stress and strain distributions obtained from this analysis were compared with the analytical solution based on the wedge problem and the photoelastic experimental results, thereby providing a numerical validation of the mechanical modeling stage.

The second finite element model was created to represent the bonded composite specimen. As in the experimental model, the pre-strained component and the initially unloaded component were modeled as separate geometries, and their contacting surfaces were connected using a tie constraint. The initial strain values to be applied to the pre-strained component were obtained from the analytical relations used in the first stage and introduced into the model accordingly. In this way, the strain incompatibility generated experimentally by the stress-freezing technique was represented numerically.

In both models, the mechanical properties of the epoxy resin at the critical temperature of 155°C were used. The elastic modulus and Poisson's ratio were defined in the model based on the values determined from the material characterization tests. The mechanical behavior of the material at this temperature had therefore been established experimentally.

In the finite element mesh of the bonded specimen, local mesh refinement was employed to capture the high stress gradients around the geometric discontinuity more accurately. An element size of approximately 0.5 mm was used in regions away from the discontinuity, while the element size was gradually reduced to approximately 0.1 mm toward the discontinuity. Following the analysis, the stress values corresponding to the photoelastic measurement locations were extracted and compared with the experimental results (Figure 6).

(a) (b)

Fig. 6. Finite element models used in the numerical analysis: (a) variable cross-section specimen for the mechanical loading stage, (b) bonded two-component model

5 Results and Discussion

After completion of the experimental study, stress values at the selected measurement points on the bonded specimen were obtained using the photoelastic method and compared with the ABAQUS finite element and analytical model results. Measurements were taken at different distances on both sides of the geometric discontinuity, and the stress distribution was observed to increase markedly as the discontinuity was approached. The highest experimental stress differences occurred around the geometric discontinuity, whereas the stress values gradually decreased in regions farther away.

Comparison of the experimental and finite element results, as shown in Figure 7, indicated that the stress distributions were particularly close in regions away from the discontinuity. For example, the experimental and ABAQUS results exhibited similar values at measurement points on the negative side, whereas the discrepancy between the two methods increased as the geometric discontinuity was approached. These differences are considered to arise from the high stress gradient near the discontinuity, the sensitivity of the photoelastic measurements to the exact measurement location, and geometric differences between the experimental specimen and the idealized numerical model.

The analytical solution provides a reference particularly for evaluating the overall behavior of the stress distribution and its variation along the radial direction. However, because the analytical model is based on axisymmetry and idealized geometric assumptions, it is not expected to represent local stress concentrations around the geometric discontinuity with the same level of detail as the experimental and finite element models. Nevertheless, the combined evaluation of the experimental, analytical, and numerical approaches indicates that the proposed mechanical modeling method can be used to experimentally investigate self-equilibrated stresses arising from thermally induced strain incompatibility.

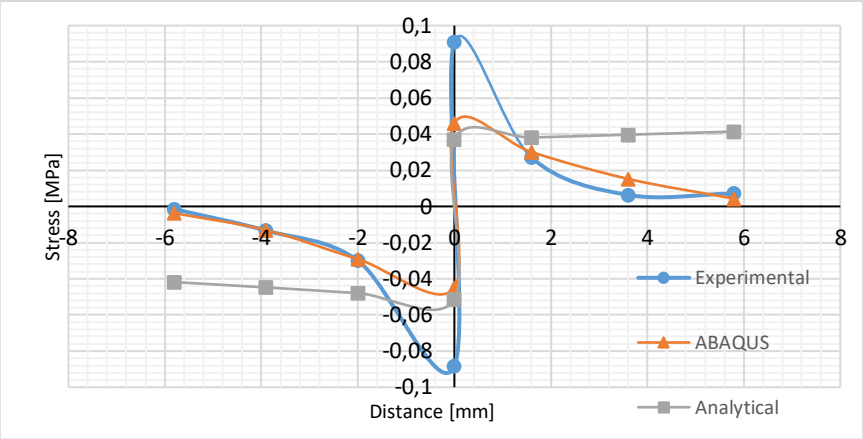


Fig. 7. Comparison of experimental, finite element and analytical stress distributions.

6 Conclusion

In this study, a two-stage mechanical modeling approach was implemented to investigate, using photoelasticity, strain incompatibilities and the associated self-equilibrated stresses that may develop in composite elements due to temperature differences. In the first stage, the target radial strain distribution was generated by applying a mechanical load to a variable cross-section specimen and was permanently retained within the specimen using the stress-freezing technique. In the second stage, pre-strained components obtained from this specimen were bonded to initially unloaded components, and a second thermal cycle generated self-equilibrated stresses resulting from the strain incompatibility between the two components.

Photoelastic measurements revealed a pronounced stress concentration around the geometric discontinuity. Comparison of the experimental results with the finite element analysis showed similar stress distributions particularly in regions away from the discontinuity, whereas more pronounced differences were observed in regions of local stress concentration. The analytical solutions enabled the two stages of the experimental procedure to be evaluated theoretically and the overall stress distribution to be interpreted. The results indicate that the combined use of mechanical modeling and stress-freezing provides a feasible approach for experimentally modeling stresses arising from thermal incompatibility.

Abstract. This study investigates the influence of material properties on the seismic performance of RC frame structures through nonlinear static (pushover) analysis and provides a mechanical interpretation of construction-period-dependent material assessment adopted in rapid seismic screening methodologies. A five-story RC frame building is selected as the structural model. The C25–S500 material combination is adopted as the reference model representing the best material conditions. To investigate the influence of material degradation, additional models are developed using C20–S420, C15–S220, and C10–S220 material combinations. The C20–S420 model represents typical contemporary construction practice, whereas the C15–S220 and C10–S220 models represent the material characteristics commonly associated with aging Turkish RC building stock. All models possess identical geometry, member dimensions, loading conditions, and structural configuration. Nonlinear static analyses are performed in SAP2000 using the default ASCE 41-13 plastic hinge definitions. Structural performance is evaluated under four earthquake hazard levels (DD1–DD4) in terms of lateral load capacity, yielding behavior, target displacement, and nonlinear deformation characteristics.
The observed progressive reduction in structural capacity provides analytical support for construction-period-dependent material scoring, where building age represents the cumulative effects of historical construction practice, material quality, reinforcement characteristics, structural detailing, and long-term deterioration. Although the numerical models primarily represent the characteristics of the Turkish RC building stock, the proposed engineering interpretation is equally applicable to countries such as Germany, where construction period reflects the historical evolution of structural standards, ductility requirements, and seismic design philosophy rather than concrete strength alone. The findings contribute to a better understanding of the seismic behavior of aging RC buildings and provide an analytical basis for rapid seismic prioritization, performance-based assessment, and retrofit decision-making of existing building inventories.

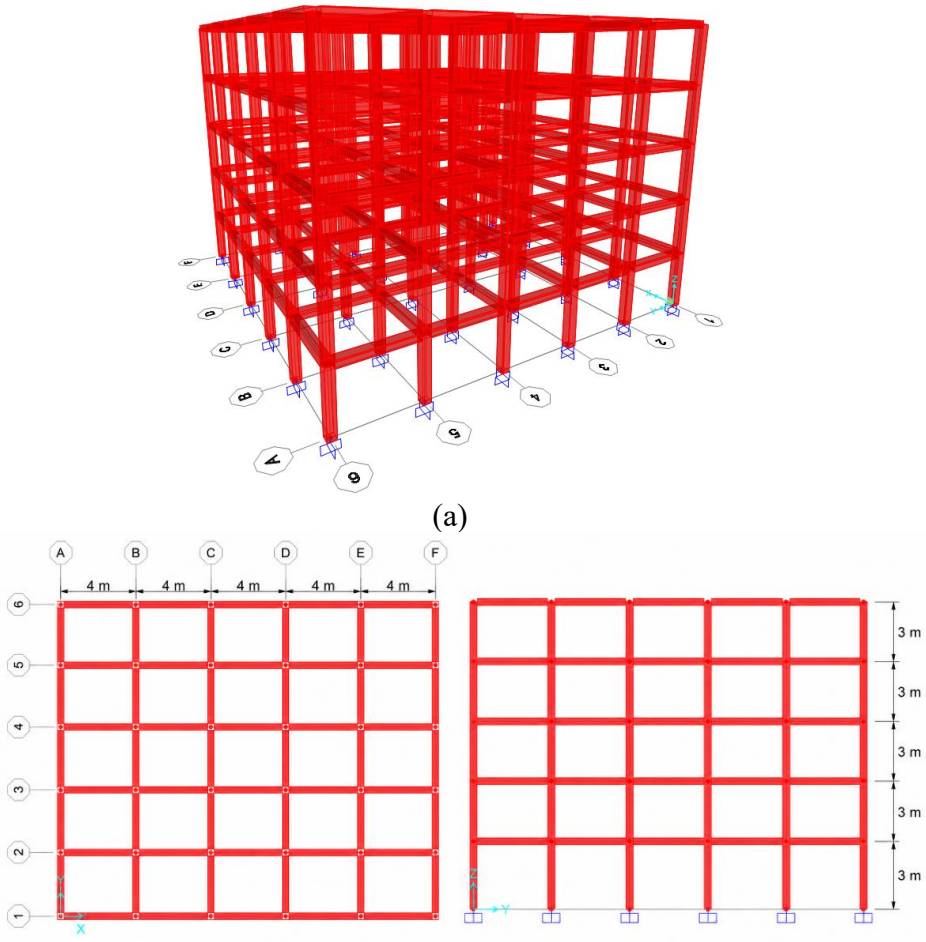
1 Introduction

The seismic assessment of existing reinforced concrete (RC) buildings has become an increasingly important challenge in earthquake engineering due to the large number of aging structures that were constructed before the implementation of modern seismic design provisions. In many countries, these buildings constitute a significant portion of the existing building stock and may exhibit deficiencies related to material quality, reinforcement detailing, structural configuration, and long-term deterioration. Since detailed nonlinear evaluation of every existing building is practically infeasible, reliable methods for rapid seismic assessment and prioritization have become essential for effective seismic risk mitigation. Türkiye represents one of the most critical examples of this problem. Rapid urbanization during the second half of the twentieth century resulted in an extensive RC building stock constructed with varying levels of engineering supervision and quality control. Istanbul alone contains approximately 1.16 million buildings, nearly 70% of which were constructed before the 1999 Marmara earthquakes, while approximately 800.000 buildings were built before 2000 [1, 2]. Assessing such a large inventory using detailed nonlinear analyses is unrealistic because of the required time, cost, and engineering effort. Consequently, efficient rapid assessment methodologies are indispensable for identifying buildings that require detailed investigation. Numerous field investigations have demonstrated that the material properties of the Turkish RC building stock are strongly related to the construction period. Based on core tests performed on representative substandard buildings in Istanbul, Aydoğdu et al. [2] reported an average in-situ concrete compressive strength of approximately 14.6 MPa and identified the coexistence of S220 plain reinforcement and S420 deformed reinforcement within the investigated buildings. Similarly, Özmen et al. [3] represented buildings designed according to the 1975 Turkish Seismic Code using concrete strengths of 10 and 16 MPa, whereas buildings designed according to the 1998 code were represented using concrete strengths of 16 and 25 MPa. Their nonlinear analyses demonstrated that buildings designed according to newer seismic provisions possess considerably higher lateral strength and deformation capacity, while inadequate concrete quality and transverse reinforcement detailing may reduce structural ductility by approximately 50% at the Life Safety performance level and by as much as 58% at the Collapse Prevention level. These findings indicate that, for the Turkish RC building stock, construction period serves as a practical engineering indicator of expected material quality, reinforcement characteristics, construction practice, and overall seismic performance. Recent numerical studies have further emphasized the importance of material properties and detailing in the seismic performance assessment of existing RC buildings. Özmen and İnel [4] investigated 48 nonlinear models representing Turkish residential RC buildings designed according to the 1975 and 1998 seismic codes by considering different concrete strengths and lateral reinforcement detailing conditions. Their results demonstrated that seismic damage rates are strongly influenced by concrete strength, transverse reinforcement detailing, and the applicable seismic design code, with the influence of these parameters becoming increasingly pronounced at higher performance levels and under greater nonlinear displacement demands. Işık et al. [5] investigated the influence of different structural and seismic parameters on the target displacement of reinforced concrete buildings. Their results showed that concrete strength is one of the parameters affecting the seismic displacement demand of RC structures.

The aging of the building stock is also an important issue in Germany, although the characteristics of the existing RC inventory differ from those in Türkiye. National housing statistics indicate that approximately two-thirds of the residential buildings located in the federal states associated with Germany's comparatively more seismically active regions including Baden-Wuerttemberg and North Rhine-Westphalia were constructed before 1980 [6].



Although Germany is characterized by a substantially lower overall seismic hazard than Türkiye, the coexistence of aging building inventories and regions of relatively elevated seismicity highlights the importance of systematic assessment and prioritization. Unlike the Turkish building stock, where construction period is closely associated with significant differences in concrete quality and reinforcement characteristics, the evolution of construction practice in Germany is primarily reflected by successive improvements in structural standards, seismic design philosophy, and detailing requirements. Early versions of DIN 4149 [7] mainly provided general recommendations regarding structural configuration, bracing, foundations, and overall structural layout. Later revisions progressively introduced explicit requirements concerning structural regularity, ductility, reinforcement detailing, and limitations on simplified seismic design. The introduction of DIN 4149:2005 established minimum concrete strength requirements for ductile seismic design, while Eurocode 8 [8] subsequently incorporated capacity design principles together with ductility classes (DCL, DCM, and DCH), defining comprehensive rules for material properties, reinforcement detailing, and energy dissipation capacity. Consequently, in Germany, construction period should be interpreted not merely as an indicator of concrete strength, but as a proxy for the historical evolution of structural design philosophy, detailing practice, and expected seismic reliability. Despite these national differences, construction period remains one of the most effective parameters for rapid seismic prioritization because it reflects the expected structural quality associated with the corresponding design era. Within the rapid earthquake risk assessment methodology previously developed by the authors, this concept is incorporated through the Damage and Material Degradation category, which combines indicators related to concrete quality, deterioration, cracking, corrosion, reinforcement exposure, inappropriate repairs, and remaining service life. Accordingly, the construction period dependent coefficients assigned to this category represent the expected influence of historical construction practice, material characteristics, and long-term deterioration on structural vulnerability rather than simply the chronological age of a building. Among available analytical techniques, nonlinear static (pushover) analysis provides an efficient means of quantifying the mechanical consequences of material degradation. By evaluating lateral load capacity, yielding behavior, target displacement, and nonlinear deformation characteristics, pushover analysis enables the direct assessment of how progressive variations in concrete compressive strength and reinforcing steel yield strength influence the global seismic response of RC structures under different seismic demand levels. Such analytical evidence also provides a mechanical basis for interpreting material-related vulnerability indicators adopted in rapid seismic assessment procedures.

In the present study, four structural models of a representative five-story Turkish RC frame building are developed. The models have identical geometry, member dimensions, loading conditions, and structural configuration but differ in concrete compressive strength and reinforcing steel yield strength. The model with a concrete compressive strength of 25 MPa and reinforcing steel yield strength of 500 MPa (C25–S500) is adopted as the reference model, representing the best material conditions. The C20–S420 model represents typical contemporary construction practice in Türkiye, whereas the C15–S220 and C10–S220 models represent the material characteristics commonly associated with the older Turkish RC building stock. Consequently, the observed differences in structural response originate exclusively from variations in material properties. Nonlinear static analyses are performed for four decreasing seismic hazard levels (DD1, DD2, DD3 and DD4), allowing the combined influence of progressive material degradation and increasing seismic demand on structural performance to be systematically evaluated.

The primary objective of this study is to quantify the influence of concrete compressive strength and reinforcing steel yield strength on the nonlinear seismic performance of RC frame structures. Particular attention is given to the variation of lateral load capacity, yielding behavior, target displacement, and deformation capacity as both the material quality and seismic demand change. While the numerical models were developed to represent the Turkish RC building stock, the engineering interpretation presented in this study can also be extended to countries such as Germany, where construction period reflects the historical evolution of seismic design philosophy, structural standards, and ductility provisions. Consequently, the findings provide not only insight into the seismic behavior of aging RC buildings but also a mechanical interpretation of the material-related vulnerability concept adopted in rapid seismic assessment methodologies, thereby supporting the engineering rationale behind construction-period-dependent prioritization of existing building stocks.

2 Numerical Modeling

A five-story reinforced concrete (RC) moment-resisting frame building representative of conventional Turkish construction practice was used as the benchmark structure in this study. The building has a square floor plan measuring 20 × 20 m, corresponding to a footprint area of 400 m². Both principal directions consist of five equal bays with a span length of 4.0 m, while the interstory height is 3.0 m, resulting in an overall structural height of 15 m (Fig. 1).

(a) (b) (c)

Fig. 1. Reference reinforced concrete building adopted in the numerical study: (a) three-dimensional view, (b) plan view, and (c) elevation view.

The structural members were modeled using 40 × 40 cm square columns and 40 × 35 cm rectangular beams. Columns were reinforced with 12Ø20 longitudinal bars and Ø10 transverse reinforcement spaced at 100 mm, whereas the beams contained 4Ø16 top and 3Ø16 bottom longitudinal reinforcement. A uniformly distributed gravity load of 10 kN/m² (G + nQ) was assigned to all floors. The structure was assumed to be located in Pazarcık on ZE soil conditions and evaluated under the DD1-DD4 earthquake levels specified by the Turkish Seismic Code. The nonlinear model was developed in SAP2000 using the default ASCE 41-13 [9] plastic hinge definitions. Since predefined hinge properties were employed, the transverse reinforcement detailing was not explicitly incorporated into the hinge formulation. In addition, the effective stiffness reduction factors recommended by ASCE 41-13 were assigned to all structural members. Flexural and shear stiffness modifiers of 0.7 and 0.4 were used for columns, while the corresponding values for beams were taken as 0.3 and 0.4, respectively.

To examine the influence of material degradation, four different material combinations were analyzed: C25–S500, C20–S420, C15–S220, and C10–S220. The C25–S500 model, representing improved material quality, was adopted as the reference model, whereas the C20–S420 model represents material properties commonly used in modern Turkish reinforced concrete buildings. The C15–S220 and C10–S220 models were introduced to simulate older reinforced concrete buildings constructed before 1975, when lower concrete strengths and plain reinforcing bars were widely used in Turkish construction practice. Throughout the analyses, all geometric characteristics, reinforcement detailing, boundary conditions, loading conditions, and modeling assumptions were kept unchanged. Consequently, the differences observed in the structural response can be attributed solely to variations in material properties.

3 Nonlinear Analysis Procedure and Results

Nonlinear static analyses were carried out in SAP2000 using a displacement-controlled pushover procedure. The lateral load distribution was defined according to the first vibration mode, which was verified through modal analysis to be predominantly translational without significant torsional participation. Owing to the regular and symmetric layout of the building, together with identical geometric characteristics in the two principal directions, comparable structural responses were expected in both the X and Y directions. Consequently, the nonlinear analyses were performed in a single principal direction, which was considered sufficient to represent the global seismic behavior of the structure. To evaluate the influence of material degradation, the same analytical procedure was applied to four material configurations (C25–S500, C20–S420, C15–S220, and C10–S220) while preserving the structural geometry, support conditions, and loading scheme. Before the pushover analyses, gravity loads corresponding to G + nQ = 10 kN/m² were assigned to the structure. Cracked-section behavior was represented by adopting the effective stiffness reduction factors recommended in ASCE 41-13. Beam nonlinearity was modeled using the default ASCE 41-13 flexural hinge properties implemented in SAP2000, whereas the column response was determined based on the corresponding material properties assigned to each model. The seismic demand was represented by elastic design response spectra defined in the Turkish Seismic Code for the DD1, DD2, DD3, and DD4 earthquake levels. The structural performance was subsequently assessed using the FEMA 440 [10] performance evaluation procedure, from which the performance point and the corresponding target displacement were obtained for each material model. Figure 2 presents the pushover curves obtained from the nonlinear analyses of the four investigated structural models.

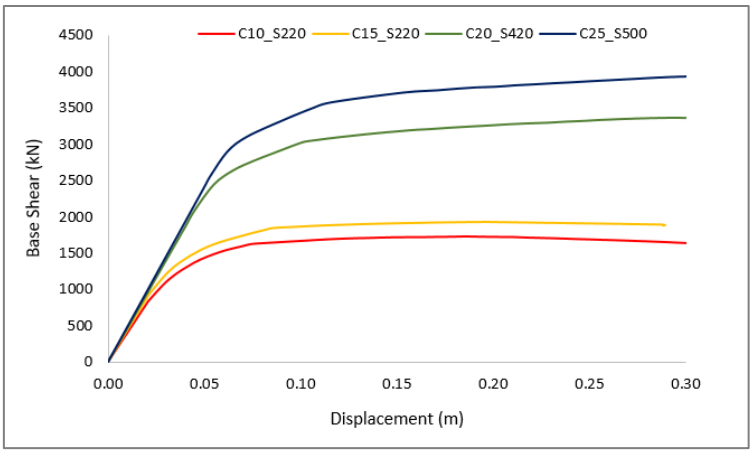


Fig. 2. Nonlinear pushover capacity curves for the models.

Table 1 summarizes the peak base shear capacities and corresponding target displacements obtained at the performance point for all material models under the four earthquake intensity levels. N.A. denotes "Not Available" and indicates cases in which a performance point could not be obtained for the corresponding earthquake intensity level; therefore, the associated base shear and target displacement values could not be determined.

Table 1. Base shear capacity and performance-point displacement of the models under different earthquake intensity levels.

Model	Earthquake Level	Base Shear (kN)	Target Displacement (m)
C25-S500	DD1	3783.00	0.408
	DD2	3810.00	0.210
	DD3	3174.00	0.078
	DD4	2650.64	0.055
C20-S420	DD1	3350.00	0.270
	DD2	3234.72	0.181
	DD3	2731.54	0.072
	DD4	2212.40	0.048
C15-S220	DD1	N.A.	N.A.
	DD2	1923.88	0.216
	DD3	1628.53	0.056
	DD4	1304.42	0.034
C10-S220	DD1	N.A.	N.A.
	DD2	1531.84	0.373
	DD3	1672.80	0.099
	DD4	1508.42	0.057

As expected, the reference model (C25–S500) consistently exhibited the highest base shear capacity, while a progressive reduction in concrete and reinforcing steel strengths resulted in a systematic decrease in lateral load-carrying capacity. The influence of material degradation became particularly evident at the DD2 earthquake level, where the base shear capacity decreased from 3810 kN for the C25–S500 model to 1531.84 kN for the C10–S220 model,

corresponding to an approximately 60% reduction in lateral strength. In contrast, the target displacement showed an opposite trend, increasing from 0.210 m to 0.373 m as the material properties deteriorated. This indicates that weaker material properties not only reduce the strength capacity of the structure but also lead to larger deformation demands. Under the most severe earthquake level (DD1), the C15–S220 and C10–S220 models failed to reach a performance point, indicating that their lateral capacities were insufficient to satisfy the seismic demand. At the lower earthquake intensity levels (DD3 and DD4), the target displacement did not follow a monotonic trend, with the C15–S220 model exhibiting smaller target displacements than the reference model despite its considerably lower strength. This behavior suggests that the performance-point displacement is governed by the interaction between the structural capacity curve and the seismic demand spectrum rather than by material strength alone. Therefore, target displacement should always be interpreted together with the corresponding lateral load capacity when evaluating the seismic performance of structures with degraded material properties.

Table 2. Relative variation in base shear capacity and target displacement with respect to the reference model (C25–S500).

Material Model	Earthquake Level	V (kN)	ΔV (%)	D (m)	ΔD (%)
C25–S500	DD1	3783.000	—	0.408	—
C20–S420		3350.000	−11.4	0.270	−33.8
C15–S220		N.A.	N.A.	N.A.	N.A.
C10–S220		N.A.	N.A.	N.A.	N.A.
C25–S500	DD2	3810.000	—	0.210	—
C20–S420		3234.720	−15.1	0.181	−13.8
C15–S220		1923.880	−49.5	0.216	+2.9
C10–S220		1531.842	−59.8	0.373	+77.6
C25–S500	DD3	3174.000	—	0.078	—
C20–S420		2731.542	−13.9	0.072	−7.7
C15–S220		1628.533	−48.7	0.056	−28.2
C10–S220		1672.797	−47.3	0.099	+26.9
C25–S500	DD4	2650.640	—	0.055	—
C20–S420		2212.400	−16.5	0.048	−12.7
C15–S220		1304.420	−50.8	0.034	−38.2
C10–S220		1508.420	−43.1	0.057	+3.6

To provide a clearer comparison of the influence of material degradation on structural performance, the results were normalized with respect to the reference model (C25–S500) at each earthquake intensity level (Table 2). For each material model, the corresponding base shear capacity and target displacement at the performance point were compared with those of the reference model, and the relative percentage changes were calculated. This approach enables the influence of material degradation to be evaluated independently for each earthquake level and facilitates a direct comparison of the variations in strength and deformation capacity among the investigated material models.

As presented in Table 2, the C25–S500 model consistently achieved the highest base shear capacity under all earthquake intensity levels. Under the DD1 earthquake, the C15–S220 and C10–S220 models were unable to reach the performance point, indicating that their lateral resistance was insufficient to satisfy the highest seismic demand. For the remaining earthquake levels, the C20–S420 model exhibited a relatively moderate reduction in base shear capacity, ranging from 11.4% to 16.5%, whereas the reductions became much more significant for the

C15–S220 (48.7–50.8%) and C10–S220 (43.1–59.8%) models. In terms of target displacement, the C10–S220 model exhibited the most unfavorable response, reaching an increase of 77.6% under the DD2 earthquake level. However, unlike the base shear capacity, the target displacement did not vary monotonically with decreasing material strength. For example, the C15–S220 model exhibited lower target displacements than the reference model under the DD3 (−28.2%) and DD4 (−38.2%) earthquake levels. To further investigate the influence of material degradation on structural damage, the distribution of plastic hinge states was evaluated at the performance point corresponding to the DD2 earthquake level. At the corresponding performance point of each model, the hinge state of every beam and column was extracted from the nonlinear pushover analysis and classified according to the ASCE 41-13 performance limits as Immediate Occupancy (A–IO), Life Safety (IO–LS), and beyond Collapse Prevention (CP). The total number of hinges within each performance range, together with their corresponding percentages, was subsequently determined to quantify the distribution of structural damage and to evaluate the influence of material degradation on the seismic performance of the investigated models.

Table 3. Distribution of plastic hinge performance states at the performance point under the DD2 design earthquake.

Model	A–IO	IO–LS	>CP	A–IO (%)	IO–LS (%)	>CP (%)
C10–S220	637	136	187	66.4	14.2	19.5
C15–S220	724	236	0	75.4	24.6	0.0
C20–S420	744	216	0	77.5	22.5	0.0
C25–S500	756	204	0	78.8	21.3	0.0

Table 3 presents the distribution of plastic hinge states at the performance point for the DD2 earthquake level. As the material strength increased, the proportion of hinges remaining within the A–IO range increased from 66.4% for the C10–S220 model to 78.8% for the C25–S500 model, indicating an improvement in the overall structural performance. Conversely, the percentage of hinges within the IO–LS range remained relatively stable, varying between 14.2% and 24.6%. The most significant difference was observed in the collapse-level hinge distribution. While no hinges exceeded the Collapse Prevention (CP) limit in the C15–S220, C20–S420, and C25–S500 models, the C10–S220 model developed 187 hinges (19.5%) beyond the CP state. This result indicates that the combination of low concrete and reinforcement strength leads to a substantial increase in severe damage, whereas moderate improvements in material properties are sufficient to prevent collapse-level hinge formation under the DD2 earthquake demand. Figure 3 shows the distribution of plastic hinge performance states at the performance point under the DD2 earthquake level for the investigated material models. A clear reduction in both the extent and severity of plastic hinge formation is observed as the material properties improve from C10–S220 to C25–S500. The C10–S220 model exhibits the most extensive nonlinear response, with numerous hinges progressing to advanced damage states, whereas the C25–S500 model shows a more favorable hinge distribution, with damage remaining comparatively limited.

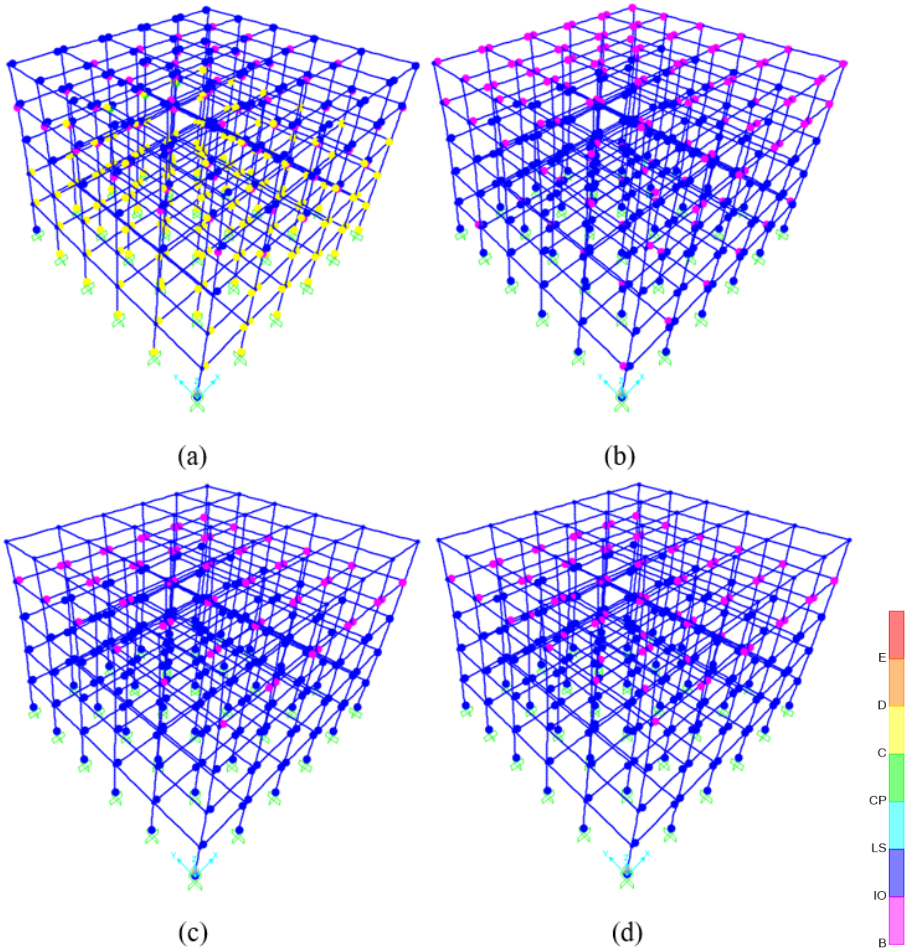

Fig. 3. Distribution of plastic hinge performance states at the DD2 performance point: (a) C10–S220, (b) C15–S220, (c) C20–S420, and (d) C25–S500.

3.1 Material Performance Index (MPI)

Although the base shear capacity and plastic hinge distribution provide valuable information regarding the seismic performance of the investigated material models, these parameters describe different aspects of structural behavior and are generally evaluated separately. To provide a single quantitative measure of the influence of material degradation, a new Material Performance Index (MPI) is proposed (Eq.1). The proposed index combines the normalized lateral load-carrying capacity with the proportion of hinges remaining below the Collapse Prevention (CP) limit, thereby incorporating both the global structural response and the extent of severe local damage into a single performance indicator. Higher MPI values indicate better seismic performance, whereas lower values reflect a greater deterioration in structural capacity and damage resistance.

$$MPI = \frac{1}{2}\left[\frac{V_{Model}}{V_{Ref}} + \left(1 - \frac{N_{>CP}}{N_{total}}\right)\right] \text{(Eq. 1)}$$

Where V_{Model} is the base shear capacity of the investigated material model at the performance point, V_{Ref} is the base shear capacity of the reference model (C25–S500), $N_{>CP}$ is the number of plastic hinges exceeding the Collapse Prevention (CP) limit, and N_{total} is the total number of plastic hinges in the structure. The first term represents the normalized lateral load-carrying capacity, while the second term reflects the proportion of hinges that remain below the CP limit. Consequently, the proposed MPI provides a combined measure of global structural strength and

local damage severity. As presented in Table 4, the proposed MPI successfully captures the influence of material degradation on the overall seismic performance of the investigated structures. The reference model (C25–S500) achieved an MPI value of 1.000, representing the highest structural performance. A moderate reduction in material strength (C20–S420) resulted in a relatively small decrease in MPI to 0.925, indicating that the structure maintained a high level of seismic performance. In contrast, the C15–S220 model exhibited a significant reduction in MPI (0.752), primarily due to its substantially lower base shear capacity.

Table 4. Material Performance Index (MPI) values for the investigated material models at the DD2 earthquake level.

Model	V_{Model}/V_{Ref}	$1-\frac{N_{>CP}}{N_{total}}$	**MPI**
C10–S220	0.402	0.805	0.604
C15–S220	0.505	1	0.752
C20–S420	0.849	1	0.925
C25–S500	1	1	1

The lowest MPI value (0.604) was obtained for the C10–S220 model, reflecting not only the considerable loss of lateral load-carrying capacity but also the occurrence of plastic hinges beyond the Collapse Prevention (CP) limit. These results demonstrate that the proposed MPI effectively combines global structural capacity and local damage characteristics into a single performance indicator, providing a straightforward quantitative measure of the adverse effects of material degradation on seismic behavior.

4 Conclusions

The nonlinear analyses demonstrated that reductions in concrete compressive strength and reinforcing-steel yield strength substantially impair the seismic performance of reinforced concrete frame structures. At the DD2 earthquake level, the base shear capacity decreased by approximately 60% from the C25–S500 reference model to the C10–S220 model, while the C10–S220 model also developed 19.5% of its plastic hinges beyond the Collapse Prevention limit. In addition, the C15–S220 and C10–S220 models were unable to reach a performance point under the DD1 demand. These results show that very low material strength affects both the global lateral resistance and the severity of local structural damage.

The proposed Material Performance Index provides a mechanical basis for calibrating material-related penalty factors used in rapid seismic screening methodologies. For the Turkish building stock, where concrete strengths of approximately 10–15 MPa are frequently encountered in older reinforced concrete buildings, the obtained MPI values support penalty factors of about 20–25% for C15 concrete and about 40% for C10 concrete. When Schmidt hammer measurements indicate an in-situ concrete strength below approximately 10 MPa, a penalty factor in the range of 40–50% may be considered for preliminary screening. These findings may serve as a basis for calibrating penalty factors in rapid seismic screening methodologies, allowing poor concrete quality to be more explicitly reflected in building prioritization.

For Germany, concrete quality is generally not the dominant source of seismic vulnerability; however, material-related penalty factors may still be appropriate for older reinforced concrete buildings. For buildings constructed before approximately 1980, particularly those with concrete strengths in the C15–C20 range, penalty factors of up to about 20% may be considered as a preliminary estimate, reflecting not only lower material properties but also the limitations

of earlier seismic provisions and detailing practices. Therefore, the proposed index offers a practical framework for defining country-specific penalty factors and for improving the consistency of rapid seismic prioritization in both Türkiye and Germany.

Abstract. The seismic performance of existing reinforced concrete (RC) buildings is strongly influenced by structural irregularities. Rapid Seismic Screening (RSS) methods are therefore widely used to prioritize large building inventories for detailed assessment and retrofit planning. In these methodologies, severe vertical and plan irregularities are typically penalized through substantial score reductions. However, irregularities are generally evaluated independently, and the quantitative validation of such penalty mechanisms against nonlinear structural performance remains limited. This may lead to unconservative prioritization outcomes, particularly when multiple unfavorable mechanisms coexist and interact under seismic loading.

This study presents a numerical investigation of five-story RC buildings exhibiting torsional irregularity and the combined presence of torsional and soft-story irregularities. The parametric analysis employs systematically modified structural models in which selected mass- and stiffness-related characteristics are varied while the principal member properties and material characteristics are maintained. A key methodological feature is the implementation of Incremental Response Spectrum Analysis (IRSA), a multi-modal nonlinear analysis procedure, which enables higher-mode participation and torsional response mechanisms to be explicitly considered. The nonlinear response of the structural models is evaluated through global pushover curves, together with base shear response, target displacements, and structural performance states under the design earthquake.

Comparative evaluation of the capacity curves is performed to quantify the reduction in lateral load-carrying capacity associated with the introduced irregularities. Capacity reduction ratios are subsequently examined in relation to the penalty scores assigned to structural irregularities in rapid seismic assessment methodologies. The results indicate that the combined presence of torsional and soft-story irregularities produces a substantially greater reduction in structural capacity than torsional irregularity alone. The study provides a performance-based perspective for interpreting irregularity penalty scores and contributes to

establishing a stronger methodological connection between nonlinear structural performance and rapid seismic vulnerability assessment.

Keywords: Rapid Seismic Screening, Nonlinear Capacity Assessment, Soft-Story and Torsional Interaction, Incremental Response Spectrum Analysis.

1 Introduction

Structural irregularities are among the major factors influencing the seismic response of reinforced concrete (RC) buildings. Although structural regularity provides a convenient basis for seismic analysis and design, actual buildings frequently exhibit variations in mass, stiffness, strength, geometry, or the arrangement of lateral-load-resisting elements. Seismic codes generally classify these features as either plan or vertical irregularities; however, this distinction does not imply that the two occur independently. De Stefano and Pintucchi [1] emphasized that real buildings may exhibit combinations of plan and vertical irregularities, although the two categories have traditionally also been treated separately in much of the research literature.

Among plan irregularities, torsional irregularity is particularly important because asymmetric distributions of mass, stiffness, or strength can produce rotational response in addition to the translational motion of the floor system. Consequently, lateral deformation and seismic demand may become non-uniform across the plan. The torsional response of multistory buildings is influenced not only by the magnitude of eccentricity but also by the distribution of stiffness and strength and by the dynamic characteristics of the structural system. Bhasker and Menon [2] further demonstrated that different measures used to characterize torsional irregularity do not necessarily maintain the same relationship with structural demand throughout the elastic and inelastic response ranges. This highlights the importance of evaluating torsional behavior within the nonlinear structural response rather than relying exclusively on an initial measure of eccentricity or irregularity.

The complexity of irregular structural response has also motivated the development of nonlinear procedures capable of accounting for modal contributions beyond the fundamental translational mode. Chopra and Goel [3] proposed the Modal Pushover Analysis (MPA) procedure to estimate seismic demands by independently evaluating modal responses and subsequently combining their contributions. The procedure was later extended to unsymmetric-plan buildings [4]. For vertically irregular structures, Chintanapakdee and Chopra [5] compared modal pushover predictions with nonlinear response-history analyses for frames containing stiffness, strength, and combined irregularities, demonstrating the relevance of higher-mode contributions in the evaluation of such structural configurations.

An alternative multi-mode formulation was introduced by Aydınoğlu [6] through the Incremental Response Spectrum Analysis (IRSA) procedure. IRSA was developed as a theoretically based multi-mode pushover approach in which response spectrum analysis is applied incrementally throughout the nonlinear response, allowing modal displacement increments and corresponding structural response quantities to be evaluated at successive analysis steps. The procedure is not restricted to two-dimensional response and can be applied to three-dimensional structural systems while incorporating multiple vibration modes and P-delta effects. Aydınoğlu [7] subsequently demonstrated the procedure on a three-dimensional building model with artificial mass eccentricity, where multiple modes were considered to represent coupled lateral–torsional response. This formulation provides the methodological basis for the incremental multi-modal nonlinear analysis adopted in the present study.

Vertical stiffness irregularity represents another important source of unfavorable seismic behavior. A soft story may develop when the lateral stiffness of one story is substantially lower than that of adjacent stories, resulting in concentration of deformation and nonlinear demand at that level. Dya and Oretaa [8] investigated soft-story RC buildings using pushover analysis and introduced different irregularity levels by increasing the first-story height while maintaining the remaining structural configuration. Their results showed that increasing soft-story severity progressively concentrated structural damage at the irregular story. This modeling concept is particularly relevant to existing buildings in which increased ground-story height can produce a pronounced reduction in lateral stiffness.

The seismic response may become more unfavorable when vertical stiffness irregularity coexists with asymmetry in plan. Ouazir et al. [9] investigated torsionally unbalanced structures with a soft first story and demonstrated that coupling between the two response mechanisms can substantially influence displacement demand, particularly on the flexible side of the structure. Earlier work by Goh and Pan [10] similarly examined the torsional response of nonductile structures with a soft first story and identified significant displacement amplification associated with the coupled response. More recently, Satheesh et al. [11] investigated the effect of in-plan eccentricity on vertically stiffness-irregular buildings and found that eccentricity can amplify the unfavorable response associated with stiffness irregularity, particularly when the irregular story is located in the lower portion of the building. Their findings led them to emphasize the importance of considering in-plan eccentricity when evaluating buildings containing vertical stiffness irregularities.

The importance of interaction between different irregularity mechanisms has also been examined for other combinations of structural irregularities. Sadashiva et al. [12] investigated the seismic response of structures with coupled vertical stiffness–strength irregularities, providing additional evidence on the response of buildings containing more than one form of vertical irregularity. Hareen and Mohan [13] subsequently examined the torsional response of ductile RC buildings with soft first stories using nonlinear static and bidirectional nonlinear dynamic analyses. Their results showed that damage to bottom-story columns can reduce both lateral and torsional stiffness and amplify the torsional response at the irregular story. In the investigated buildings, this amplification resulted in larger displacements and more severe damage at the flexible side. Collectively, these studies demonstrate that the simultaneous presence of different irregularity mechanisms warrants explicit consideration when evaluating seismic response.

Such findings are particularly relevant to rapid seismic screening (RSS), where structural irregularities are incorporated as indicators of potential seismic vulnerability. FEMA P-154 [14], for example, provides a rapid visual screening procedure for identifying and prioritizing potentially hazardous buildings using basic structural scores and score modifiers associated with building characteristics and seismic deficiencies. The technical basis underlying the screening procedure and its scoring methodology is documented in FEMA P-155 [15]. Rapid assessment procedures are intended to prioritize large building inventories for subsequent detailed evaluation rather than to reproduce the results of comprehensive nonlinear analysis. A direct example of linking nonlinear structural response to such a screening parameter was presented by Dya and Oretaa [8]. Rather than treating soft-story irregularity solely as a binary condition, they used pushover-derived vulnerability measures to develop score modifiers corresponding to different levels of soft-story severity. Their approach demonstrates that nonlinear structural response can provide a quantitative basis for interpreting and refining irregularity-related parameters used in preliminary seismic assessment.

However, an important distinction exists between the available literature on structural response and that on rapid seismic screening. Previous studies have provided substantial evidence that torsional irregularity and soft-story irregularity can interact and amplify nonlinear seismic response [9–11,13], but their primary objective has generally been to characterize structural behavior rather than to examine how this deterioration should be represented in rapid screening. Conversely, the use of nonlinear response to derive or interpret screening score modifiers has been demonstrated for an individual irregularity such as the soft story [8]. Thus, although the nonlinear consequences of combined torsional and soft-story irregularities have been investigated, the translation of these consequences into the interpretation of irregularity-related penalties in rapid seismic screening has received comparatively limited attention.

The present study addresses this gap by quantitatively examining the performance deterioration associated with torsional irregularity and its coexistence with a soft-story configuration. Five-story RC buildings are investigated using two complementary mechanisms for producing torsional response: mass eccentricity in moment-resisting frame models and stiffness eccentricity introduced through the location of an RC core wall in wall-frame models. The nonlinear response is evaluated using an incremental multi-modal analysis procedure, with particular emphasis on modal characteristics, pushover response, base shear and displacement at the DD-2 target point, structural damage distribution, and secant stiffness. By comparing torsion-only and combined torsional–soft-story configurations, the study quantifies the associated reductions in lateral resistance and secant stiffness and subsequently interprets these reductions from the perspective of irregularity-related penalty mechanisms used in rapid seismic screening.

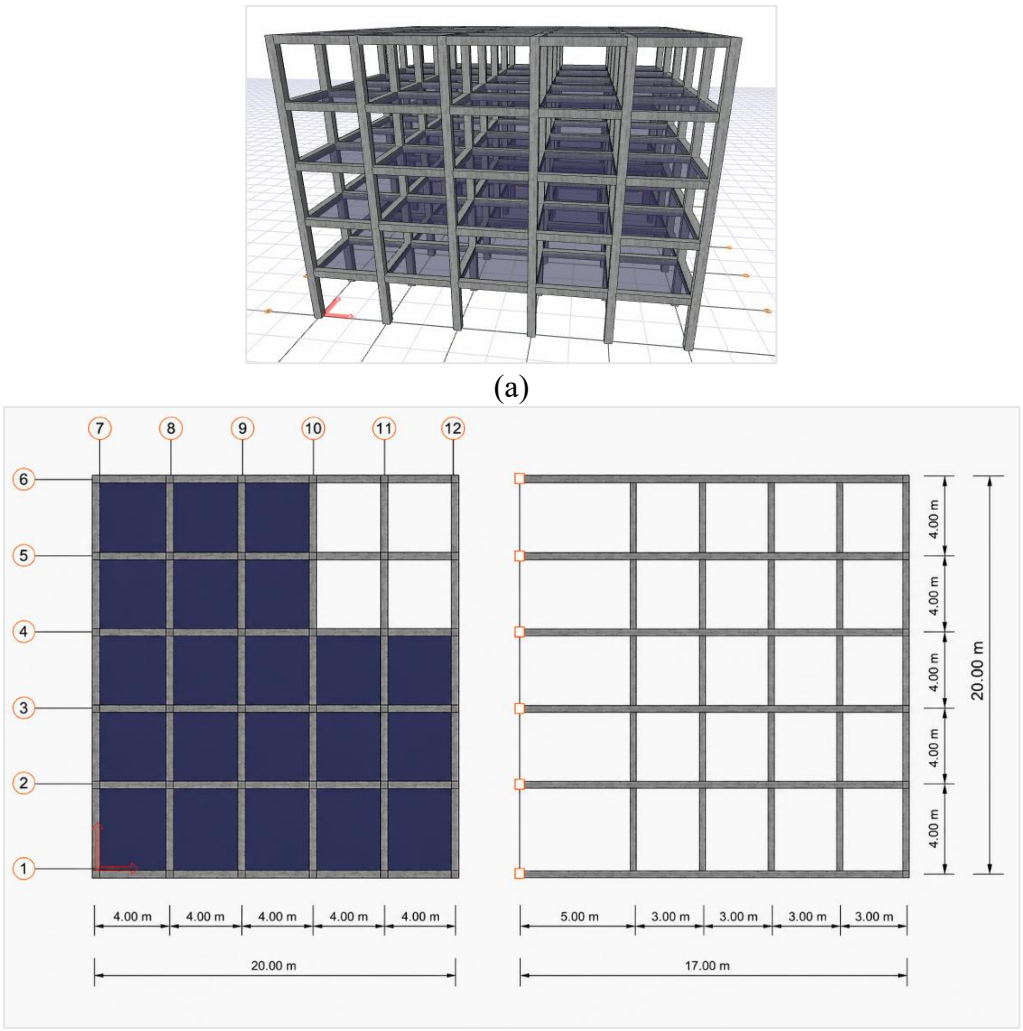
2 Numerical Modeling

A five-story reinforced concrete (RC) moment-resisting frame building representative of conventional Turkish construction practice was adopted as the reference structure in this study. The building has a square floor plan measuring 20 × 20 m, corresponding to a footprint area of 400 m². Both principal directions consist of five equal bays with a span length of 4.0 m. The reference model has a uniform story height of 3.0 m, resulting in a total structural height of 15 m (Fig. 1). Reinforced concrete slabs with a uniform thickness of 110 mm were assigned at every floor level and were assumed to act as rigid diaphragms.

To investigate the influence of structural irregularities on the global seismic behavior, five finite element models were developed while maintaining the same basic frame dimensions, material properties, and total gravity loading. The models differ in terms of plan irregularity, vertical irregularity, and the presence and location of a structural wall core.

The Reference (R0) model represents a regular RC moment-resisting frame without any intentional irregularity. The second model, designated IR1_T, incorporates a plan mass irregularity. Four slab panels located at the upper-right corner of the floor plan were removed from every story (Fig. 1). To preserve the total seismic mass of the building, the gravity loads associated with the removed slab panels were redistributed to the slab located at the lower-left corner of the plan. Consequently, the total building mass remained unchanged while the center of mass shifted, producing a pronounced torsional irregularity.

The third model, IR2_TS, includes the same plan mass irregularity as the IR1_T model together with a soft-story configuration. The ground-story height was increased from 3.0 m to 5.0 m, whereas all upper stories retained a height of 3.0 m.



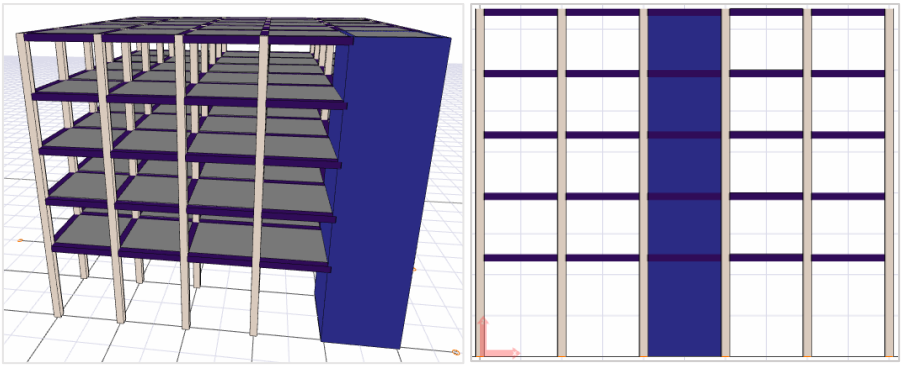


Fig. 1. Geometrical configuration of the frame models: (a) 3D view of the reference model (R0), (b) plan view of the IR1_T model, and (c) elevation view of the IR2_TS model.

The fourth model, IR3_EW, represents a wall-frame structural system. In addition to the 5.0 m ground-story height adopted in the IR2_TS model, a reinforced concrete core wall was introduced at the upper-right corner of the floor plan. Unlike IR1_T and IR2_TS, the floor slabs remained continuous throughout the building. The eccentric location of the core wall produces an asymmetric distribution of lateral stiffness and was adopted to investigate torsional response associated with stiffness eccentricity.

The fifth model, IR4_CW, has the same structural configuration, story heights, member properties, and core wall geometry as IR3_EW, but the reinforced concrete core wall was positioned at the center of the floor plan. The centrally located core provides a more balanced distribution of lateral stiffness compared with IR3_EW. Therefore, comparison of IR3_EW and IR4_CW allows the influence of core-wall location and the resulting stiffness eccentricity on the torsional response to be investigated while maintaining the same soft-story configuration (Fig. 2).

(a) (b)

Fig. 2. Geometrical configuration of the wall-frame models: (a) 3D view of the eccentrically located core wall model (IR3_EW), and (b) elevation view of the centrally located core wall model (IR4_CW).

The beams have rectangular cross-sections of 400 × 350 mm and were reinforced with 4Ø16 top and 3Ø16 bottom longitudinal bars, together with 2Ø10/100 mm transverse reinforcement. The columns have square cross-sections of 400 × 400 mm and were reinforced with 12Ø20 longitudinal bars and Ø10/100 mm transverse reinforcement. The same reinforcement configuration was maintained throughout the building height. The reinforced concrete core walls in IR3_EW and IR4_CW had dimensions of 250 × 4300 mm and were designed to satisfy the minimum reinforcement requirements in accordance with the Turkish Building Earthquake Code [16]. A uniformly distributed gravity load of 10 kN/m² (G + nQ) was assigned to all floors. C20 concrete and S420 reinforcing steel were used in all structural models. Nonlinear analyses were performed using ideCAD Structural, where the nonlinear behavior of reinforced concrete members was represented using concentrated plasticity models.

3 Nonlinear Analysis Procedure and Results

Nonlinear seismic analyses were carried out using the Incremental Response Spectrum Analysis (IRSA) method implemented in ideCAD Structural. The method provides a multi-modal nonlinear analysis framework in which the response spectrum is incorporated directly into the incremental analysis procedure. Rather than representing the seismic demand by a single invariant lateral load pattern, the structural response is determined by considering the contributions of multiple vibration modes throughout the nonlinear analysis. This feature is particularly important for irregular structures, where higher-mode effects and coupling between translational and torsional response may become significant. During the analysis, the structural state is updated as yielding and plastic hinge formation progress. The modal properties corresponding to the current stiffness state are recalculated, and the response contributions associated with the considered vibration modes are determined and combined at each stage. Consequently, changes in the dynamic characteristics of the structure resulting from stiffness degradation are reflected in the subsequent response increments. The procedure therefore provides an adaptive representation of nonlinear seismic response while retaining the response-spectrum-based formulation of modal analysis [6,7].

The use of IRSA is particularly suitable for the present study because torsional response constitutes a principal component of the investigated irregularities. In the frame models, translational–torsional coupling is induced by the asymmetric mass distribution, whereas in the wall-frame models it is influenced by the location of the structural wall core and the corresponding stiffness distribution. By simultaneously accounting for multiple modes, the adopted procedure enables these coupled response mechanisms to be represented within the

nonlinear analysis. The method also generates modal capacity curves in modal pseudo-acceleration–modal displacement coordinates for the contributing modes, while the global base shear–displacement response was adopted herein for comparison of the five structural models. Prior to the evaluation of the nonlinear response, the modal characteristics of the five structural models were examined to identify the influence of the introduced irregularities on their dynamic behavior. Table 1 summarizes the first three natural periods of the five structural models obtained from modal analysis.

Table 1. First three natural periods of the structural models.

Model	Structural configuration	T_1 (s)	T_2 (s)	T_3 (s)
R0	Regular frame	0.8885	0.8885	0.7906
IR1_T	Mass-eccentric frame	0.9046	0.8800	0.7486
IR2_TS	Mass-eccentric frame + soft story	1.1603	1.1276	0.9561
IR3_EW	Eccentric-core wall-frame + soft story	0.7886	0.4693	0.3121
IR4_CW	Central-core wall-frame + soft story	0.5442	0.4558	0.4558

As shown in Table 1, R0 and IR1_T exhibit very similar natural periods. This was an intended feature of the model configuration, as the torsional response in IR1_T was introduced by modifying the spatial distribution of mass while leaving the stiffness properties of the frame members unchanged. Thus, the close modal periods of R0 and IR1_T indicate that torsional effects were introduced without a substantial alteration of the overall translational dynamic characteristics. In IR2_TS, however, increasing the ground-story height from 3.0 to 5.0 m led to a clear increase in the natural periods, reflecting the reduction in lateral stiffness associated with the soft-story configuration. For the wall-frame models, identical member properties and core-wall dimensions were maintained, with only the location of the core being changed. Nevertheless, IR3_EW and IR4_CW exhibited noticeably different modal periods. Relocating the core from the center to the corner alters the spatial distribution of stiffness relative to the mass center and introduces stronger translational–torsional coupling. Therefore, although the sectional stiffness properties of the structural members remain unchanged, the global dynamic characteristics of the system are modified, resulting in different modal periods. Examination of the modal response indicated that the introduced irregularities modify the torsional characteristics of the structural response. While the first two modes of R0 are predominantly translational and the third mode is essentially torsional, the mass eccentricity introduced in IR1_T leads to coupled translational–torsional response. A similar modal pattern is retained in IR2_TS, accompanied by longer periods due to the soft-story configuration. For the wall-frame models, the centrally located core in IR4_CW results in a clearer separation between torsional and translational modes, whereas relocating the core to the corner in IR3_EW produces stronger translational–torsional coupling. These modal characteristics support the use of a multi-modal nonlinear analysis procedure for evaluating the capacity of the irregular models considered herein. Figure 3 compares the nonlinear pushover responses of the R0, IR1_T, and IR2_TS frame models. The curves presented are shown up to the target displacement determined for the DD-2 seismic demand. The capacity curve of IR1_T remains relatively close to that of the regular R0 model, although a moderate reduction in lateral load-carrying capacity is observed as a result of the introduced mass-induced torsional irregularity. This behavior is consistent with the model configuration, in which torsional response was introduced without modifying the stiffness properties of the frame members. In contrast, IR2_TS exhibits a substantially lower capacity curve over the entire displacement range. The additional soft-story irregularity, introduced by increasing the ground-story height, reduces both the lateral stiffness and the base shear attained at the DD-2 target point. The comparison therefore indicates that torsional irregularity alone produces a relatively limited reduction in global lateral capacity, whereas the

coexistence of torsional and soft-story irregularities results in a markedly greater deterioration of the nonlinear response.

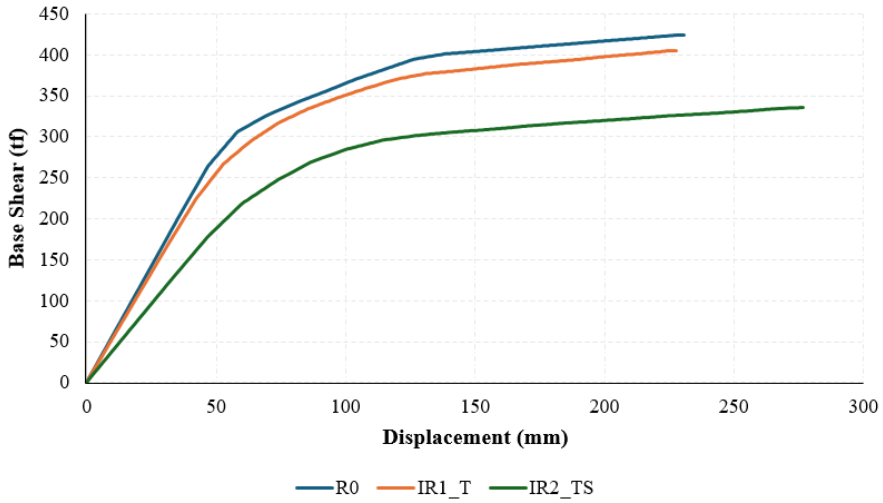

Fig. 3. Comparison of nonlinear pushover curves for the frame models.

Figure 4 compares the nonlinear pushover responses of the two wall-frame models.

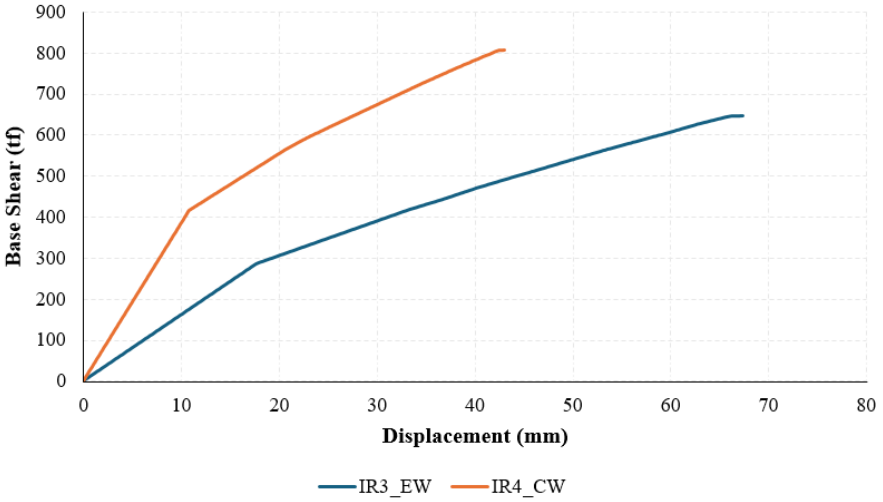

Fig. 4. Comparison of nonlinear pushover curves for the wall-frame models.

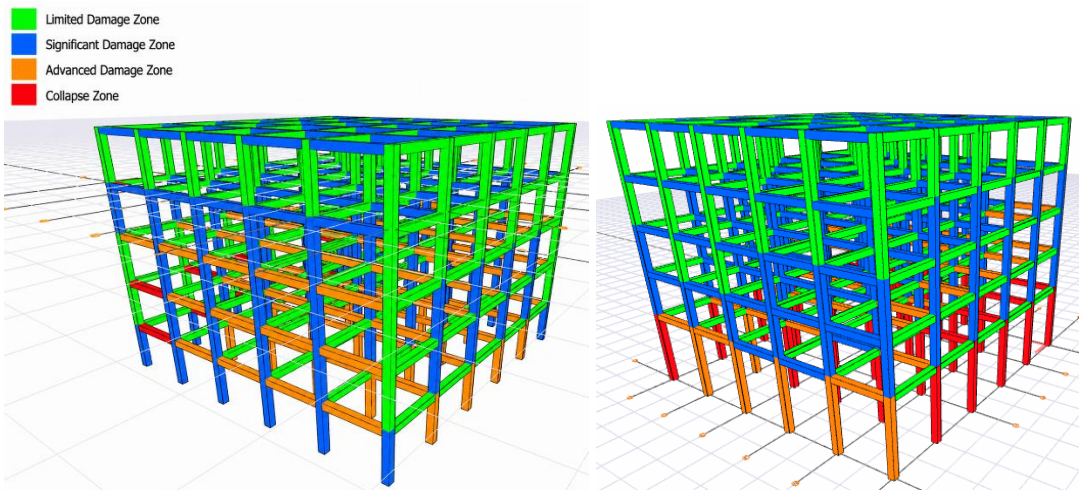

Although the wall-frame models exhibit higher absolute lateral capacities than the reference frame due to the presence of the RC core, the comparison between IR3_EW and IR4_CW provides a complementary evaluation of the influence of torsional response. Both wall-frame models have the same soft-story configuration and identical core-wall properties; however, the eccentric core location in IR3_EW produces stronger translational–torsional coupling and a lower lateral capacity than IR4_CW. Under the DD-2 earthquake demand, IR4_CW achieved the Limited Damage performance level, whereas all other models were classified at the Controlled Damage level. More importantly, the more pronounced capacity reduction observed in IR2_TS compared with IR1_T highlights the adverse response associated with the coexistence of torsional and soft-story irregularities. This interaction is particularly relevant to rapid seismic screening methodologies, where the simultaneous presence of these irregularities may require greater consideration than their independent evaluation alone.

Table 2. Relative variation in base shear at the DD-2 target point for the investigated model comparisons.

Comparison	Baseline capacity (tf)	Compared-model capacity (tf)	Capacity reduction (%)
R0 → IR1_T	424.261	404.467	**4.67**
IR1_T → IR2_TS	404.467	335.558	**17.04**
R0 → IR2_TS	424.261	335.558	**20.91**
IR4_CW → IR3_EW	808.498	647.220	**19.95**

Table 2 quantifies the capacity reductions associated with the investigated irregularity scenarios. The introduction of mass-induced torsional irregularity alone reduced the base shear capacity by only 4.67% relative to the regular reference model. When the soft-story condition was added to the torsionally irregular frame, an additional capacity reduction of 17.04% was observed, resulting in an overall reduction of 20.91% relative to R0. A comparable sensitivity to torsional response was observed in the wall-frame systems. Although both models contained the same soft-story configuration, relocating the core from the center to the plan corner resulted in a 19.95% reduction in base shear at the DD-2 target point. This comparison demonstrates that, within an already vertically irregular system, the spatial distribution of lateral stiffness and the associated torsional coupling can substantially influence the nonlinear response.

The software provides member damage distributions for the different analysis cases considered in the performance assessment. To illustrate the development and spatial distribution of nonlinear damage, the G+0.3Q+E_x analysis case was selected, representing the structural response under gravity loads combined with the seismic action in the positive X direction. Figure 5 compares the resulting damage distributions of the regular reference model (R0) and the model with combined torsional and soft-story irregularities (IR2_TS). While damage in R0 is more distributed over the structural system, IR2_TS exhibits a pronounced concentration of severe damage in the ground-story columns. Several columns in this story reach the advanced damage and collapse zones, indicating localization of the nonlinear response at the elongated ground story. This observation is consistent with the lower lateral response obtained for IR2_TS and demonstrates the pronounced localization of nonlinear damage associated with its combined irregular configuration.

(a) (b)

Fig. 5. Comparison of member damage distributions under the G+0.3Q+E_x performance analysis: (a) R0 and (b) IR2_TS.

The pushover results indicate that the influence of structural irregularities is reflected not only in the lateral load-carrying capacity but also in the force–deformation response of the structural system. Therefore, in addition to the base shear attained at the DD-2 target point, the corresponding secant stiffness was evaluated to provide a complementary measure of the response. The secant stiffness, K_{sec}, was calculated as V_{DD2}/Δ_{DD2}, where V_{DD2} and Δ_{DD2} denote the base shear and displacement at the DD-2 target point, respectively. The resulting values and their percentage reductions are summarized in Table 3.

Table 3. Comparison of lateral capacity and secant stiffness at the DD-2 target point.

Model	V_{DD2} (tf)	Δ_{DD2} (mm)	Ksec (tf/mm)	Capacity reduction (%)	Secant stiffness reduction (%)
R0	424.261	230.770	1.838	–	–
IR1_T	404.467	227.550	1.778	**4.67**	**3.29**
IR2_TS	335.558	276.660	1.213	**20.91**	**34.03**
IR3_EW	647.220	67.390	9.604	**19.95**	**48.92**
IR4_CW	808.498	43.000	18.802	–	–

For the frame models, reductions were calculated relative to R0, whereas IR4_CW was adopted as the baseline for the wall-frame comparison. Torsional irregularity alone in IR1_T resulted in relatively small reductions of 4.67% in lateral capacity and 3.29% in secant stiffness. In contrast, IR2_TS, in which torsional and soft-story irregularities coexist, exhibited reductions of 20.91% and 34.03%, respectively. The wall-frame comparison shows a similar sensitivity to torsional response, with IR3_EW exhibiting 19.95% lower lateral capacity and 48.92% lower secant stiffness than IR4_CW. Overall, the results demonstrate that the combined irregular configuration is associated with deterioration in both lateral resistance and force–deformation response, with substantially larger reductions observed for IR2_TS than for the torsion-only frame model. This distinction is particularly relevant to rapid seismic screening, where the simultaneous presence of torsional and soft-story irregularities may warrant greater attention than torsional irregularity alone.

4 Conclusions

This study investigated the nonlinear seismic response of five-story RC buildings with different configurations of torsional and soft-story irregularities using a multi-modal nonlinear analysis procedure. The results demonstrate that the influence of structural irregularities becomes particularly significant when unfavorable plan and vertical configurations coexist.

For the frame systems, introducing mass-induced torsional irregularity alone produced relatively limited changes in the global response. Compared with the regular R0 model, IR1_T exhibited a 4.67% reduction in lateral capacity and a 3.29% reduction in secant stiffness at the DD-2 target point. In contrast, when the torsional irregularity was accompanied by the soft-story configuration in IR2_TS, the reductions increased to 20.91% in lateral capacity and 34.03% in secant stiffness. The damage distribution further supported this trend, showing a pronounced concentration of severe nonlinear damage in the ground-story columns of IR2_TS. The wall-frame models provided a complementary assessment of torsional response associated with stiffness eccentricity. Relocating the core wall from the center to the plan corner resulted in a 19.95% reduction in lateral capacity and a 48.92% reduction in secant stiffness. In addition, the centrally located core model, IR4_CW, achieved the Limited Damage performance level

under DD-2 demand, whereas the remaining models were classified at the Controlled Damage level. These findings demonstrate that the spatial distribution of lateral stiffness can substantially influence both the dynamic characteristics and nonlinear force–deformation response, even when the structural member and wall properties remain unchanged.

The results also highlight the importance of multi-modal analysis in structures with significant torsional response. Although single-mode analyses were also performed, their detailed results were omitted due to space limitations. For IR2_TS, the single-mode analysis underestimated the displacement response by approximately 47.6% compared with the multi-modal IRSA result. This substantial difference indicates that neglecting higher-mode and torsional contributions may lead to a significant underestimation of seismic displacement demand.

Overall, the results show that evaluating torsional irregularity independently may not fully represent the severity of the structural response when it coexists with a soft-story configuration. While torsional irregularity alone resulted in comparatively small reductions in the investigated frame system, the combined irregular configuration was associated with substantially greater losses in both lateral resistance and secant stiffness, together with increased localization of structural damage. From a rapid seismic screening perspective, these findings suggest that buildings exhibiting both torsional and soft-story irregularities should receive particular attention and that their simultaneous occurrence may warrant a more severe assessment than that implied by considering each irregularity independently. Further studies involving a broader range of building geometries and irregularity levels are required before quantitative modifications to existing rapid-screening penalty schemes can be proposed.

Abstract. International codes do not allow the application of bending moment along with axial compression on timber spaced columns except for minor dead-load-related moments. This study attempts to derive an interaction relationship between axial load and bending moment on spaced (built-up) columns using gussets. The capacity is determined using Finite Element Modeling (FEM), especially for slender spaced columns. The approach considers a) buckling (local or global) stability of the whole column and b) compressive strength of members considering allowable stresses. Two lengths of 3 m and 5.8 m were selected for the FEM models, and buckling loads were obtained to determine three-dimensional P-M diagrams. An attempt was made to fit equations to the obtained P-M curves. Although the study is purely numerical, it highlights important missing aspects of spaced-column design and should be supported with experimental studies in the future. The results of this work might help to improve international timber design codes. Significant efforts are underway to enhance the utilization of structural timber in construction, while an international race to construct taller timber high-rise buildings is gathering momentum. Several countries, including Canada, USA, and New Zealand, as well as European countries, have established wood research centers to foster a sustainable construction industry and promote the widespread use of structural wood. The extensive application of timber in both regular and high-rise buildings may require the adoption of spaced-column designs capable of accommodating bending moments.

Keywords: Mass Timber, Spaced-Column, P-M Diagram

1 Introduction

Structural wood is a sustainable material, and timber buildings are efficient while also contributing to carbon sequestration by capturing and storing CO_2 from the atmosphere. Although timber houses constitute about 1.5% of the building stock in Turkiye, their use and importance are gradually increasing both locally and throughout Europe and Asia. One of the underrated structural elements is the spaced column, which is not commonly used in light-frame and post-and-beam construction.

Timber Columns can be used in two different cross-sections: solid (Fig. 1.a) and built-up cross-section columns (Fig. 1.b-d2). The built-up cross-section columns are used in 3 different patterns: mechanically jointed columns (Fig. 1.b), spaced columns (with gussets (Fig. 1.c1) and packs (Fig. 1.c2)), and lattice columns (N-type (Fig. 1.d1) and V-type (Fig. 1.d2)). Mechanically jointed columns consist of bringing n number of shafts of the same size, side by side and connecting them with fasteners (bolts, nails, etc.) or adhesives. Elements of spaced columns are comprised of placing gussets or packs between shafts of the same size and

connecting them with fasteners such as bolts, nails, etc. A lattice column's elements are generally formed by combining two struts with diagonal and horizontal wooden elements by means of fasteners such as bolts, nails, etc.

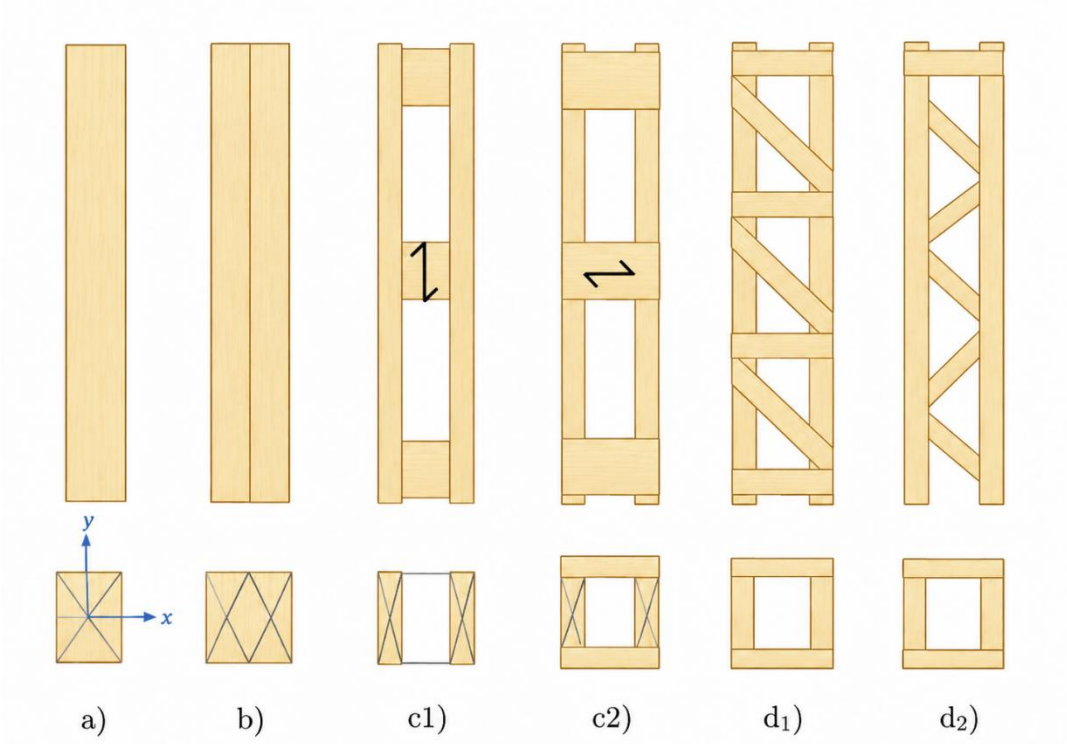

Fig. 1. Types of timber columns: a) Solid column, b) Mechanically jointed column, c_1) Spaced column with gussets, c_2) Spaced column with packs, d) Lattice column, d_1) N type, d_2) V type

Since long, single piece large-sized solid timber columns are difficult to obtain, spaced columns are generally preferred for supporting high ceilings. Additionally, solid columns may present problems such as shrinkage during drying and increased material costs. Therefore, there is a need for a better and more fundamental understanding of the behavior of built-up cross-section timber columns and for the development of appropriate design formulas [1]. International codes do not allow for bending moments in the design of spaced columns; however, all columns may experience bending moments, and special, impractical pinned connections may be required to almost fully eliminate them. Additional problems such as shrinkage and deformation (e.g., cupping, bowing, and twisting) may also be reduced by using built-up members [2]. Consequently, the current practice of designing spaced columns considering only axial loads represents a major limitation, which is addressed in this study.

The derivation of the interaction between axial load and bending moment on spaced (built-up) columns using gussets is attempted using analytical methods. The capacity calculations based on Finite Element Modeling (FEM) are conducted using SAP2000 software [3]. Gussets are assumed to be rigidly connected using glue; nailed or screwed connections may introduce additional flexibility and load capacity results may be overestimated. Especially slender spaced columns are used in the study, due to the fact that linear analysis software can only conduct elastic buckling, and plastic buckling for shorter columns has to be backed up by laboratory testing using actual physical models. The approach followed in this study considers a) buckling (local or global) stability of the whole column and b) compressive strength of members considering allowable stresses. Mainly two different lengths of 3m (10 feet) and 5.8m (19.3 feet) are used for the same cross section that was produced by two 50mm × 100mm (2 by 4)

members with gussets at every 0.7m (2.3 feet) apart along the length. Three-dimensional (3D) P-M diagrams and generalized equations to fit 2D P-M curves were obtained.

2 Previous Works

There are some previous studies to obtain P-M diagrams of timber columns. Van Dyer (1976) [4] experimentally investigated the strength of timber columns under axial compressive load in his PhD thesis; however, his work included only concentric load (he emphasized that eccentric loading should also be examined). Van Dyer and Malhotra (1985) [1] carried out both experimental and theoretical studies to obtained strength of spaced columns for the purpose of i) to verify pre-developed theoretical information, ii) to compare efficiency of spaced columns with different types (i.e., first within themselves and then against solid and mechanically connected columns, iii) to investigate the effect of number of blocks on the strength of columns. They pointed out that the axial strength of columns changed depending on the number of elements, member sizes, and number of blocks. Jumaat (1991) [2] conducted both numerical and experimental studies for the purpose of determining the buckling strength of columns in his study. He tested 89 columns with mechanically nailed joints and spaced columns that are under axial load effect. He did not consider any bending moment effect though. Van Dyer (1992) [5] presented a rational procedure in order to obtain the strength of spaced columns. He tested 40 spaced columns with gussets and observed a good correlation between the experimental results and theoretical predictions. Again, bending moment effects have not been taken into account. Van Dyer and Masih (1993) [6] investigated the effectiveness of mechanically jointed column elements and their contribution to strength for different sizes and different eccentric loads. A total of 216 compression tests were conducted for 72 columns. The load capacities of 'mechanically jointed columns' in pure axial and eccentrically loadings conditions were compared against each other. In that study, spaced columns have not tested. Śliwka (2017) [7] tested spaced columns with gussets that were made using different materials such as lumber, plywood, chipboard, and fiberboard. Based on the theory presented by Timoshenko and Gere, the author derived various formulas describing the column critical force, slenderness ratio, shear force applied to the column, and the maximum shear force capacity of a column; however, bending moment effects, again, have not been taken into account.

Spaced columns have been used in the construction industry for many years. Although they are relatively easy to construct, their analysis is complex due to the numerous factors affecting their strength and structural behavior. In addition, columns may be subjected to eccentric loading due to various factors. The strength of eccentrically loaded spaced columns is primarily governed by the combined effects of axial force and bending moment. Therefore, bending moments should be taken into account under eccentric loading conditions. A review of previous studies indicates that mechanically jointed columns have been investigated under eccentric loading; however, studies on spaced columns have generally been limited to concentric axial loading.

3 Material Properties, Geometric Dimensions and Finite Element Model of Timber Elements

For the analysis of spaced columns under eccentric loading, the cross-sectional dimensions of the shafts were selected as 50 × 100 mm (2 × 4 in.), while the gusset dimensions were adopted as 50 × 200 mm, since 25 mm-thick gussets themselves exhibited local buckling, in a way considering highly rigid gussets. Buckling analyses were performed for column heights of 3 m and 5.8 m. The clear horizontal spacing between the shafts was taken as 150 mm, while the clear vertical spacing between the gussets was taken as 500 mm.

The shafts were modeled using frame elements, whereas the gussets were modeled using shell elements. The shafts and gussets were connected by rigid links simulating a glued rigid connection (Fig. 2). A total of five gussets, including those at the top and bottom ends, were modeled to connect the two shafts in the 3m model and 9 gussets were used in the 5.8m model. The horizontal translations of the columns in both the x- and y-directions were restrained at the top and bottom ends. The vertical translation at the base was also restrained to represent an idealized pinned support condition. Torsional instability of the columns was prevented by assigning rotational restraints about the vertical axis at both the top and bottom joints.

The shafts and gussets were assigned the same material properties, with an elastic modulus of 11 GPa, a Poisson's ratio of 0.3, and a unit weight of 4.28 kN/m³. The rigid links connecting the shafts and gussets were modeled as 100 mm-diameter steel rods with an elastic modulus of 210 GPa and zero mass. The Poisson's ratio of wood has been reported to vary in the longitudinal, tangential, and radial directions for both low- and high-density wood species, ranging from 0.18 to 0.43. Therefore, a value of 0.3 was adopted as an approximate average. The use of Poisson's ratios of 0.25 and 0.35 had no significant effect on the buckling results (less than 0.1‰).

The spaced columns were modeled using the SAP2000 finite element analysis program based on the selected dimensions and material properties. Linear buckling analyses were performed using the buckling analysis option available in the program. Since SAP2000 does not provide a practical option for plastic buckling analysis, relatively long columns were considered to ensure that buckling occurred within the elastic range. The columns were subjected to loads with different eccentricities ranging from 0.1 m to 184 m. The eccentricity was increased geometrically by a factor of 1.6 at each step, resulting in a total of 17 loading cases.

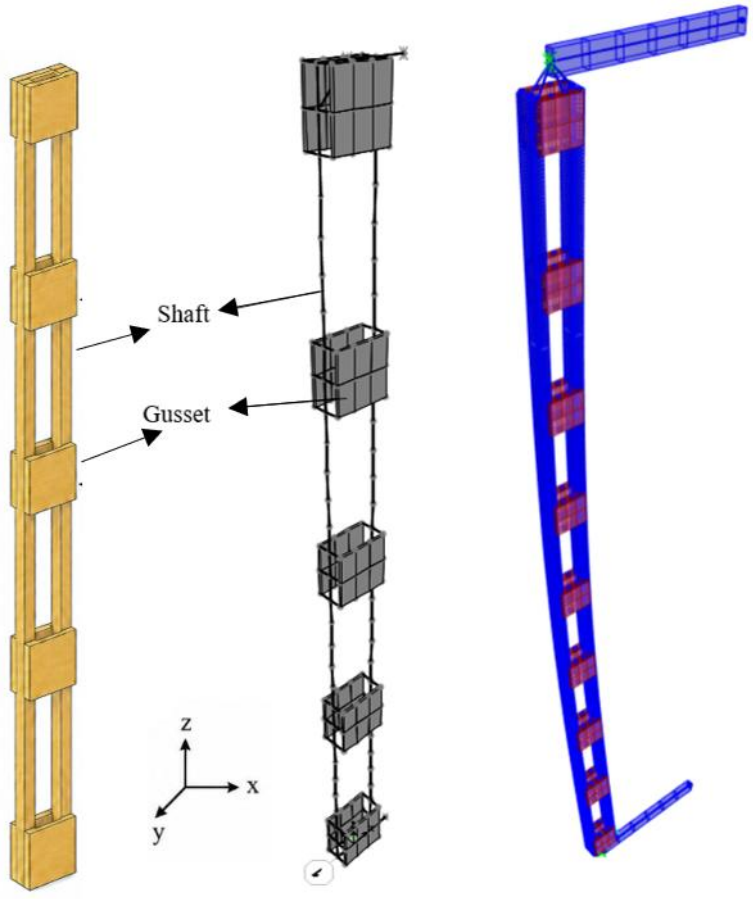

Fig. 2. Solid and SAP2000 model of the spaced column with gussets

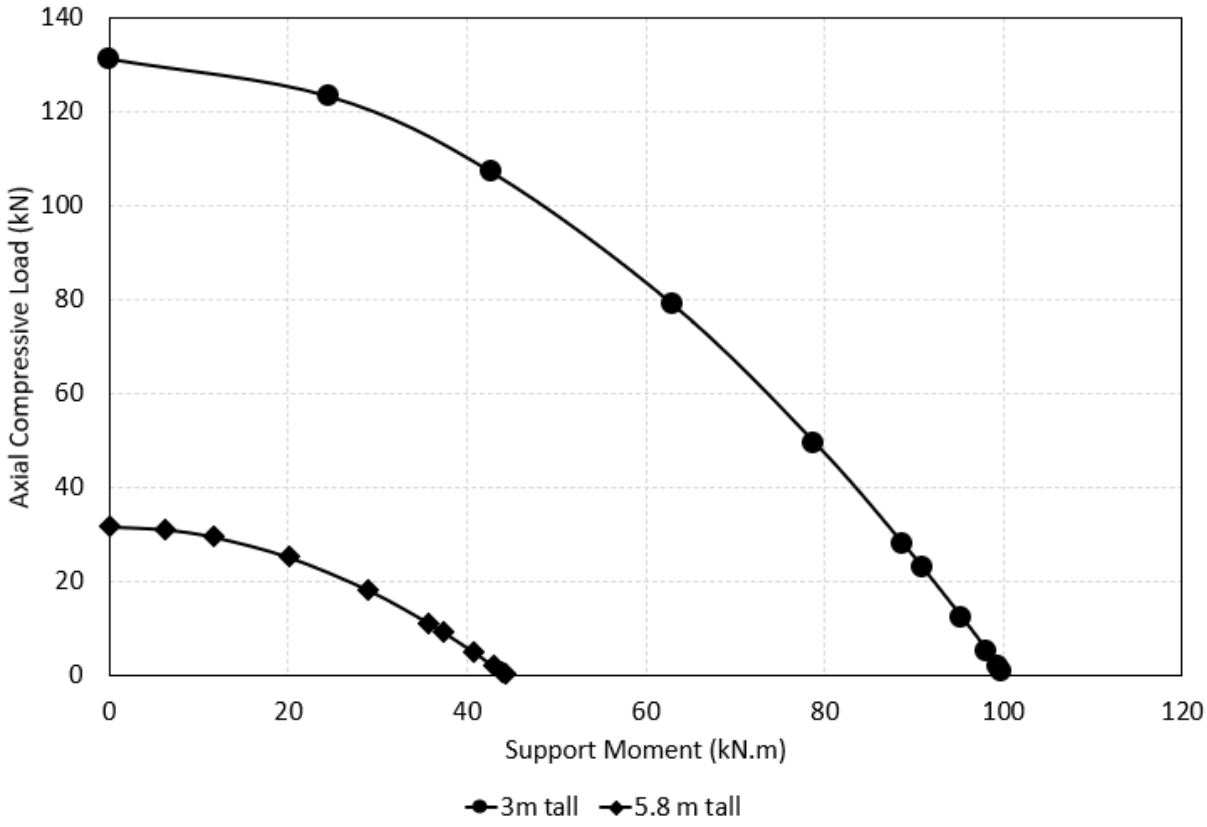
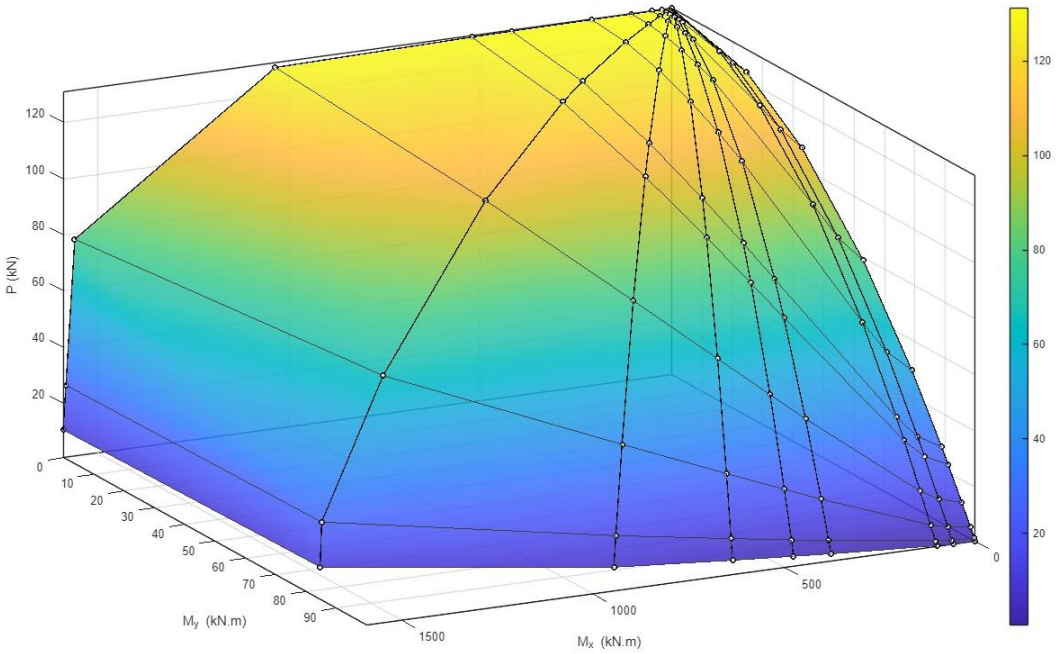
A large number of data points was required to construct the P–M interaction diagram. If the eccentricity had been increased at constant intervals, the resulting data points would have been concentrated in the moment-dominated region of the interaction diagram. In theory, reaching the point where P = 0 on the horizontal axis requires an infinitely large eccentricity, which cannot be achieved in practice. For this reason, very large eccentricities with geometric increments were considered. At low eccentricities, the axial force P is dominant, whereas at high eccentricities, the bending moment M becomes dominant (Fig. 3). Based on the analysis results, the axial load–moment interaction diagrams (P–M diagrams) were obtained analytically.





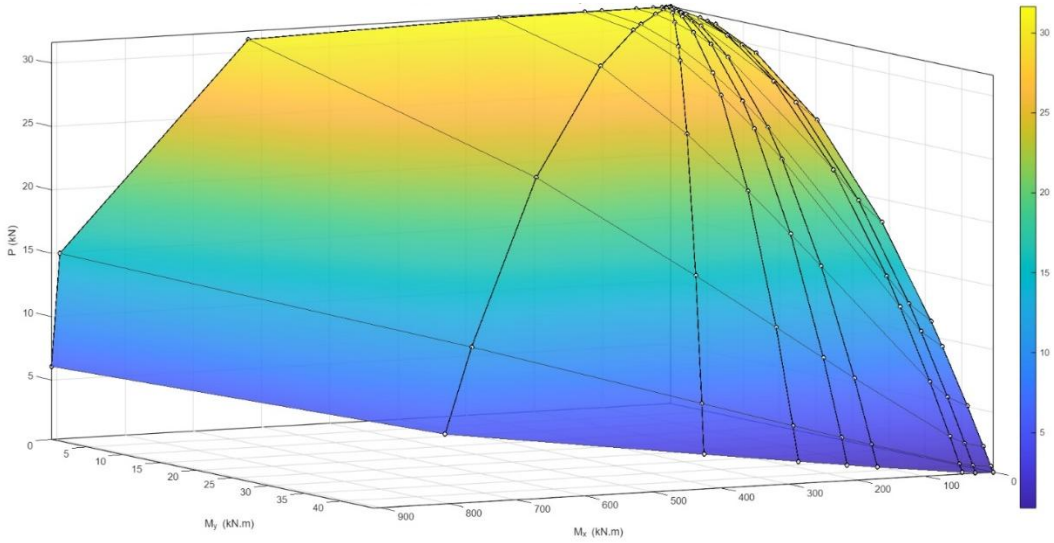


Fig. 3. P-M diagrams of 3m and 5.8m tall spaced columns

An attempt was also made to construct a three-dimensional P–M interaction diagram by developing an OAPI code in Matlab to control SAP2000 externally and perform numerous buckling analyses. The direction of the bending moment was varied from 0° to 90° in 15° or less increments, together with its magnitude. At a rotation of 90°, the P–M interaction diagram corresponds to bending about the weak axis. The results indicated that the buckling capacity increased significantly for bending about the weak axis, which is counterintuitive (Fig. 4). This trend became more pronounced as the eccentricity increased. For the 3 m column, for example, the critical buckling load increased from 78.8 kN at 0° to 131.1 kN at 90° for an eccentricity of 0.8 m, while at an eccentricity of 3.2 m, the corresponding values were 27.8 kN and 130.8 kN, respectively. A similar directional dependence was also observed for the longer column, indicating a strong influence of the bending direction on the buckling response of the spaced columns.

(a)

(b)

Fig. 4. 3D P–Mx–My interaction diagrams for the spaced columns: (a) 3 m column; (b) 5.8 m column.

The effect of gusset thickness on the buckling capacity of the spaced column was also investigated by comparing models with 10 mm and 50 mm thick gussets (Fig. 5). A noticeable increase in capacity was observed as the gusset thickness increased. For a nearly concentric loading condition with an eccentricity of 0.01 m, the critical axial load increased from 116.2 kN for the 10 mm gusset to 131.1 kN for the 50 mm gusset, corresponding to an increase of approximately 12.8% for the 3m long spaced column (Fig. 5). This result indicates that gusset stiffness has a significant influence on the buckling behavior of spaced columns, likely due to the enhanced interaction and restraint provided between the individual shafts.

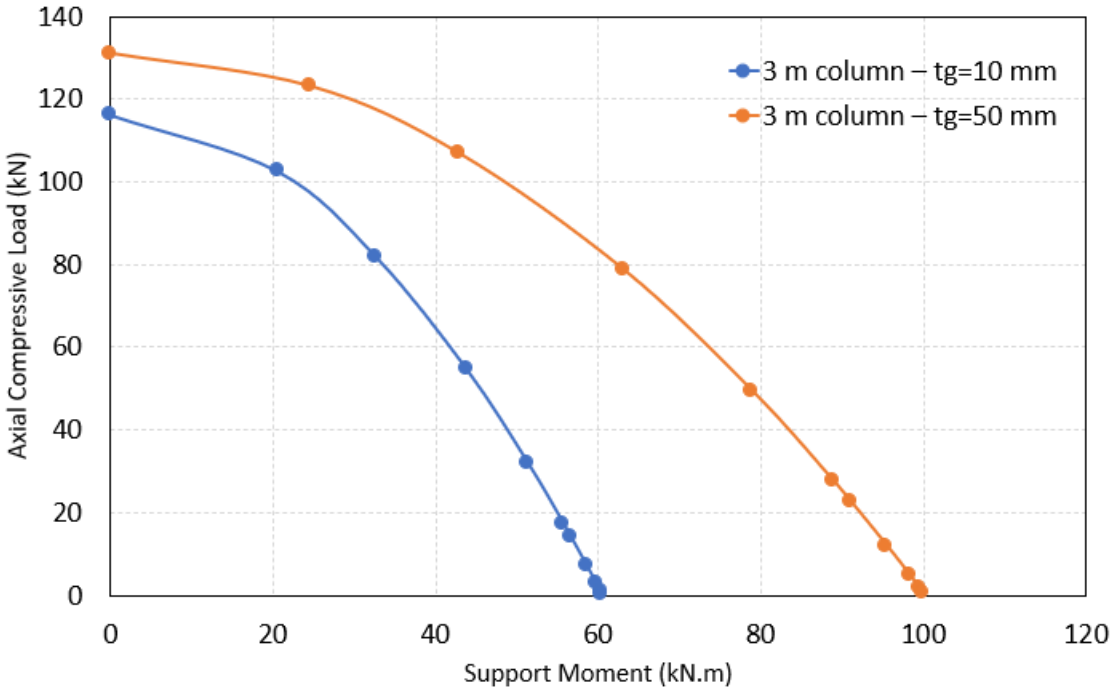

Fig. 5. Effect of gusset thickness (t_g) on the P–M interaction behavior of the 3 m spaced column

4 Discussions and Conclusions

Buckling analyses were conducted for two different column lengths using a two-shaft spaced column composed of 50 × 100 mm timber members with 200 mm distance between shaft centers. The results were used to construct linear-elastic eigenvalue-buckling P–M envelopes for the spaced columns. Local buckling of the gussets was suppressed by increasing their thickness to 50 mm, and the gussets were rigidly connected to the shafts. To assess whether flexural instability would precede compression failure in the compression-dominated region, the Eurocode 5 procedure for concentrically loaded spaced columns was applied. For the 3 m column, the effective slenderness ratios (λ_{eff}) were calculated as 88.8 and 201 for buckling about the strong and weak axes, respectively. The corresponding relative compression slenderness ratios, calculated as $\lambda_{rel,i}=(\lambda_{eff,i} / \pi) * (f_{c,0,k} / E_{0.05})^{(0.5)}$, were 1.5 and 3.4 in the strong axes. These values correspond to ideal Euler critical stresses of approximately $0.44*f_{c,0,k}$ and $0.086*f_{c,0,k}$, respectively; i.e., instability (buckling) occurs before the material reaches half of its characteristic compressive strength. However, SAP2000 based P-M interaction diagrams indicated that the bending moments to cause buckling are extremely high generating bending stresses well beyond material bending strength. This initial contradiction is actually a verification of stability being insensitive to bending action. When the shafts are bent in their weak axis, the buckling was not affected since parallel shafts rigidly connected to each other using gussets generated a stable condition for shafts; they did not go through buckling similar to a standard beam, since the compression generated by bending could not buckle sideways.

Defining the transition to elastic buckling by $\sigma_{Elastic}= 0.5f_{c,0,k}$ gives $\lambda_{rel,crit}=1.414$ as we consider elastic buckling to be $1/(\lambda_{rel,crit})^2=0.5$. Since the minimum relative compression slenderness obtained in the study was 1.5, the compression-dominated buckling modes of both

the 3 m and 5.8 m columns were considered to lie on the elastic-buckling side of the adopted transition criterion. As the bending stresses climb up to 50-100 kN.m on M_y and 900-1500 kN.m on M_x, the bending stresses are beyond any reasonable material capacity (Fig. 4). This is an indication of spaced column being insensitive to the bending moment even for 5.8 m tall case.

Various curve-fitting analyses in the M_y vs P case (Fig. 3) when M_x=0 indicated that a second-order polynomial provided the best fit, with $R^2 = 1$. Assuming a zero slope at M = 0, the interaction curve can be expressed in the form $P=B-AM^2$ (Fig 6). The axial load capacity at M = 0 is denoted by P_0, while the bending moment capacity at P=0 is denoted by M_0. Substituting these boundary conditions gives

$$P = P_0 - \frac{P_0}{M_0^2} M^2 \tag{1}$$

which can be rearranged as

$$P = P_0 \left(1 - \frac{M^2}{M_0^2}\right) \tag{2}$$

and finally expressed in normalized form as in Equation 3.

$$\frac{P}{P_0} + \left(\frac{M}{M_0}\right)^2 = 1 \tag{3}$$

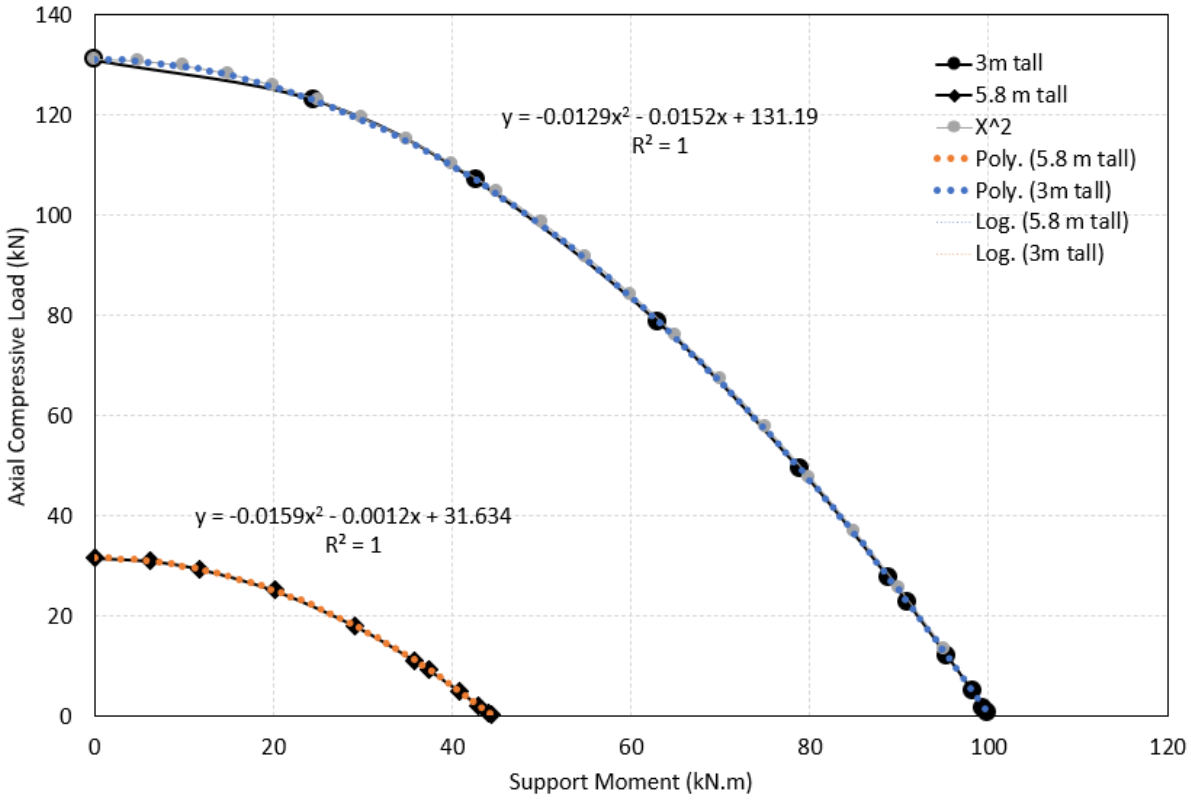

Fig. 6. 2D P-M diagrams of 3m and 5.8m tall spaced columns with curve fit

Even if end moments quickly exceed material capacities indicating insensitivity between buckling load and end moments, a generalized Eq. (3) would be useful for defining the relationship between the axial load, P, and bending moment, M, acting on a extremely slender spaced timber column; where, P_o is the uniaxial buckling strength and M_o is the bending strength including lateral torsional buckling. The selected 50x100 mm shafts orientation did not

buckle in the weak axis because of bending moment. The proposed interaction relationship can be established if the concentric buckling load and the corresponding moment capacity are known. These values can be readily obtained from the FEM of the spaced column by applying a concentric axial load and equal and opposite end moments, respectively. Once these two values, P_0 and M_0, are determined, the P-M interaction curve can be constructed using Eq. (3). It should be noted that both end moments are the same and moment is constant along the column (shear is zero); additional analyses are necessary if the moment is changing and additional shear's effect on the gussets. Nevertheless, constant bending moment is deemed as the upper limit for buckling, and unequal or opposite sign end moments would make the buckling less critical. Selected 3m and 5.8m columns had small contribution to buckling although they are slender and expected to go through elastic buckling. If the column moment is not constant, the moment effect is expected to be even smaller on the buckling. The buckling moments are generating stresses beyond material capacity.

The results obtained from the three-dimensional P-M interaction diagram indicate that bending about the weak axis governs is actually stronger regarding moment and axial load buckling interaction. The moment direction causing compression in one of the shafts also very large although more critical than the other direction as a single shaft can buckle easier. The buckling capacity of the selected spaced columns are primarily governed by the axial load causing buckling about the weak axis. An additional bending moment around the strong axis results in only a minor reduction in the buckling load, since the three-dimensional interaction surface is nearly flat in this direction. Therefore, buckling and stress capacities should be considered simultaneously, similar to the considerations associated with Euler buckling, for which the elastic buckling assumption becomes invalid at high stress levels.

The authors also conclude that the current study had surprising results, although (a) the present study is based solely on linear finite element analysis, and experimental testing is required to validate the numerical results and (b) the results are limited to linear elastic buckling. As the spaced column enters the plastic buckling range, the interaction curve is expected to approach a more linear relationship.

Abstract. Seismic evaluation of reinforced concrete buildings requires numerical models capable of capturing nonlinear behavior, strength degradation, and large deformations. This study compares two nonlinear modeling approaches: fiber-based distributed plasticity and lumped plasticity for 3D reinforced concrete frames. A five-story three-dimensional flexural frame was modeled in OpenSees. The lumped plasticity model employed the modified Ibarra–Krawinkler (ModIMK) formulation, with post-peak parameters estimated using Haselton's empirical relationships. Model performance was assessed through nonlinear static and time-history analyses. Both models predicted similar peak base shear and story drift demands. At the section level, however, the fiber model maintained its moment over a wider curvature range. When code-based damage limits were checked, a portion of the fiber locations exceeded the Controlled Damage and Collapse Prevention strain limits, whereas no hinge in the lumped plasticity model exceeded its rotation limits. Overall, the calibrated lumped plasticity model reproduced the base shear and story drift demands of the fiber model and may serve as a practical alternative, although the damage assessment depends on the modeling approach and the criteria used.

Keywords: Distributed Plasticity; Lumped Plasticity; Nonlinear Time-History Analysis; OpenSees; Reinforced Concrete Frames.

1 Introduction

Performance-based earthquake engineering requires numerical models that can capture the nonlinear and post-peak response of reinforced concrete (RC) members. Two widely used approaches are distributed plasticity and concentrated plasticity [1–3]. Distributed plasticity models discretize the cross-section into fibers representing confined concrete, unconfined concrete, and reinforcing steel, allowing inelasticity to spread along the member length according to the material response of the constituent fibers. Concentrated plasticity models instead lump the inelastic response into nonlinear rotational springs at the member ends, with the spring behavior defined by a calibrated moment-rotation backbone, such as the Ibarra-Medina-Krawinkler (IMK) deterioration model [3]. The backbone parameters are commonly estimated using the empirical relationships proposed by Haselton et al. [2], which were derived from a large database of column tests. Comparisons of concentrated and distributed plasticity models in terms of seismic fragility have also been reported [9]. This study compares fiber-based and lumped-plasticity models for the same five-story, 3D RC moment-resisting frame and evaluates their predicted performance according to TBEC 2018 [4].

2 Numerical Modeling

Both models were implemented in OpenSeesPy [5] for the same five-story, 3D RC moment-resisting frame. The frame has three 6.0 m bays in the X direction and three 5.0 m bays in the Y direction, with a uniform story height of 3.0 m. At each story, the frame consists of four interior columns (C1) and twelve exterior/corner columns (C2). The beams are classified into two section types based on story level: B1 for stories 1-4, and B2 for story 5. The concrete compressive strength (fc) is 39 MPa, and the longitudinal reinforcing steel yield strength (fy_L) is 504 MPa for all members.

2.1 Fiber Model

Columns and beams are modeled as force-based beam-column elements with Gauss–Radau plastic-hinge integration (*HingeRadau*), with the plastic hinge length taken as $Lp = 0.5h$ in accordance with TBEC 2018 Section 5.3.1.2, where h is the section depth in the direction of bending. Each cross-section is discretized into confined core fibers, unconfined cover fibers, and discrete longitudinal reinforcing bar fibers. Concrete is modeled with *Concrete02* [6], with the confined-concrete parameters including peak stress, strain, and ultimate strain, derived from the Mander confinement model [7]. Longitudinal reinforcing steel is modeled using *Steel02* (*Giuffre-Menegotto-Pinto*) [8] with strain-hardening ratio of 1%.

2.2 Lumped Plasticity Model

In the lumped-plasticity model, beam-column members are modeled using an elastic beam-column element with zero-length rotational springs at both ends. The springs use the *ModIMKPeakOriented* material, and the backbone parameters $\mathrm{K_e}, \mathrm{M_c}, \theta_\mathrm{P}, \theta_\mathrm{pc}, \mathrm{and}\, \lambda$ are calculated using the empirical equations of Haselton et al. [2]. The yield moment (M_y) is determined separately from the moment–curvature analysis of the corresponding fiber section using the yield criterion specified in Section 5.3.1.5(b) of TBEC 2018. This yield moment is used in both models, whereas the other backbone parameters for the lumped-plasticity model are determined using the Haselton et al. [2] relationships. As shown in Fig. 1a, a zero-length element is placed at each member end to represent the nonlinear rotational response, while the remaining degrees of freedom are constrained. These elements are connected to an elastic beam-column element with a modified-stiffness section. Fig. 1b shows the resulting idealized backbone for the first-story interior column (C1, (P=1941.5) kN), based on the trilinear moment–chord rotation relationship of Haselton et al. [2].

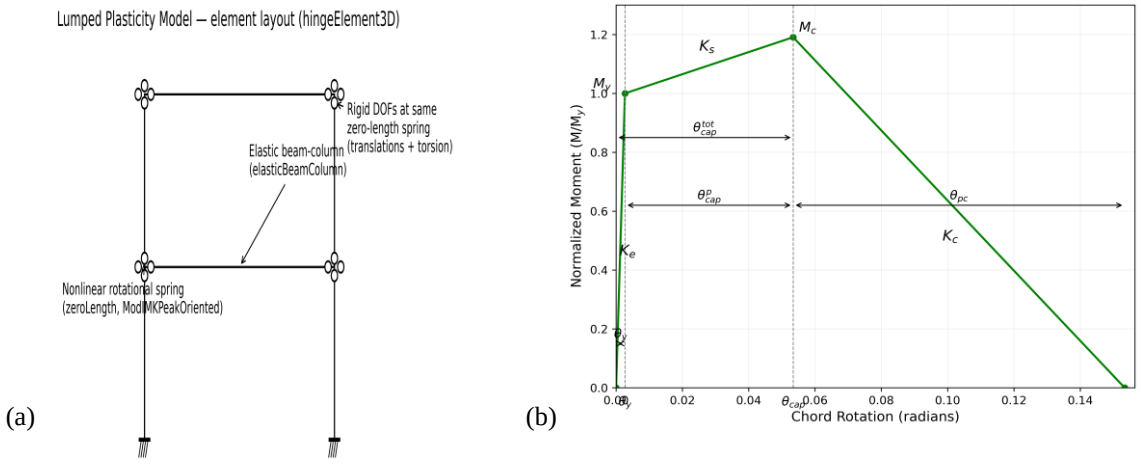

Fig. 1. Lumped plasticity model element layout (a) and idealized trilinear backbone for the first-story interior column (C1) (b).

2.3 Performance Levels

TBEC 2018 Section 5.8.1 defines strain limits for reinforced-concrete members of new buildings at three performance levels: Limited Damage (LD), Controlled Damage (CD) and Collapse Prevention (CP). For the fiber model, the limiting compressive strain for confined concrete at the CP level is calculated with TBEC 2018 Eq. (5.4a), which is given here as Eq. (1):

$$\varepsilon_c^{CP} = 0.0035 + 0.04\sqrt{\omega_{we}} \leq 0.018 \quad (1)$$

where ω_{we} is the effective confinement mechanical volumetric ratio. The corresponding tensile-strain limit for reinforcing steel $\varepsilon_s^{CP} = 0.4\,\varepsilon_{su}$ is taken from TBEC 2018 Eq. (5.5), where ε_{su} is the strain corresponding to the tensile strength of the reinforcing steel. At the CD level, limiting strains are taken as 75% of the CP limits (Eq. 5.7a). At the LD level, the limiting strains are $\varepsilon_c^{LD} = 0.0025$ and $\varepsilon_s^{LD} = 0.0075$, and no plastic-hinge rotation is permitted ($\theta_p^{(LD)} = 0$). For the lumped plasticity model, TBEC 2018 Section 5.8(b) specifies that the LD criterion for models using the effective-stiffness formulation of Section 5.4.5.2 is that no plastic hinge may form ($\theta_p = 0$); the CD and CP plastic-rotation capacities are obtained from an independent moment-curvature analysis pushed to the same strain limits, via TBEC Eq. 5.6, given here as Eq. (2):

$$\theta_{p(CP)} = \left(\frac{2}{3}\right)\left[(\varphi_u - \varphi_y)L_p\left(1 - \frac{0.5L_p}{L_s}\right) + 4.5\varphi_u d_b\right] \quad (2)$$

with $\theta_p^{CD} = 0.75 \times \theta_p^{CP}$ *(Eq. 5.7b).* The LD criterion differs fundamentally between the two models: for the fiber model it is a strain threshold reached during the actual pushover response, whereas for the lumped plasticity model it is, by definition, the onset of any inelastic rotation.

3 Case-Study Building

The case-study building is a five-story, symmetric 3D reinforced-concrete moment-resisting frame with three 6.0 m bays in the X direction and three 5.0 m bays in the Y direction, corresponding to overall plan dimensions of 18.0 m × 15.0 m. The story height and slab thickness are 3.0 m and 0.20 m, respectively. The dead and live loads are 7.26 and 2.00 kN/m², while the exterior and interior wall line loads are 10.50 and 6.25 kN/m, respectively. The mean concrete compressive strength is 39 MPa, with an elastic modulus of 34.3 GPa, whereas the reinforcing steel has a mean yield strength of 504 MPa, an elastic modulus of 200.1 GPa, and a strain-hardening ratio of 1%. The column and beam section properties and material definitions adopted in both models are summarized in Table 1.

Table 1. Column and beam cross-section properties (B = width, H = depth).

Section	B (mm)	H (mm)	Cover (mm)	Bottom bars	Top bars	Side bars	Stirrups
C1	700	700	50	4Ø25	4Ø25	2Ø25	5L10 @ 100
C2	600	600	50	5Ø20	5Ø20	3Ø20	4L10 @ 100
B1	400	500	50	2Ø25	4Ø25	–	2L10 @ 100
B2	400	500	50	2Ø25	3Ø25	–	2L10 @ 100

The confined concrete properties were calculated using the Mander model [7]. The values obtained for C1 were ($f_{cc} = 54.0$) MPa and ($\varepsilon_{ccu} = 0.0179$). For C2, the corresponding values were 53.8 MPa and 0.0175. For B1, ($f_{cc} = 46.1$)MPa and ($\varepsilon_{ccu} = 0.0170$), while for B2 they were 45.9 MPa and 0.0171.

Before applying the lateral loads, the gravity-load results of the two models were compared. The total vertical reaction at the base was calculated for the ($G + 0.3Q$) load combination. The reaction was 20864.26 kN in both models. Therefore, the gravity loads and mass assignment resulted in the same total vertical response in the two models. The first three modes were calculated for the SAP2000 model and the three OpenSees models. The periods and mode

directions are given in Table 2. The mode direction was determined from the eigenvector components in X, Y, and RZ. The results are close for the four models. In all models, the first mode is in the X direction, the second mode is in the Y direction, and the third mode is mainly torsional. The mode shapes are shown in Fig. 2.

Table 2. Modal periods

Mode	Lumped Plasticity	Fiber (HingeRadau)	Elastic (OpenSees)	SAP2000 (Elastic)

4 Analysis and Results

4.1 Static Pushover Analysis

A displacement-controlled pushover analysis was performed in both the X and Y directions using the first-mode eigenvector and story masses to define the lateral load pattern. The resulting capacity curves are shown in Fig. 3, with the LD, CD, and CP performance points defined by TBEC 2018. The corresponding values are summarized in Table 3.

In the X direction, the two models give similar peak base shear values. The fiber model reaches 4979.3 kN, while the lumped-plasticity model reaches 4742.5 kN, giving a difference

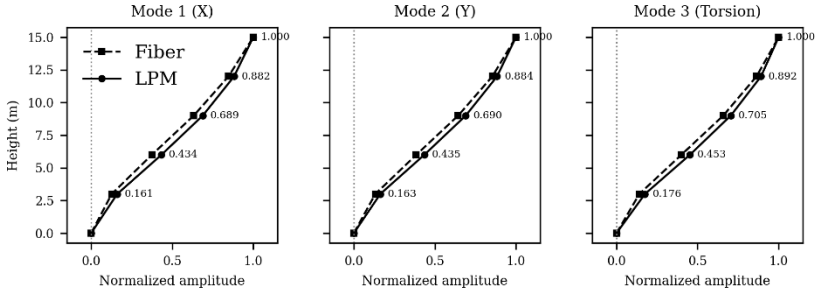

Fig. 2. First three mode shapes (X, Y, torsional) for the fiber and lumped plasticity models.

of about 5%. This relatively close agreement is expected because the same yield moment M_y, obtained from the fiber-section analysis, is used in both models. The curves, however, differ after yielding because K_e, M_c, θ_P, and θ_{PC} in the lumped-plasticity model are obtained from the Haselton et al. [2] equations rather than directly from the fiber response.

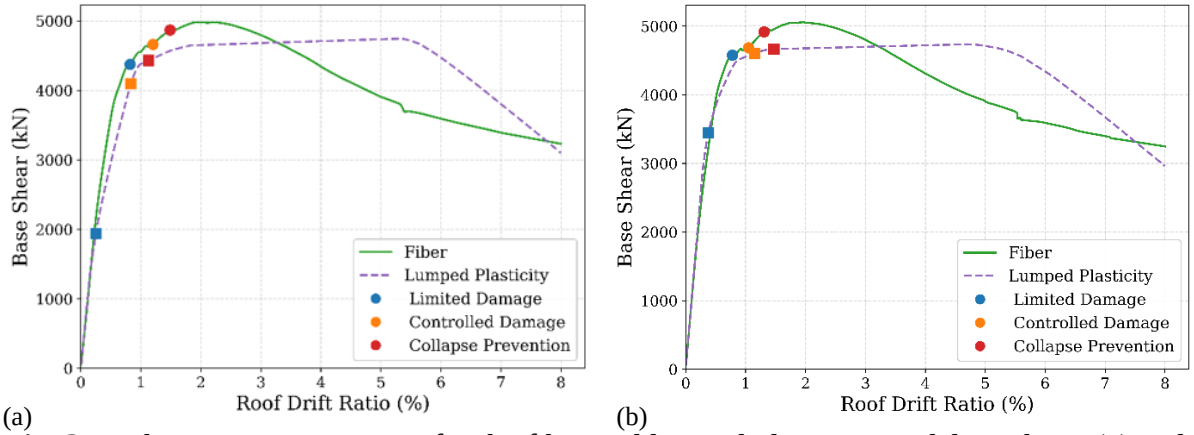

Fig. 3. Pushover capacity curves for the fiber and lumped plasticity models in the X (a) and Y (b) direction, with TBEC 2018 LD/CD/CP performance points.

Table 3. TBEC 2018 performance points and peak base shear (V_{max}) for both models, X and Y directions.

Direction	Level	Fiber model			Lumped plasticity model		
		Δ_{roof} (cm)	Drift (%)	V (kN)	Δ_{roof} (cm)	Drift (%)	V (kN)
X	LD	12.3	0.82	4372.1	3.8	0.25	1942.9
	CD	18	1.2	4659.6	12.5	0.83	4023.2
	CP	22.3	1.49	4866.6	16.9	1.13	4420.3
	Vmax	29	1.93	4979.3	79.9	5.33	4742.5
Y	LD	11.7	0.78	4576.6	5.7	0.38	3447.7
	CD	15.7	1.05	4684	17.2	1.15	4603.5
	CP	19.6	1.31	4916.9	22.1	1.47	4665.1
	Vmax	29.4	1.96	5056.6	70.4	4.69	4735.6

4.2 Moment-Curvature Comparison

Moment–curvature analyses were also carried out for two first-story columns to compare the post-yield response of the two models. The first was the interior column C1, subjected to an axial load of P=1941.5 kN. The second was the exterior column C2, subjected to an axial load of P=1277.9 kN, representing the maximum axial load among the first-story C2 columns. The lumped-plasticity response was obtained from the *ModIMKPeakOriented* backbone, while the fiber-section analysis was continued to large curvature. The results are shown in Fig. 4. The difference between the two models becomes more noticeable after the capping point. The capping curvatures of the lumped-plasticity model are 0.153 1/m for C1 and 0.145 1/m for C2. After capping, the fiber model keeps almost the same moment over a larger curvature range, whereas the lumped-plasticity model decreases according to the Haselton post-capping branch. The plastic rotation capacities are also different. The values from TBEC Eq. (5.6) are 0.00815 rad for C1 and 0.00994 rad for C2, while the Haselton backbone gives 0.0507 rad and 0.0467 rad, respectively. At large curvature, a small decrease in moment is observed in the fiber model when the confined-concrete strain reaches ε_{ccu}, at 0.139 1/m for C1 and 0.160 1/m for C2.

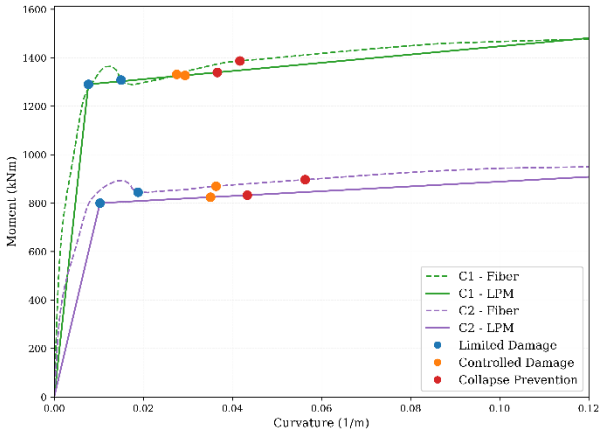

Fig. 4. Moment-curvature response of the first-story interior (C1) and exterior (C2) columns.

4.3 Dynamic Analysis and Fragility Curves

Nonlinear time-history analyses (NTHA) were carried out using ground-motion records from the PEER NGA-West2 database. Twenty-two records were initially considered from the FEMA P695 [10] far-field set, and 21 records were finally used after applying the scaling and convergence criteria. The records were scaled to the DD-2 target spectrum based on the AFAD seismic hazard map of Türkiye. The response spectra and selected records are given in Table

A1 and Fig. A2 in the Appendix. Both horizontal components of each record were applied to the fiber and lumped-plasticity models. For each analysis, the maximum interstory drift ratio, (D), was obtained and related to the spectral acceleration at the fundamental period, S_{aT_1}. A log-linear regression was used for the 21 records [11]:

$$\ln(D) = a + b \ln[Sa(T1)] \quad (3)$$

The dispersion, σ, was calculated as the standard deviation of the regression residuals. The resulting PSDMs for the two models are shown in Fig. 5. For the fiber model, the fitted PSDM is given by:

$$ln(D) = -4.458 + 0.565\, ln[Sa(T1 = 0.588\, s)]$$

with $\beta D = 0.327$. For the lumped plasticity model, the corresponding relationship is

$$\ln(D) = -4.406 + 0.664 \ln[Sa(T1 = 0.705\, s)]$$

with $\beta D = 0.215$.

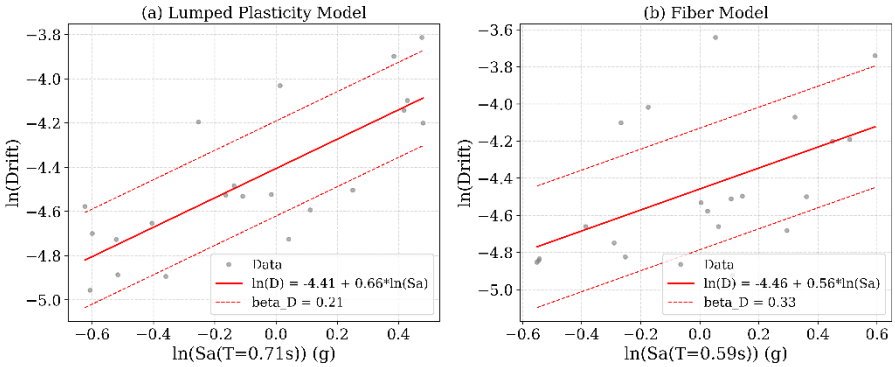

Fig. 5. Probabilistic seismic demand models (PSDM) for the lumped plasticity model (a) and fiber model (b).

Fig. 6a compares the peak drift demands from the 21 ground motions. The logarithmic residuals between the LPM and fiber results remain close to zero, with no clear trend as (Sa) increases.

The residual regression is given by $\ln(Residual) = -0.002 + 0.019\, ln(Sa)$, with $\sigma = 0.112$. The residuals are close to zero, with a small slope and low dispersion, and the two models give similar drift demands for the individual records. The fragility curves for the LD, CD and CP levels (Fig. 6b) were obtained from the fitted PSDMs using the corresponding drift capacities given in Table 3. The median $Sa_{(T1)}$ was obtained by inverting the PSDM at each drift capacity, and the dispersion was taken as β_D. The resulting median Sa values and dispersions are reported in Table 4. The LPM-LD median is not tabulated because it falls below the range of spectral accelerations covered by the selected ground motions, so the plotted LPM-LD curve is an extrapolation of the PSDM. The fragility curves differ even though the drift demands are similar, partly because the performance limits used for the two models are different.

Table 4. Median Sa(T1) (g) and logarithmic dispersion of the fragility curves.

Level	**Lumped plasticity model (LPM)**		**Fiber model**	
	Median Sa (g)	Dispersion	Median Sa (g)	Dispersion
LD	-	0.215	0.543	0.327
CD	0.563	0.215	1.065	0.327
CP	0.888	0.215	1.557	0.327

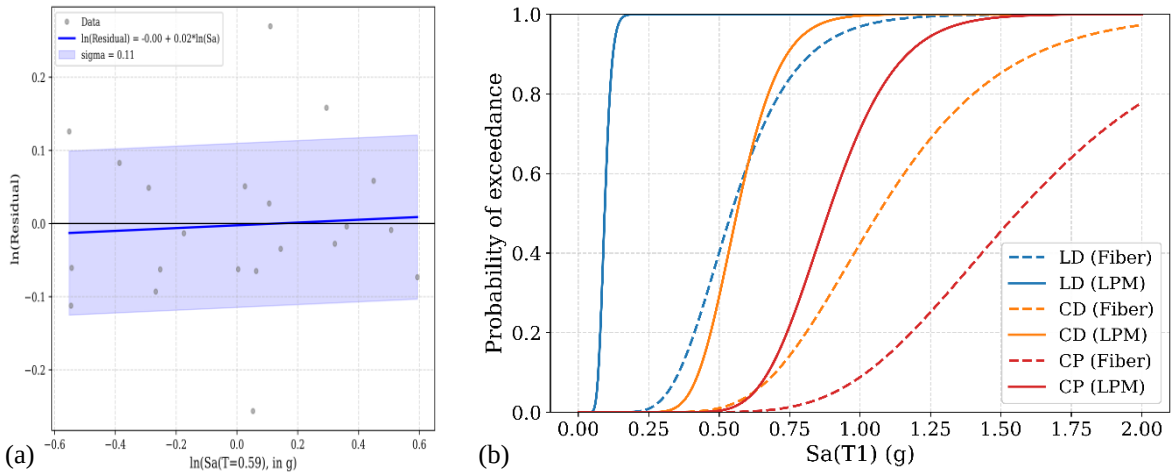

Fig. 6. Comparison of the LPM and fiber models: logarithmic residuals of peak drift demands for the 21 ground motions (a) and fragility curves for the LD, CD and CP performance levels (b).

The median spectral accelerations at the CD and CP levels are lower for the lumped plasticity model than for the fiber model. At the CD level, the median $Sa_{(T1)}$ is 0.563 g for the LPM and 1.065 g for the fiber model. At the CP level, the corresponding values are 0.888 g and 1.557 g. The dispersion is also lower for the LPM (βD = 0.215) than for the fiber model (βD = 0.327). The LD level is considered separately because the two models use different criteria. The effective story drift was checked according to TBEC 2018 Eq. (4.34a), given here as Eq. (4). For the building without a flexible joint between the infill walls and the frame, the limiting value is 0.008. The λ factor is the ratio of the DD-3 to DD-2 spectral ordinates. Since the periods of both models fall within the constant-velocity range for the two hazard levels, the same value, λ = 0.445, is used for both models, and the condition becomes:

$$\lambda \frac{\delta_{i,\max}^{(X)}}{h_i} \leq 0.008\kappa \qquad (4)$$

The maximum mean story drift ratios from the 21 ground motions were used to calculate the effective drift ratios in the X and Y directions. Both models satisfy the 0.008 limit in the X and Y directions after applying the DD-3/DD-2 factor. The values are given in Table 5. The effective drift ratios range from 0.421% to 0.505%, which are below the 0.8% limit. The mean story-drift profiles of the two models are similar in both directions. The maximum drift occurs at the second or third story rather than at the roof. The drift profiles for the 21 ground motions and their mean values are shown in Fig. 7.

The individual ground motions show some variation in the story-drift profiles, with a few records exceeding 2%; however, the mean profiles are similar for both models in each direction. According to TBEC 2018 Section 5.7.4, the mean maximum demands were compared with the corresponding performance-level capacities. For the fiber model, demands at 2696 beam and

Table 5. Maximum and effective interstory drift ratios in the X and Y directions

Model / Direction	Maximum drift (%)	Effective drift, κλΔ/h (%)	Limit
Fiber, X	0.971	0.432	PASS
LPM, X	0.947	0.421	PASS
Fiber, Y	1.135	0.505	PASS
LPM, Y	1.122	0.499	PASS

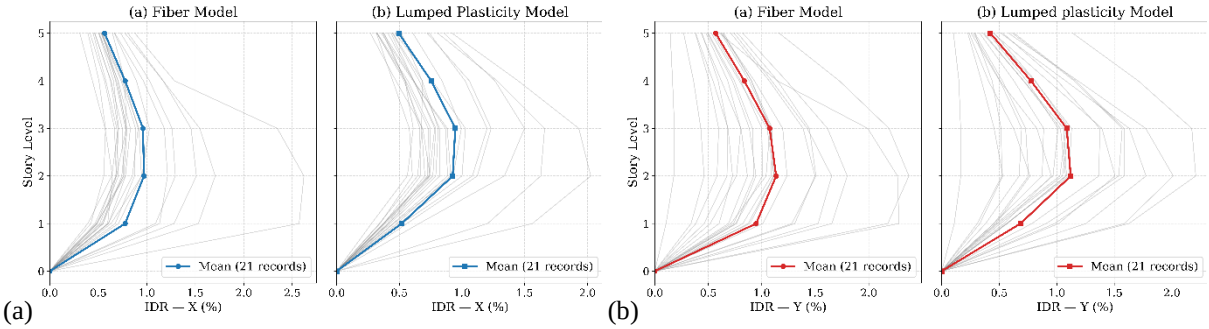

Fig. 7. Story-drift profiles for all 21 records and their mean: fiber model (a) and lumped plasticity model (b); X-direction (left) and Y-direction (right).

column fiber locations were evaluated against the strain limits in TBEC 2018 Eqs. (5.4a)-(5.5) with 692 (25.7%), 314 (11.6%), and 221 (8.2%) exceeding the LD, CD, and CP limits, respectively. For the lumped-plasticity model, 166 of 560 hinge DOFs (29.6%) exceeded the LD limit, while no CD or CP exceedances were observed.

The two models show similar LD exceedance rates (25.7% for the fiber and 29.6% for the LPM). CD and CP exceedances occur only in the fiber model (11.6% and 8.2%), while the LPM remains within these limits, with maximum demand-to-capacity ratios of 0.52 and 0.39, respectively. This difference partly reflects the use of fiber strains in the fiber model and hinge rotations in the LPM (Fig. 8).

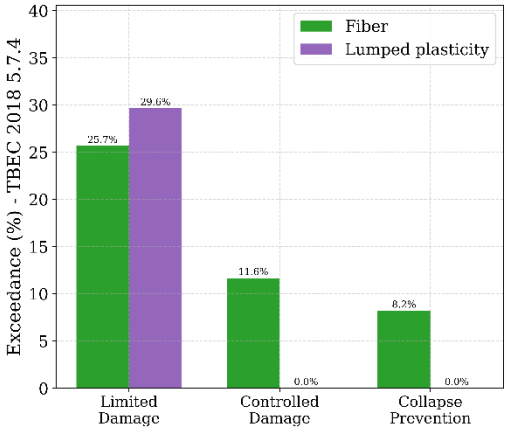

Fig. 8. Mean-demand exceedance rates for the fiber and lumped-plasticity models.

5 Conclusions

The static pushover results show that the fiber and lumped-plasticity models provide similar overall responses. The peak base shear differs by about 5%, while the capacity curves follow similar trends. The difference in the first-mode period is mainly attributed to the effective secant stiffness used in the lumped-plasticity model. The most noticeable difference is at the LD level, where the two models are evaluated using different acceptance criteria. The nonlinear time-history analyses of 21 ground motions yield similar findings. The residual sigma is 0.112, with no clear trend in the residuals as the intensity increases. Both models satisfy the story-drift requirements and show similar LD exceedance rates. CD and CP exceedances occur only in the fiber model, which also has higher fragility medians. Because the two models use different damage criteria (strain limits in the fiber model, rotation limits in the lumped model), these differences partly reflect the criteria and not only the modeling approach. For this frame, the calibrated lumped-plasticity model reproduces the base shear and drift demands of the fiber

model, whereas the damage assessment depends on the modeling approach and the criteria used. The fiber model, in turn, provides a more direct representation of local nonlinear behavior.

Parametric Analysis of Load-Carrying Capacity and Reinforcement Optimization in Slab-on-Grade Foundations

Mehmet Sefa Orak
0000-0002-5783-479X, Department of Civil Engineering, Maltepe University, Istanbul, Türkiye, sefaorak@maltepe.edu.tr

Abstract. In an industrial setting, a concrete slab-on-grade (SOG) is an essential structural element for handling the uniform, linear, and point live loads one might expect. The bearing capacity of this type of foundation is not a simple matter; it is a function of several interacting variables, from the subgrade reaction modulus to where the load is applied, as well as the flexural strength of the concrete and its reinforcement. With that in mind, this study assessed how these slabs perform under a range of design conditions in terms of thickness, behavior, and load-bearing ability. A group of unreinforced concrete, rebar mesh, and steel fiber-reinforced concrete (SFRC) were tested, pitting analytical Westergaard closed-form solutions against shell finite element models in SAP2000. The results show just how much of an impact a stiff subgrade can have. Take a 100 kPa storage load, for example: moving from a soft clay subgrade (7 MN/m³ modulus of elasticity) to crushed rock (45 MN/m³) allows for a 44.4 percent drop in slab thickness, from 360 mm down to 200 mm. A step up in concrete grade from C25/30 to C40/50 will see another 20.0 to 21.4 percent reduction. Then the question is where the load is placed. Interior loading is of little concern when compared with the stress concentrations at the edges and corners of the structure, which carry a 35 and 72.2 percent penalty, respectively. To help determine the impact of soil improvement, reinforcement, and slab size, an iso-thickness response map is presented to define the relevant decision boundaries.

Keywords: Slab-on-Grade, Load-Carrying Capacity, Subgrade Reaction Modulus, SAP2000 Shell FEA, Reinforcement Optimization.

1 Introduction

The concrete ground slab, or Slab-on-Grade (SOG), is still the structural foundation of choice in modern construction. One finds this to be the case in all manner of present-day operations, from manufacturing and logistics to port terminals. It is not to be confused with a suspended slab on beams and columns; the SOG is something quite different in nature. As a ground-supported element, it has an ongoing and selective relationship with the soil continuum, which is never still. What determines its load-bearing capacity and overall performance is the way the subgrade support stiffness, the demands placed upon the facility, and the flexural rigidity of the concrete itself come into play [1, 2].

In practice, the subgrade support is typically defined by Winkler's linear spring model, with the subgrade reaction modulus k (in MN/m3 or kN/m3) as the descriptor. This is the linear assumption put forward in most concrete design standards such as TR34 [2], ACI 360R-10 [3] and EN 1992-1-1 [4]. Yet at the outset of a design, proper subgrade site preparation often gets short shrift. A failure to account for the true stiffness of the subgrade will result in an unnecessarily thick slab being specified, with all the attendant costs in materials, embodied carbon and construction that entails.

The classical analytical solutions for ground slabs are due to the pioneering efforts of Westergaard [1], who put together closed-form formulations for loading at the interior, edge and corner from Kirchhoff thin-plate theory on a Winkler foundation. For a preliminary figure, these equations are handy, but they make some heavy idealizations, not least of which are infinite slab dimensions and uncracked elastic behavior with no shear deformation. Where greater accuracy is needed to deal with finite geometries, non-uniform subgrade, or the pressure patch of a forklift wheel, advanced numerical modeling is called for. Advanced numerical modeling using Mindlin-Reissner thick-shell theory [5] in SAP2000 [6] is called for. Finite element re-evaluations of Westergaard formulations were provided by Ioannides et al. [7], and airport pavement wheel load extensions were detailed by Guo and Marsey [8].

There is much to be said for the use of Steel Fiber Reinforced Concrete (SFRC) in industrial floor construction as a workable substitute for conventional steel mesh. By introducing discrete fibers, one can improve joint stability and energy absorption without sacrificing the residual flexural strength ($f_{R,1k}$, $f_{R,3k}$) that remains after cracking. These gains have been shown to allow for a thinner slab [9, 10], a point the fib Model Code [11] backs up. One would think the literature would have more to offer on the subject, with parametric studies tying SFRC performance and subgrade reaction modulus to the concrete grade and load position under a range of industrial scenarios; but for the time being, those are not to be found.

With that in mind, this work has three objectives. It sets out to assess the sensitivity of the load capacity and necessary slab thickness (h) to the subgrade reaction modulus and the strength of the concrete. It also aims to quantify the stress-concentration penalties for loads placed at the corner, edge, or interior. Finally, it puts Westergaard's closed-form predictions to the test against 3D Mindlin-Reissner shell FEA in SAP2000 [6]. The intent is to produce an iso-thickness design response map with decision boundaries useful to the practicing engineer.

2 Methodology

2.1 Analytical Formulation (Westergaard Plate Theory)

The design of a slab-on-grade foundation has its theoretical basis in Westergaard's differential equation. This equation is used to represent an elastic plate on an isotropic Winkler subgrade [1]. In this context, the radius of relative stiffness, l (mm), is the variable that exerts the most control. It is what defines the elastic flexural radius of influence:

$$l = \sqrt[4]{\frac{E \cdot h^3}{12 \cdot (1-\nu^2) \cdot k}} \tag{1}$$

where E is the concrete elastic modulus (MPa), h is the slab thickness (mm), ν is Poisson's ratio ($\nu = 0.20$ for concrete), and k is the subgrade reaction modulus (N/mm^3). Under an interior uniformly distributed storage load q (kPa) over a footprint radius a, the maximum flexural bending moment M_{int} (kN·m/m) and corresponding tensile stress σ_{int} (MPa) are given by:

$$M_{\text{int}} = 0.169 \cdot q \cdot l^2, \sigma_{\text{int}} = \frac{6 \cdot M_{\text{int}}}{h^2} \tag{2}$$

For concentrated point or wheel axle loads P (kN) acting over an equivalent circular contact area of radius b, the interior (σ_{int}), free edge (σ_{edge}), and free corner (σ_{corner}) tensile stresses are expressed as:

$$\sigma_{\text{int}} = \frac{3 \cdot P \cdot (1+\nu)}{2 \cdot \pi \cdot h^2} \cdot \left[\ln\left(\frac{l}{b}\right) + 0.615\right] \tag{3}$$

$$\sigma_{\text{edge}} = \frac{0.572 \cdot P}{h^2} \cdot \left[3 \cdot (1+\nu) \cdot \log_{10}\left(\frac{l}{b}\right) + 0.359\right] \tag{4}$$

$$\sigma_{\text{corner}} = \frac{3 \cdot P}{h^2} \cdot \left[1 - \left(\frac{b \cdot \sqrt{2}}{l}\right)^{0.6}\right] \tag{5}$$

Design compliance requires that the maximum tensile stress σ_{max} does not exceed the design flexural tensile strength of concrete $f_{ctd,fl}$, incorporating Eurocode 2 (EN 1992-1-1 Eq. 3.23) size-effect factor [4]:

$$f_{ctd,fl} = \frac{f_{ctk,0.05}}{\gamma_c} \cdot \left[1 + \sqrt{\frac{200}{h}}\right] \leq 2.0 \cdot f_{ctd} \tag{6}$$

The structural safety factor (SF) is evaluated as:

$$SF = \frac{f_{ctd,fl}}{\sigma_{max}} \geq 1.0 \tag{7}$$

2.2 Finite Element Model (SAP2000)

The analytical formulations for the test under complex load footprints were developed by means of 3D numerical models in SAP2000 [6]. These were built on 4-node Mindlin-Reissner shell elements of the Shell-Thick type [5]; the theory's ability to handle transverse shear deformation makes it well suited for the precision required with thick ground slabs having a small span-to-thickness ratio [5].

To characterize the subgrade interaction, a two-dimensional area spring mesh with linear Winkler stiffness (k_z = k) is used for each unit of area. The springs were assigned non-linear behavior so as to admit compression but rule out any false tensile reaction from the ground. As for the 12 m by 12 m slab, it was modeled in 0.25 m square shell elements; this degree of refinement was found to be sufficient after convergence tests indicated stress variations of under 0.5%.

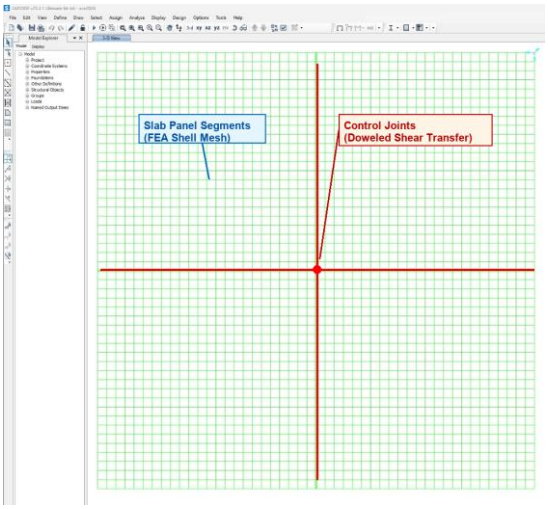

Fig. 1. SAP2000 shell finite element model setup showing slab meshing, area springs, and load application grid.

2.3 Parametric Matrix Description

A comprehensive matrix demonstrating several unique evaluation cases was constructed across five major parameters, as summarized in Table 1.

Table 1. Summary of parametric analysis variables.

Parameter	Investigated Range / Classes	Design Purpose
Subgrade Reaction Modulus k	7, 15, 20, 30, 45 MN/m^3	Evaluate soil stiffness impact
Concrete Strength Class	C25/30, C30/37, C35/45, C40/50	Quantify concrete material effect
Storage Uniform Load q	12, 25, 50, 75, 100, 125, 150, 175, 200 kPa	Industrial storage load range
Forklift Axle Load P	4t (20kN), 8t (40kN), 12t (60kN), 16t (90kN)	Concentrated wheel pressure
Load Position	Interior, Free Edge, Free Corner	Stress concentration penalty

3 Results and Discussion

3.1 Benchmarking Westergaard Analytical vs. SAP2000 FEA Models

Table 2 and Fig. 2 offer a side-by-side view of the maximum flexural tensile stresses, with the Westergaard closed-form analytical figures set against what the SAP2000 3D shell finite element models have to show. The case in point is a C35/45 concrete slab of 350 mm thickness under a uniform q = 100 kPa load, where one will note the subgrade stiffness is not uniform.

Table 2. Westergaard analytical versus SAP2000 FEA flexural tensile stress comparison (C35/45, h = 350 mm, q = 100 kPa).

k (MN/m³)	Soil Type	l (mm)	Westergaard σ (MPa)	SAP2000 FEA σ (MPa)	Divergence (%)
7	Soft Clay	2022	2.41	2.49	+3.3%
15	Medium Clay	1672	1.94	2.00	+3.1%
20	Stiff Clay	1556	1.78	1.83	+2.8%
30	Dense Sand	1406	1.66	1.70	+2.4%
45	Crushed Rock	1270	1.58	1.63	+3.2%

Table 3 compares flexural tensile capacity formulations, size-effect provisions, design strengths, and structural safety implications between ACI 360R-10 and Eurocode 2 (EN 1992-1-1) for C30/37 concrete.

Table 3. Flexural tensile capacity: ACI 360R-10 vs. Eurocode 2 (C30/37 concrete).

Criterion	ACI 360R-10	Eurocode 2 (EN 1992-1-1)	Design Impact
Governing Formula	$f_r = 0.373 \cdot \sqrt{f_c'}$ [MPa]	$f_{ctm} = 0.30 \cdot f_{ck}^{(2/3)}$; $f_{ctd,fl} = (1.6 - h/1000) \cdot f_{ctm} / \gamma_M$	EC2 includes depth size effect
Design Strength	2.05 MPa	2.41 MPa ($\gamma_M = 1.5$)	EC2 ~17% higher for C30/37
Unfactored Strength	2.05 MPa	3.62 MPa (h = 350 mm, factor = 1.25)	EC2 size factor benefits thinner slabs
Size Effect	Neglected	$(1.6 - h/1000) >= 1.0$	Thinner slabs stronger per EC2
Conservatism	Higher (10–15% more concrete)	Realistic (scale-adjusted)	ACI yields thicker sections

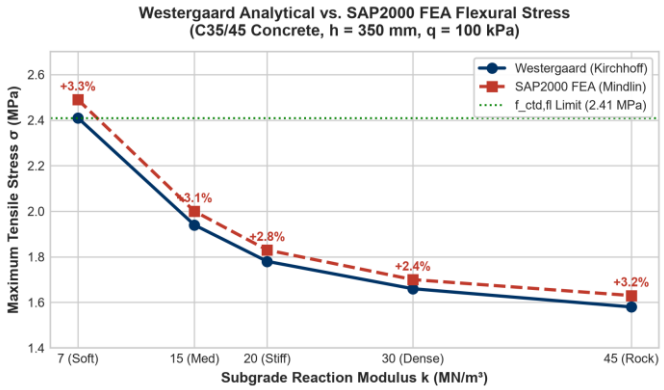

Fig. 2. Comparison of Westergaard analytical model predictions versus SAP2000 FEA flexural stresses across subgrade stiffnesses (C35/45, h = 350 mm, q = 100 kPa).

The FEA results agree well with Westergaard analytical predictions, with maximum divergence ranging from +2.4% to +3.3%. The slightly higher stresses in FEA stem from

transverse shear deformation captured by Mindlin shell theory, which classical Kirchhoff thin-plate formulations neglect.

3.2 Subgrade Stiffness Impact on Required Slab Thickness

As can be seen in Fig. 3, the subgrade reaction modulus k and the slab thickness h are linked for C35/45 concrete when subjected to a q = 100 kPa load. With a soft subgrade of k = 7 MN/m3, one would need a 360 mm thickness. But if the subgrade is made stiffer at k = 15 MN/m3, that requirement comes down to 290 mm, a 19.4% reduction. A more substantial gain is possible with a crushed aggregate subbase (k = 45 MN/m3), where the necessary thickness is only 200 mm, for an overall saving of 44.4%.

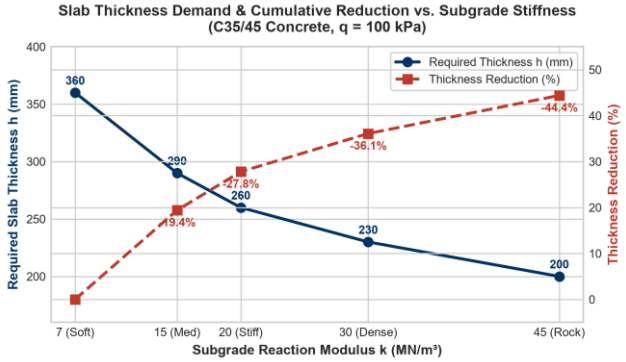

Fig. 3. Slab thickness demand h (mm) and cumulative percentage reduction vs. subgrade reaction modulus k (MN/m^3) for C35/45 concrete under q = 100 kPa uniform load.

3.3 Stress Concentration Penalties and Load Positioning Sensitivity

Fig. 4 presents required slab thickness curves for interior, free-edge, and free-corner load positions under q = 100 kPa. Free-edge loading imposes a 35.0% thickness penalty (h increases from 360 mm to 490 mm for k = 7 MN/m3), while free-corner loading imposes a 72.2% thickness penalty (h increases to 620 mm).

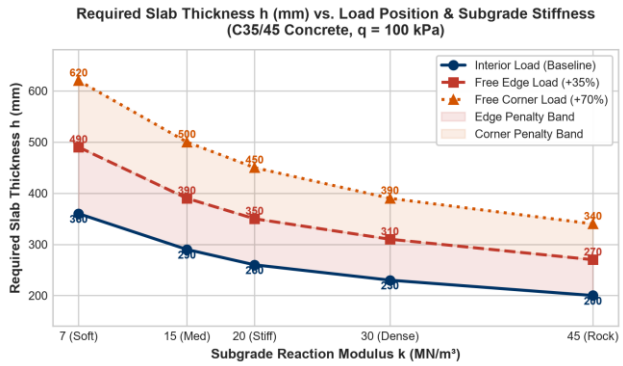

Fig. 4. Multi-series thickness response curves h (mm) vs. subgrade reaction k for three loading positions (interior/free edge / free corner) with shaded penalty bands (C35/45, q = 100 kPa).

3.4 Concrete Strength Class Sensitivity

A comparison of the slab thicknesses called for in four concrete strength grades, C25/30 through C40/50, is provided in Fig. 5. On a soft subgrade (k = 7 MN/m3), moving to a higher grade of concrete in the range of C40/50 as opposed to C25/30 will see the necessary thickness drop by 21.4 per cent, from 420 mm down to 330 mm. The figures are similar for a stiff subgrade (k = 20 MN/m3), where an upgrade in strength yields a 20.0 percent reduction in thickness, going from 300 mm to 240 mm.

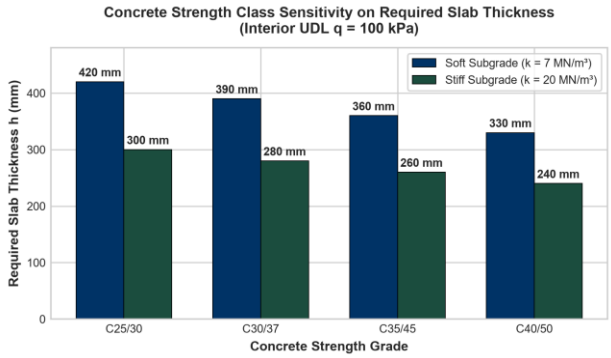

Fig. 5. Concrete strength class sensitivity on required slab thickness h (mm) for soft (k = 7 MN/m^3) and stiff (k = 20 MN/m^3) subgrades under q = 100 kPa storage load.

3.5 Iso-Thickness Design Response Map & Decision Boundaries

To synthesize the 540 parametric scenarios into a practical engineering tool, Fig. 6 presents an Iso-Thickness Design Response Map mapping required slab thickness h as a function of subgrade reaction modulus k and storage load q for C35/45 concrete.

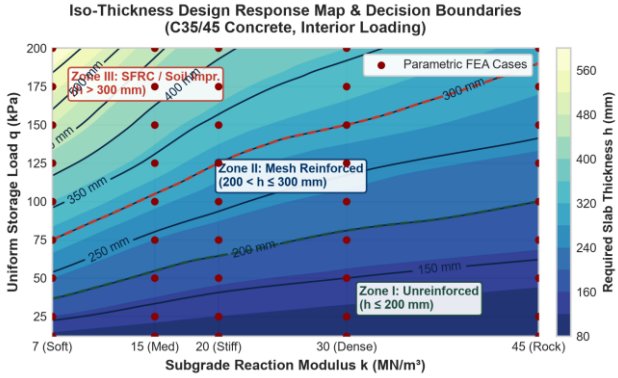

Fig. 6. Iso-thickness design response map h (mm) vs. subgrade reaction k (MN/m^3) and uniform load q (kPa) (C35/45, interior loading) with annotated structural decision boundaries (Zones I, II, and III).

The response map delineates three separate structural decision zones.

Zone I (h ≤ 200 mm) is for unreinforced or lightly meshed concrete slabs of the kind one would find in commercial or light industrial settings; here k is at least 30 MN/m3 and q does not exceed 75 kPa.

Where h is between 200 and 300 mm, Zone II calls for double rebar mesh reinforcement, a specification well suited to heavy manufacturing floors and standard logistics warehouses.

Finally, for any slab over 300 mm in thickness, Zone III employs Steel Fiber Reinforced Concrete (SFRC, 30-45 kg/m3) along with subgrade soil stabilization so as to keep the slab thickness from becoming uneconomical.

3.6 Heavy Forklift Loading and SAP2000 FEA Stress Contours

Fig. 7 and Fig. 8 illustrate the SAP2000 3D FEA load application and resulting principal flexural tensile stress contours (S_{11}) under a 16-ton heavy forklift axle load (90 kN per dual-wheel patch, 360 kPa pressure).

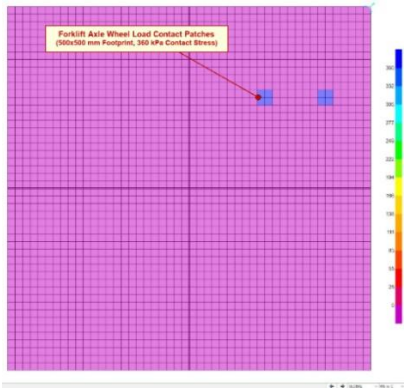

Fig. 7. SAP2000 FEA load setup interface showing localized patch pressure distribution for 16-ton heavy forklift axle loading.

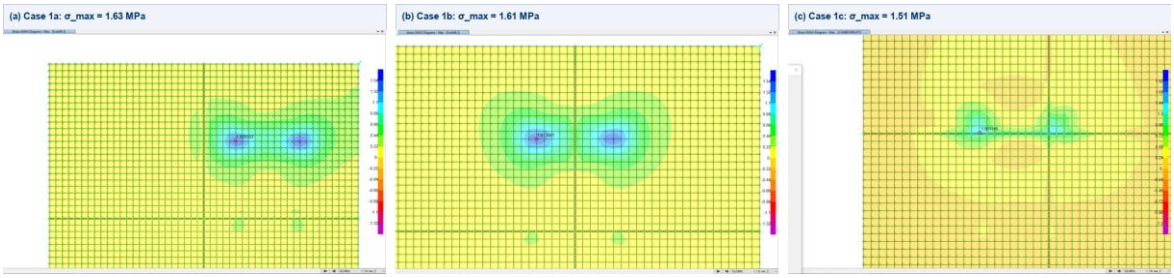

Fig. 8. SAP2000 FEA flexural tensile stress contour output S_{max} (MPa) displaying peak stress concentrations under forklift dual-wheel loading.

For C30/37 concrete, maximum tensile stress reaches 1.63 MPa (close to $f_{ctd,fl}$ = 2.05 MPa limit). Upgrading to C40/50 concrete reduces peak tensile stress to 1.45 MPa, providing a robust safety margin against fatigue cracking.

4 Conclusions

In this research, a thorough parametric optimization was carried out on industrial concrete slab-on-grade foundations for a range of design configurations. To put Westergaard's analytical equations to the test, they were benchmarked with 3D Mindlin shell finite element work in SAP2000; the results left no room for doubt as to their validity. The closed-form solutions from Westergaard are in close accord with the three-dimensional analysis, showing a stress deviation of no more than +2.4 to +3.3 percent at most.

What the study brings to light is that one cannot optimize slab thickness without considering how well the subgrade soil has been prepared. Take the subgrade reaction modulus as an example: moving it up from 7 to 45 MN/m³ will see the necessary slab thickness drop by as much as 44.4 percent, from 360 mm down to 200 mm. Then there is the matter of load placement and its effect on stress concentration. Free-edge or free-corner loading demands a 35.0 and 72.2 percent increase in thickness over what is needed for interior loading, making the use of edge dowel bars and thickened edge beams compulsory. Even with the subgrade held constant, a step up in concrete strength to C40/50 from C25/30 will cut the required thickness by between 20.0 and 21.4 percent.

For the structural engineer in the conceptual phase of a foundation design, an Iso-Thickness Design Response Map is a handy visual aid. It is intended to allow for the quick determination of the right concrete grade and slab thickness, as well as the best approach to reinforcement and overall optimization.

Abstract. In this study, the free vibration behavior of homogeneous porous beams with edge cracks is investigated using the finite element method (FEM) based on the higher-order shear deformation theory (HSDT). Beams with rectangular cross-sections are considered, and the material properties are assumed to be homogeneous and isotropic. Three different porosity distribution patterns are considered across the beam cross-section, and their influence on the dynamic response is examined comparatively. The crack is modeled as a geometric open crack located on the upper surface of the beam, where material is removed over a finite element width. It is assumed that the crack affects only the stiffness matrix of the finite element model, while the mass matrix remains unchanged. Analyses are performed under three different boundary conditions, simply supported (S-S), clamped-clamped (C-C), and clamped-free (C-F). The effects of porosity ratio, crack depth ratio, and crack location on the natural frequencies of the beam are examined through parametric studies. When crack depth, porosity ratio, different boundary conditions, and crack positions are examined, they are found to affect the natural frequency. The numerical results are validated against the literature, and different parametric results are presented.

Keywords: Free vibration, porosity, finite element method, higher-order shear deformation theory, boundary conditions.

1 Introduction

Functionally graded materials (FGMs) offer exceptional durability, thermal resistance, and structural efficiency by blending distinct constituents, such as metals and ceramics, across a continuous gradient. This smooth transition reduces internal stress concentrations. Incorporating internal void networks and porous structures into these materials reduces weight while introducing valuable energy-absorption, acoustic, and thermal performance capabilities. However, internal pores simultaneously alter both mass and stiffness, meaning that the dynamic response depends heavily on both total porosity and its cross-sectional distribution.

Cracks, which represent a critical factor governing the dynamic behavior of beams, predominantly originate from fatigue degradation, manufacturing defects, or excessive mechanical loading. Even stable cracks induce localized stiffness degradation, consequently perturbing the fundamental natural frequencies and mode shapes. In this regard, the quantitative evaluation of these modal shifts constitutes a fundamental prerequisite for robust vibration-based damage identification and structural health monitoring (SHM) frameworks.

The free vibration analysis of porous and functionally graded beams has been extensively investigated over the years [1-4]. Early analytical studies established a foundational framework for graded beam dynamics [5], while subsequent finite element methods accelerated this progress by expanding into sandwich and multi-layered configurations [6,7]. These studies confirm that the porosity ratio and its distribution govern the balance between mass and stiffness; however, they frequently couple porosity with material gradation [4], making their

individual effects difficult to isolate. In this study, a homogeneous isotropic base material is employed, and solely the porosity distribution and crack parameters are varied.

The modeling of cracked beams commonly relies on local flexibility matrices, rotational spring analogies, or direct cross-sectional reductions, where the resulting frequency shifts are governed by the crack depth and its relative position with respect to the mode shapes [8,9]. Furthermore, higher-order shear deformation theories eliminate the need for a shear correction factor, thereby yielding superior accuracy, particularly in the dynamic analysis of deep (short) beams [10].

Comprehensive studies simultaneously addressing cracking and porosity remain limited, particularly across extensive combinations of crack depths, locations, porosity patterns, and boundary conditions [11,12]. This conference paper utilizes a three-node, 12-degree-of-freedom higher-order finite element model to address this gap. Three distinct porosity patterns (G-1, G-2, G-3) and three boundary conditions (S-S, C-C, C-F) are investigated. The crack is incorporated directly into the element stiffness matrix as a localized geometric reduction. Following validation through mesh sensitivity analyses and benchmark literature data, the model comprehensively demonstrates how the porosity ratio, crack depth, and crack location collectively influence the fundamental natural frequency.

2 Theoretical Formulation

2.1 Physical Model and Material Properties

The physical beam model considered in this work is illustrated in Fig. 1. The beam has a length of L and a rectangular cross-section of width b and height h. A single open edge crack of depth a is located along the top surface at a distance L_c from the left support, and the figure also shows the resulting uncracked and cracked cross-sections. In the finite element formulation, the crack is modeled within a single element by reducing the local cross-sectional height from h to $h - a$.

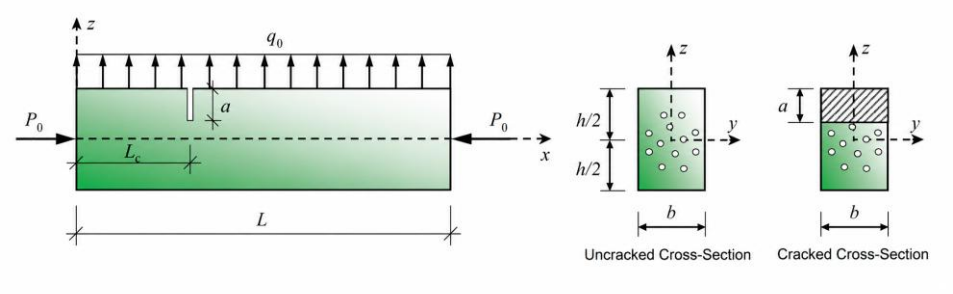

Fig. 1. Beam geometry with uncracked and cracked cross-sections (L, L_c, a, b, h); P_0, q_0 not applied in the free vibration analysis

Material gradation terms from the general 2D-FGM model are omitted here to focus on a homogeneous base structure. Setting the gradation exponents to zero leaves a fully ceramic base matrix, where the effective properties of the porous material simplify to [13]

$$P(z) = P_c - \frac{e(z)}{2}(P_c + P_m), \qquad P = E, \rho, \tag{1}$$

with P_c and P_m representing ceramic and metal constituents used for porosity correction. The metal property P_m is retained exclusively within this correction term, ensuring that $P(z) \to P_c$ as $e \to 0$ to maintain a homogeneous ceramic base material. The effective Young's modulus and mass density are expressed as

$$E(z) = E_c - \frac{e(z)}{2}(E_c + E_m), \qquad \rho(z) = \rho_c - \frac{e(z)}{2}(\rho_c + \rho_m) \tag{2}$$

Assuming a constant Poisson's ratio of 0.30 across constituents, the shear modulus is evaluated directly via

$$G(z) = \frac{E(z)}{2(1+\nu)}, \qquad \nu = 0.30 \tag{3}$$

The geometric and material parameters used in the free vibration analysis are listed in Table 1.

Table 1. Geometric and material parameters of the beam

Parameter	Symbol	Value
Beam length	L	1 m
Beam width	b	0.05 m
Beam height	h	0.05 m
Ceramic Young's modulus	E_c	380 GPa
Metal Young's modulus	E_m	70 GPa
Ceramic density	ρ_c	3960 kg/m³
Metal density	ρ_m	2702 kg/m³
Poisson's ratio	$\nu_c = \nu_m$	0.30

Three distinct porosity distributions (G-1, G-2, and G-3) are examined across the beam thickness, as depicted in Fig. 2. Following Turan [4], these profiles are defined as

$$e_{\text{G-1}}(z) = e, \qquad e_{\text{G-2}}(z) = e\left(1 - \frac{2|z|}{h}\right), \qquad e_{\text{G-3}}(z) = e\left(\frac{2|z|}{h}\right), \tag{4}$$

where e represents the maximum porosity ratio and $e(z)$ defines its variation through the beam thickness.

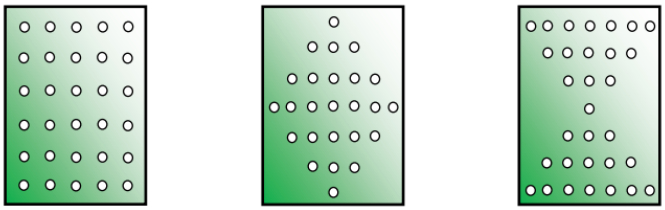

Fig. 2. Porosity distribution patterns (G-1, G-2, G-3)

In these models, G-1 represents a uniform distribution across the beam thickness, G-2 concentrates the highest porosity near the mid-plane and decreases toward the top and bottom surfaces, and G-3 exhibits the lowest porosity at the mid-plane with peak values at the outer surfaces. For the cracked element, only the stiffness matrix is modified to incorporate the reduced cross-section while the mass matrix remains unchanged [13]. Because the crack removes material over a very narrow axial span, its influence on global inertia is negligible compared to its localized effect on bending stiffness.

2.2 Mathematical Formulation

Based on the third-order shear deformation theory, the axial and transverse displacement field is expressed as [14]

$$u(x,z,t) = u_0(x,t) - z\,w_{0,x}(x,t) + \left(z - \frac{4z^3}{3h^2}\right)\phi_0(x,t), \qquad w(x,z,t) = w_0(x,t) \tag{5}$$

The corresponding normal and shear strains are defined as

$$\begin{aligned} \varepsilon_{xx} &= \frac{du_0}{dx} - z\frac{d^2w_0}{dx^2} + \left(z - \frac{4z^3}{3h^2}\right)\frac{d\phi_0}{dx}, \\ \gamma_{xz} &= \frac{dw_0}{dx} - \frac{dw_0}{dx} + \left(1 - \frac{4z^2}{h^2}\right)\phi_0 = \left(1 - \frac{4z^2}{h^2}\right)\phi_0 \end{aligned} \tag{6}$$

Constitutive relations for normal and transverse shear stresses follow linear elasticity:

$$\sigma_{xx} = E(z)\varepsilon_{xx}, \qquad \tau_{xz} = G(z)\gamma_{xz} \tag{7}$$

Strain energies for uncracked and cracked elements are evaluated separately as [13]

$$U_{\text{uncracked}} = \frac{1}{2}\int_0^{L_e}\int_{-b/2}^{b/2}\int_{-h/2}^{h/2}(\sigma_{xx}\varepsilon_{xx} + \tau_{xz}\gamma_{xz})\, dz\, dy\, dx,$$
$$U_{\text{cracked}} = \frac{1}{2}\int_0^{L_e}\int_{-b/2}^{b/2}\int_{-h/2}^{h/2-a}(\sigma_{xx}\varepsilon_{xx} + \tau_{xz}\gamma_{xz})\, dz\, dy\, dx \quad (8)$$

In Eq. (8), the presence of the crack is accounted for by adjusting the upper bound of the thickness integration from $h/2$ to $h/2 - a$. In contrast, the kinetic energy is calculated across the full cross-section for all elements:

$$T = \frac{1}{2}\int_0^{L_e}\int_{-b/2}^{b/2}\int_{-h/2}^{h/2}\rho\,(z)(\dot{u}^2 + \dot{w}^2)dz\, dy\, dx \quad (9)$$

In the absence of external forces, the system Lagrangian for free vibration analysis reduces to

$$\Pi = T - U \quad (10)$$

2.3 Finite Element Solution

The formulation employs a three-node higher-order beam element of length L_e with 12 degrees of freedom, as shown in Fig. 3. The element nodal displacement vector is defined as

$$\mathbf{u} = \{u_1\ u_2\ u_3\ w_1\ w_2\ w_3\ \phi_1\ \phi_2\ \phi_3\ w_{,x1}\ w_{,x2}\ w_{,x3}\}^T \quad (11)$$

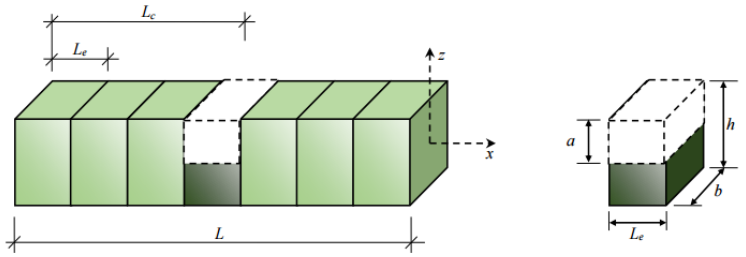

Fig. 3. Finite element discretization with localized crack

Interpolation of the generalized displacement fields across the element domain is performed using appropriate shape functions:

$$u_0(x) = \sum_{i=1}^{3}\psi_{1i}\,(x)u_i,$$
$$w_0(x) = \sum_{i=1}^{3}\psi_{2i}\,(x)w_i + \sum_{i=1}^{3}\psi_{3i}\,(x)w_{,xi}, \quad (12)$$
$$\phi_0(x) = \sum_{i=1}^{3}\psi_{1i}\,(x)\phi_i$$

Here, ψ_{1i}, ψ_{2i}, and ψ_{3i} denote the higher-order interpolation functions of the element, illustrated in Fig. 4.

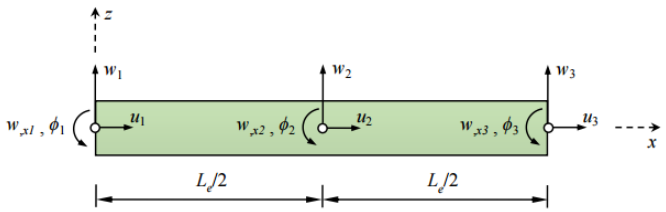

Fig. 4. Higher-order finite element

Applying the Lagrange equations,

$$\frac{d}{dt}\left(\frac{\partial \Pi}{\partial \dot{q}_i}\right) - \frac{\partial \Pi}{\partial q_i} = 0, \quad (13)$$

gives the element equation of motion

$$\mathbf{m}\ddot{\mathbf{u}} + \mathbf{k}_e\mathbf{u} = \mathbf{0} \quad (14)$$

After assembly, the free vibration equation of the beam becomes

$$\mathbf{M}\ddot{\mathbf{X}} + \mathbf{K}_e\mathbf{X} = \mathbf{0} \tag{15}$$

Introducing the harmonic solution $\mathbf{X} = \mathbf{U}e^{i\omega t}$ gives

$$(\mathbf{K}_e - \omega^2\mathbf{M})\mathbf{U} = \mathbf{0} \tag{16}$$

Here, ω is the angular natural frequency in rad/s. The natural frequency reported in Hz is obtained from

$$f = \frac{\omega}{2\pi} \tag{17}$$

All frequencies reported in the following sections are given in Hz.

The kinematic boundary conditions corresponding to the three boundary conditions considered in this study (simply supported, clamped-clamped, and clamped-free) are given in Table 2.

Table 2. Kinematic boundary conditions for each support type

Support Type	x = 0	x = L
Simply supported (S-S)	u = 0, w = 0	w = 0
Clamped-clamped (C-C)	u = 0, w = 0, φ = 0, w,x = 0	u = 0, w = 0, φ = 0, w,x = 0
Clamped-free (C-F)	u = 0, w = 0, φ = 0, w,x = 0	Free (no constraints)

3 Numerical Results and Discussion

In this section, the numerical results demonstrating the accuracy and effectiveness of the developed finite element model are presented and discussed in detail. All parameters used in the analyses are kept constant, and the effects of porosity, crack location and depth, material gradation exponents, and boundary conditions on structural behavior are examined comparatively. Throughout the study, the beam length is taken as $L = 1$ m, and the cross-sectional dimensions are $b = h = 0.05$ m. The elastic moduli of the metal and ceramic phases are assumed to be $E_m = 70$ GPa and $E_c = 380$ GPa, respectively, while the corresponding densities are $\rho_m = 2702$ kg/m^3 and $\rho_c = 3960$ kg/m^3. The Poisson's ratio is taken as constant, $\nu = 0.3$.

3.1 Mesh Convergence and Discretization

Because the geometric crack is assigned to a single finite element, changing the number of elements modifies not only the discretization but also the axial extent over which the cross-section is reduced. The following analysis should therefore be interpreted as a mesh-sensitivity study for the adopted crack representation rather than as a conventional mesh-convergence test for an unchanged crack geometry. A G-1 porous beam with $e = 0.1$ is analyzed using $N = 10$, 20, 50, 100, and 200 elements for the S-S, C-C, and C-F boundary conditions. The crack is placed at $L_c/L = 0.25$ and two crack depth ratios, $a/h = 0.2$ and $a/h = 0.4$, are considered.

The results are summarized in Table 3. For the shallower crack the predicted frequency is almost independent of the mesh, the largest change between $N = 10$ and $N = 200$ being 0.56%. The deeper crack is more sensitive, as expected for a geometric crack model in which a coarse mesh spreads the reduced cross-section over a relatively large portion of the beam: the corresponding changes reach 1.82% for S-S and 2.95% for C-F. In all cases the results stabilize rapidly, and the difference between $N = 100$ and $N = 200$ never exceeds 0.03%. Accordingly, $N = 200$ is adopted consistently in all subsequent validation and parametric analyses, so that the crack always extends over an axial length of $L_e = L/N$ and the numerical comparisons reported below are performed with the same crack representation. For reference, the fundamental frequencies of the corresponding uncracked beams at $N = 200$ are 224.1507, 501.7247, and 80.0306 Hz for the S-S, C-C, and C-F cases, respectively.

Table 3. Mesh convergence of the fundamental frequency (Hz) (G-1, $e = 0.1$, $L_c/L = 0.25$)

N	S-S		C-C		C-F	
	a/h = 0.2	**a/h = 0.4**	**a/h = 0.2**	**a/h = 0.4**	**a/h = 0.2**	**a/h = 0.4**
10	222.7072	216.7859	501.7153	500.6306	79.1439	75.6495
20	223.4871	220.7600	501.7815	501.6104	79.4971	77.3703

100	223.4660	220.8627	501.6558	501.3902	79.5861	77.9302
200	223.4545	220.8109	501.6432	501.3451	79.5897	77.9501

3.2 Validation Against Literature for the Homogeneous Case

After selecting the element number, the finite element formulation is validated for a homogeneous, isotropic reference beam against published experimental and numerical results for cracked beams [15,16]. This validation step isolates the implementation of the beam kinematics, crack representation, and boundary conditions before the effects of porosity are examined.

Table 4 compares the first two natural frequencies obtained from the present model with experimental, FEFM, and FEM results reported by Kam and Lee, Lee and Chung, and Long et al. [15-17]. Three crack locations ($L_c = 80$, 140, and 200 mm) and two crack depths ($a = 2$ and 6 mm) are considered. The first-mode predictions are consistently close to the reference values for both crack depths. Somewhat larger differences occur in the second mode, which is more sensitive to the local representation of the crack and to differences between the underlying modeling approaches. Overall, the comparison confirms that the present element reproduces the principal frequency trends associated with crack depth and location.

Table 4. Comparison of the natural frequencies of cracked and uncracked homogeneous beams with literature

L_c (mm)	Methods	a = 2 mm		a = 6 mm	
		1st mode (Hz)	**2nd mode (Hz)**	**1st mode (Hz)**	**2nd mode (Hz)**

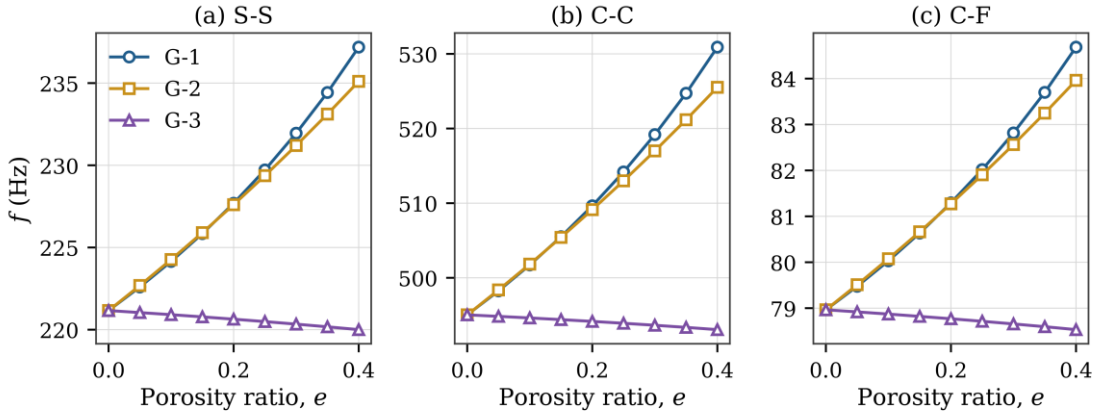
In cracked configurations, where the natural frequencies are significantly influenced by crack location (L_c) and depth (a), a decline in both the first and second mode frequencies is observed as the depth increases. This behavior stems from the loss of beam stiffness induced by the crack, which consequently weakens the overall vibration characteristics of the system. These results,

summarized in Table 4, exhibit high agreement with numerical and experimental findings from the literature.

3.3 Parametric Study

Following model validation, a parametric study evaluated how porosity ratio, crack depth, and crack location influence the S-S, C-C, and C-F boundary conditions.

Fig. 5 illustrates the fundamental frequency of the uncracked beam across varying porosity ratios (e). For patterns G-1 and G-2, the natural frequency steadily rises with increasing porosity because material density decreases faster than elastic modulus, effectively boosting the overall stiffness-to-mass ratio. Pattern G-3 shows a slight frequency reduction as porosity grows. Since porosity in G-3 concentrates near the outer surfaces where contribution to bending stiffness is most critical, the loss of structural stiffness outweighs the reduction in mass.



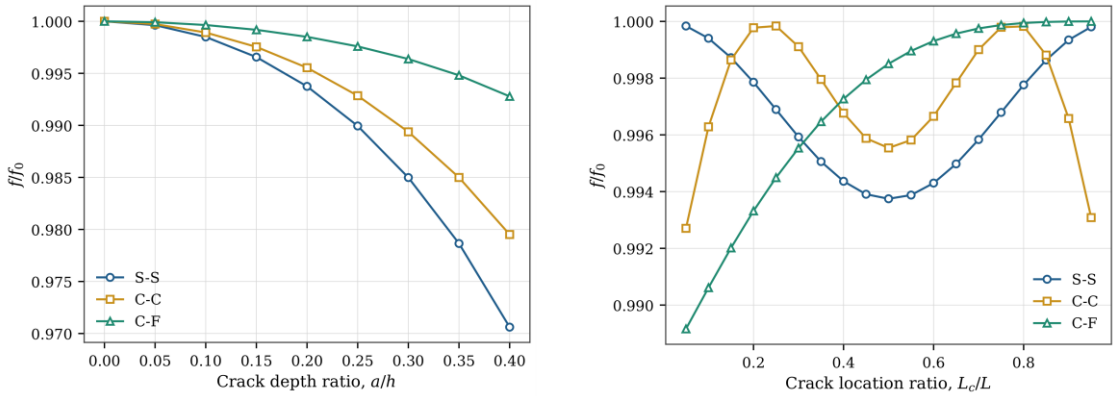


Fig. 5. Effect of porosity ratio and pattern on the fundamental frequency, (a) S-S, (b) C-C, (c) C-F

In the following analyses, the fundamental frequency of the cracked beam (f) is normalized by f_0, representing the uncracked state with matching porosity and boundary conditions.

As observed in Fig. 6(a), a pronounced decrease occurs in the normalized frequency (f/f_0) as the crack depth ratio (a/h) increases. At $a/h = 0.4$, the maximum frequency reduction is observed in the S-S boundary condition, followed by C-C, and the least reduction occurs in the C-F boundary condition. This difference in sensitivity directly depends on the local curvature distribution. A crack located at the mid-span coincides with the region of highest modal curvature under the S-S boundary condition. Conversely, because the mid-span curvature is lowest in the C-F boundary condition, the resulting impact is also minimized.

Fig. 6(b) presents the effect of the crack location ratio (L_c/L) on the normalized frequency. The frequency reduction trend directly mirrors the fundamental mode shape of the beam across all investigated cases. The highest sensitivity to the crack is observed at the S-S boundary condition, followed by C-F, whereas for the C-C boundary condition, it is seen both near the clamped support regions and at the mid-span. Peak frequency drops coincide with locations where maximum bending moments develop, while the ratios approach unity again where the modal curvature vanishes. Because the normalized frequency is calculated by referencing f_0, the curves corresponding to distinct porosity patterns nearly overlap at low porosity ratios.

(a) crack depth ratio, $L_c/L = 0.5$ (b) crack location ratio, $a/h = 0.2$

Fig. 6. Variation of normalized frequency with (a) crack depth and (b) crack location for $e = 0.1$ (G-1)

Table 5. Effect of porosity parameter (e) and distribution pattern on the cracked beam (a/h = 0.4)

e	S-S			C-C			C-F		
	G-1	**G-2**	**G-3**	**G-1**	**G-2**	**G-3**	**G-1**	**G-2**	**G-3**
0.0	2.94	2.94	2.94	2.05	2.05	2.05	0.72	0.72	0.72
0.1	2.94	2.99	2.89	2.05	2.08	2.02	0.72	0.73	0.71
0.2	2.94	3.04	2.84	2.05	2.11	1.98	0.72	0.75	0.70
0.3	2.94	3.09	2.78	2.05	2.15	1.95	0.72	0.76	0.68
0.4	2.94	3.15	2.72	2.05	2.18	1.91	0.72	0.78	0.67

The frequency variation depends directly on the porosity distribution type. For G-1, the frequency drop remains unchanged because uniform porosity degrades each layer uniformly. For G-2, porosity is concentrated at the mid-plane, leading the crack to remove material from the stiffer outer layers and increasing the stiffness reduction at higher porosity ratios. In contrast, for G-3, porosity concentrates near the outer surfaces, resulting in a lower frequency decrease. The same trend is observed for all boundary conditions.

4 Conclusions

The proposed model demonstrates strong agreement with benchmark results from the literature. The porosity distribution type plays a key role in the fundamental frequency behavior, where higher porosity increases the natural frequency for G-1 and G-2 but decreases it for G-3. With increasing crack depth, the most pronounced frequency drop is observed under the S-S boundary condition, followed by C-C, while C-F exhibits the smallest reduction. The extent of frequency loss is directly governed by the porosity pattern: it remains unchanged for G-1, increases for G-2 due to the loss of stiffer outer material, and decreases for G-3. Future studies may extend the present finite element formulation to cover multiple cracks, breathing-crack behavior, and higher vibration modes.

Abstract. The bond interaction between concrete and reinforcing steel is a critical parameter affecting the structural performance and load transfer mechanism of reinforced concrete elements. Among the major durability problems affecting reinforced concrete structures, reinforcement corrosion significantly influences bond behavior by weakening the interaction between steel and concrete.
Therefore, the bond mechanism has been extensively investigated in previous studies.

Various experimental methods have been developed to investigate bond performance. Among these, the Pull-Out test is widely preferred due to its simplicity and ease of application. However, previous studies have shown that bond strength values obtained from Pull-Out tests may overestimate actual bond performance because the stress distribution differs from real structural conditions. Furthermore, accelerated corrosion testing of specimens subjected to tensile bond evaluation presents several practical and experimental challenges.

In this study, a Modified Beam-End Test methodology was investigated to obtain a more representative assessment of steel–concrete bond behavior. The proposed experimental setup addresses several limitations associated with conventional Pull-Out testing. The modified specimen geometry and loading configuration provide a more realistic representation of the stress transfer mechanism between reinforcement and concrete. Furthermore, the geometry of the test specimen is particularly advantageous for accelerated corrosion testing, enabling a more practical and efficient implementation of the experimental procedure.

The proposed methodology is expected to provide a practical and reliable alternative for future experimental studies investigating bond degradation in corrosion-damaged reinforced concrete structures. The effectiveness of the Beam-End Test methodology is evaluated by comparison with previous studies

Keywords: Reinforcement Corrosion, Bond Strength, Modified Beam-End Test.

1 Introduction

Reinforced concrete (RC) structures rely on the bond between reinforcing steel and concrete to ensure effective stress transfer, composite action, crack control, and adequate anchorage. The integrity of this bond is therefore essential for the structural performance and serviceability of RC members.

Corrosion of reinforcing steel can significantly alter the bond response of reinforced concrete members. As steel deteriorates, the products formed at the bar surface expand against the surrounding concrete, initiating local tensile stresses and eventually causing cover cracking. Continued deterioration weakens the restraint around the bar and damages the steel–concrete contact zone, leading to reduced bond resistance and anchorage performance [1–3]. Bond behavior is also governed by several geometric and material variables, including concrete quality, cover depth, reinforcement size, bonded length, transverse confinement, and the extent of corrosion [3,4].

Among the available experimental methods, the Pull-Out Test is widely used because of its simple specimen preparation and testing procedure. However, the compressive confinement generated around the reinforcement during testing produces a stress state that differs from that occurring in actual RC members and may result in comparatively high bond strength values [5,6]. Beam-End Tests provide a more representative stress transfer mechanism, although their specimen preparation and loading arrangements are generally more complex [6–8].

The evaluation of corrosion-induced bond deterioration introduces additional experimental challenges. In conventional Pull-Out specimens, accelerated corrosion may be affected by non-uniform current distribution, electrolyte leakage, and localized corrosion, which can reduce the consistency of the corrosion process [9,10]. Therefore, a test configuration that combines representative bond conditions with practical accelerated corrosion application is required.

In this study, a Modified Beam-End Test (MBE) methodology is proposed for evaluating the bond behavior of corroded reinforcement. The proposed configuration aims to maintain a representative bond stress transfer mechanism while simplifying specimen preparation and accelerated corrosion application. Its performance is experimentally evaluated at different corrosion levels and compared with findings reported in previous studies.

2 Limitations of Conventional Bond Test Methods

2.1 Pull-Out Test

The Pull-Out Test is widely used to characterize steel–concrete bond due to its simple specimen preparation and testing procedure. In this method, tensile force is applied to a reinforcing bar embedded over a defined length, while bar slip is measured to obtain the bond–slip response [11]. However, the loading condition differs from that experienced by reinforcement in structural members. As illustrated in Fig. 1, the reaction acting on the concrete introduces compressive stresses around the bonded region, providing additional confinement [12]. This may suppress splitting cracks and lead to higher bond strengths than those developed under less confined structural conditions [13].

This effect is particularly relevant in corrosion studies, where deterioration of the concrete cover progressively reduces confinement. The confinement inherent in the Pull-Out configuration may therefore influence the measured bond degradation. In addition, its geometry can complicate accelerated corrosion procedures through difficulties in controlling electrolyte exposure, electrical isolation, and localized corrosion [14].

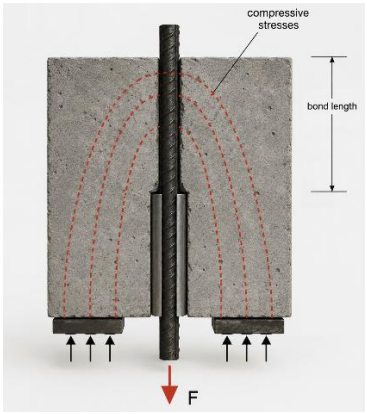

Fig. 1. Conventional Pull-Out Test configuration and associated stress transfer mechanism.

2.2 Beam and Beam-End Test

Beam-type bond tests provide an alternative approach that more closely represents the stress conditions occurring in reinforced concrete members. Unlike the Pull-Out Test, the tensile force in the reinforcement and the compressive reaction are separated, reducing the artificial confinement around the bonded region. Consequently, the resulting stress transfer mechanism and failure behavior are generally more representative of reinforcement anchored within structural members.

The Beam-End Test provides a more compact configuration while maintaining the principal advantages of beam-type testing. In this arrangement, the reinforcing bar is pulled in tension, whereas the supporting reaction is introduced into the concrete at a location separated from the active bond zone [15].

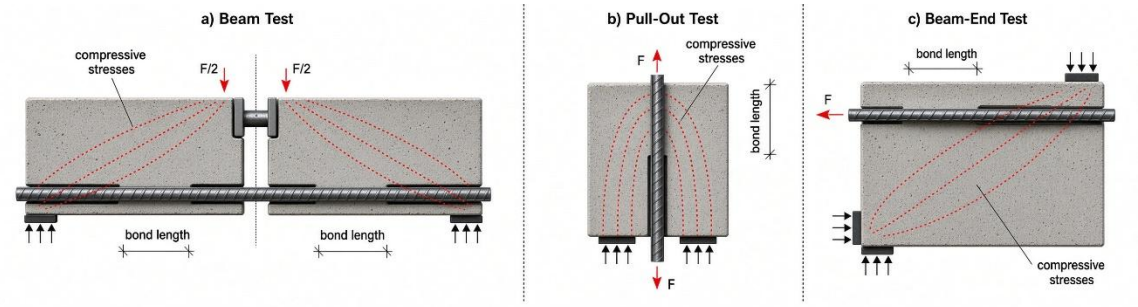

Fig. 2. Comparison of the load-transfer mechanisms in Pull-Out and Beam-End Tests.

However, conventional Beam and Beam-End Tests generally require more complicated specimen preparation and loading arrangements than Pull-Out Tests. These difficulties become more significant when accelerated corrosion is incorporated, as the specimen must simultaneously provide appropriate mechanical boundary conditions and controlled access to the reinforcement for corrosion exposure.

Therefore, conventional bond testing methods involve a trade-off between experimental simplicity and structural representativeness. While the Pull-Out Test offers practical advantages, Beam and Beam-End Tests provide a more realistic stress transfer mechanism but introduce greater experimental complexity. These considerations motivated the adoption of the Modified Beam-End approach examined in this study.

3 Development of the Modified Beam-End Test

In reinforced concrete members, tensile forces in the reinforcement are transferred to the surrounding concrete through bond along the anchorage region. The interaction between the bar ribs and concrete generates both longitudinal and radial forces. The longitudinal component transfers force along the reinforcement, whereas the radial component acts outward from the bar and can promote splitting of the concrete when confinement is inadequate.

The Modified Beam-End (MBE) configuration was developed to represent this mechanism under controlled experimental conditions. Tensile load is applied directly to the reinforcing bar, and unbonded zones are used to restrict stress transfer to a predefined bond region. This arrangement enables the measured bond stress and slip to be associated with the selected anchorage zone while allowing bond-induced cracking to develop around the reinforcement, as schematically presented in Fig. 3.

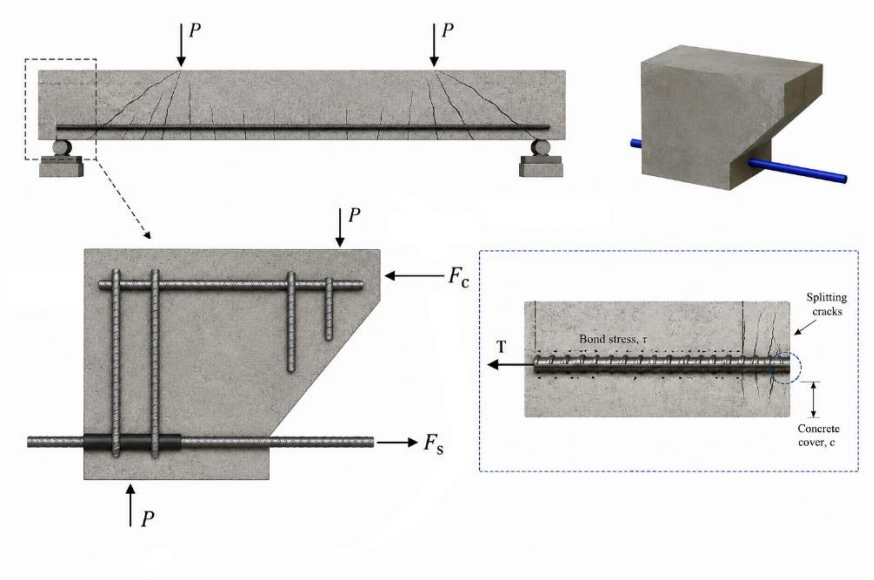

Fig. 3. Schematic representation of reinforcement–concrete interaction in the MBE configuration.

The proposed geometry is also suitable for accelerated corrosion studies. The accessible and defined bond region facilitates controlled corrosion exposure while allowing corrosion-induced expansion and cracking to develop around the reinforcement. Consequently, corrosion and its subsequent influence on bond behavior can be investigated within the same test region.

4 Experimental Program

An experimental program was conducted to evaluate the applicability of the proposed Modified Beam-End Test for investigating steel–concrete bond behavior under uncorroded and corroded conditions. For this purpose, control specimens and specimens subjected to accelerated corrosion were prepared with identical geometric and material properties. Two nominally identical specimens were tested for each condition to evaluate the consistency of the experimental response.

4.1 4.1. Materials and Specimens

Ready-mixed concrete with a target strength class of C25/30 was employed throughout the experimental program to maintain consistent material conditions among the MBE specimens. Concrete strength was evaluated using cube samples produced from the same concrete batches as the test specimens. The cube tests compressive strengths of 32.7 and 36.7 MPa.

Deformed steel reinforcement with a diameter of 14 mm was used as the main tensile reinforcement. As shown in the Fig. 3,the effective bonded length was limited to 78 mm, while PVC pipes were placed around the remaining portion of the bar to prevent bond transfer outside the intended test region. Additional reinforcement was provided within the specimen to prevent undesirable failure mechanisms and to maintain the intended load-transfer mechanism.

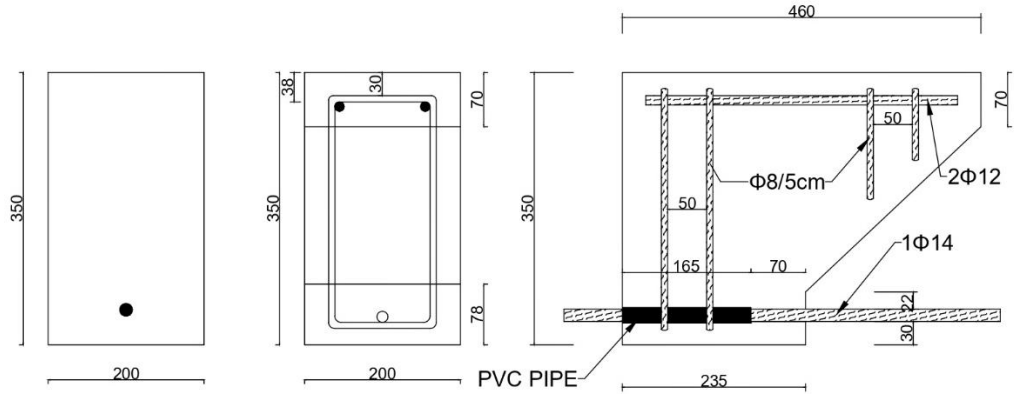

Fig. 3. Geometry and reinforcement arrangement of the Modified Beam-End specimen.

The distance between the reinforcement and the nearest concrete surface was maintained at 30 mm for the entire specimen series. The experimental matrix included five specimens representing uncorroded, low-corrosion, and moderate-corrosion conditions. Two replicate specimens were tested under the control and moderate corrosion conditions, while one specimen was evaluated at the low corrosion level. The measured corrosion rates ranged from 1.13% for the low-corrosion specimen to approximately 3% for the moderately corroded specimens. The specimen identification, corrosion condition, concrete cover, and corresponding corrosion rates are summarized in Table 1.

Table 1. Details and experimental parameters of the test specimens.

Specimen	Condition	Concrete Cover	Corrosion Rate
C_0-C_3^1	Control	30mm	%0
C_0-C_3^2	Control	30mm	%0
C_L-C_3	Low Corrosion	30mm	%1.13
C_M-C_3	Moderate Corrosion	30mm	%2.95

4.2 Accelerated Corrosion and Bond Testing Procedure

Accelerated corrosion was applied to the specimens using the impressed-current technique. The reinforcing bars were connected as anodes, while metallic plates placed in the electrolyte solution served as cathodes. The specimens were connected in parallel to a DC power supply, and the electrical current passing through each specimen was monitored throughout the corrosion process. The general configuration of the accelerated corrosion system is shown in Fig. 6. The accumulated current over the exposure period was used to estimate the theoretical corrosion level according to Faraday's law.

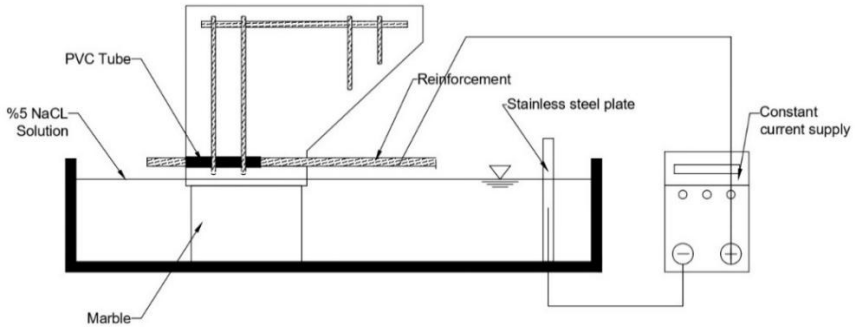

Fig. 6. Accelerated corrosion setup used for the Modified Beam-End specimens.

After completion of the corrosion stage, bond tests were performed with the MBE loading arrangement shown in Figure 7. A hydraulic system pulled the reinforcing bar while the specimen was restrained through the reaction frame. The applied force was quantified by load cells positioned along the load-transfer path. Bar slip was determined from LVDT readings referenced to the concrete body. All sensor outputs were collected by a TDS-303 data acquisition unit, providing synchronized measurements throughout the loading sequence and allowing the bond stress–slip response to be established.

Fig. 7. Modified Beam-End Test setup and instrumentation.

5 Results and Discussion

The experimental results were evaluated in terms of bond strength, bond stress–slip response, and observed failure behavior. The results obtained from the control and corroded Modified Beam-End (MBE) specimens are summarized in Table 2. The experimental results indicate that the bond response was strongly influenced by the level of reinforcement corrosion.

Table 2. Table 2. Summary of bond test results for the MBE specimens.

Specimen	Maximum Force (kN)	Bond Strength (MPa)	Corrosion Rate
C_0-C_3^1	19.33	6.28	%0
C_0-C_3^2	22.83	7.41	%0
C_L-C_3	24.66	8.01	%1.13
C_M-C_3	10.33	3.35	%2.99

The two uncorroded specimens developed bond strengths of 6.28 and 7.41 MPa, giving an average value of 6.85 MPa. This average was used as the reference for assessing the effect of corrosion. At a corrosion rate of 1.13%, specimen C_L-C_3 reached the highest bond strength of 8.01 MPa, approximately 17% above the control average. This increase may be associated with the early expansion of corrosion products at the steel–concrete interface, which can temporarily improve radial pressure and mechanical interaction between the reinforcement and concrete. A different response was observed for C_M-C_3 at a corrosion rate of 2.99%. Its bond strength decreased to 3.35 MPa, representing approximately 51% loss relative to the control average. This reduction suggests that progressive corrosion increasingly disrupts the bond zone through interface degradation and damage within the concrete surrounding the reinforcement.

Fig. 8 presents the variation in bond strength observed with increasing reinforcement corrosion. An initial increase is observed at the low corrosion level, followed by a marked decrease at approximately 3% corrosion. Within the scope of the available test data, bond performance showed a non-linear response to increasing corrosion.

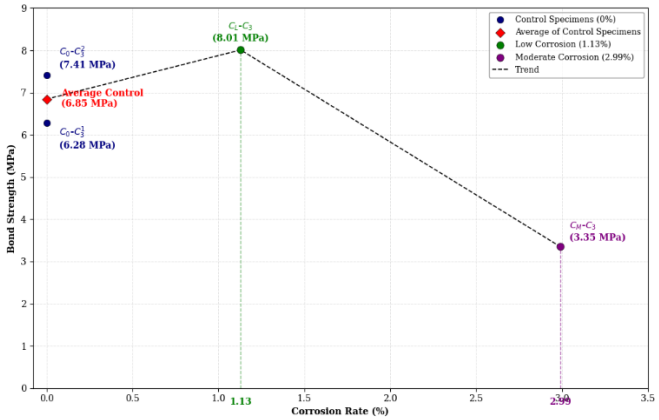

Fig. 8. Effect of reinforcement corrosion rate on bond strength of the Modified Beam-End specimens.

The corresponding bond stress–slip curves are presented in Fig. 9. The control specimens provide the baseline response, whereas C_L-C_3 develops a higher peak bond stress. In contrast, C_M-C_3 shows a considerable loss of bond resistance, demonstrating the deterioration of the bond response with increasing corrosion.

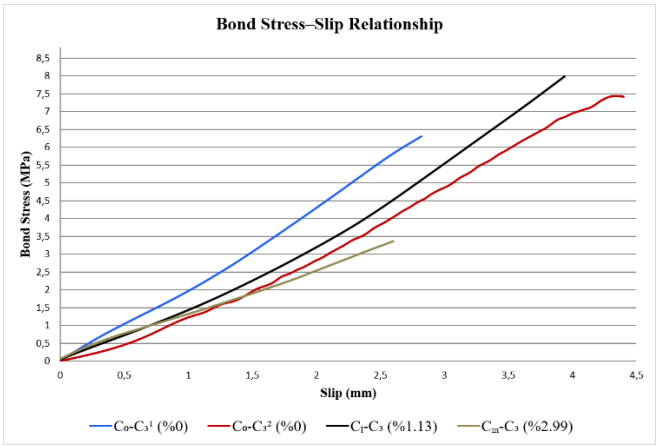

Fig. 9 . Bond stress–slip relationships of the control, low-corrosion, and moderate-corrosion Modified Beam-End specimens.

Overall, the MBE results captured two distinct stages of corrosion-related bond behavior: a limited increase in bond capacity at the early corrosion stage and a substantial reduction as corrosion approached 3%. The proposed test configuration therefore shows potential for assessing changes in steel–concrete bond behavior caused by reinforcement corrosion. Nevertheless, additional specimens and corrosion levels are required before a generalized relationship between corrosion and bond strength can be established.

5.1 Comparison with Previous Studies

The present MBE results were compared with previous studies based on Pull-Out and Beam Test configurations, as summarized in Table 3. Although differences in concrete strength, cover thickness, corrosion level, and specimen geometry should be considered, the comparison provides useful insight into the influence of the test method on measured bond strength.

The Pull-Out results reported by Yalciner et al. [2] show considerably higher bond strengths than those obtained from the present MBE specimens. For example, the uncorroded Pull-Out specimens with a 30 mm concrete cover reached bond strengths of 13.26 and 21.20 MPa, whereas the average value obtained from the MBE control specimens was 6.85 MPa. Relatively high bond strengths were also reported for the corroded Pull-Out specimens. This difference may be partly associated with the additional compressive confinement generated around the bonded region in the Pull-Out configuration, which can restrict splitting and increase the measured bond resistance. In comparison, the Beam Test results reported by Hongwei et al. [16] were closer to the range obtained from the MBE specimens. Despite differences in concrete cover and corrosion level, both beam-type configurations showed lower bond strengths than the Pull-Out results presented in Table 3. Overall, these comparisons support the importance of test configuration when evaluating bond performance and suggest that the proposed MBE method provides a less confined bond response than conventional Pull-Out testing.

Table 2. Comparison of bond strength results obtained from different test methods.

Study	Test Method	Concrete Cover (mm)	Concrete Strength (MPa)	Corrosion Level (%)	Bond Strength (MPa)
Present study	MBE	30	34,7*	0	6.85*
Present study	MBE	30	34,7*	1.13	8.01

6 Conclusions

The experimental investigation demonstrated the potential of the Modified Beam-End (MBE) approach for assessing the effect of reinforcement corrosion on steel–concrete bond. The main findings are summarized below:

- The proposed MBE configuration provided a practical approach for obtaining bond stress–slip behavior while allowing accelerated corrosion to be applied within the intended bond region.
- For the reference specimens, the mean bond strength was 6.85 MPa. With 1.13% reinforcement corrosion, the measured value reached 8.01 MPa, suggesting that slight corrosion can temporarily improve bond resistance.
- When corrosion reached 2.99%, bond strength fell to 3.35 MPa. This corresponds to a loss of approximately 51% relative to the reference condition and indicates a clear deterioration in bond performance as corrosion progresses.
- Comparison with previous studies indicates that conventional Pull-Out tests generally produce higher bond strengths, which may be associated with the additional confinement generated by their loading configuration.
- Overall, the MBE method offers a promising alternative for studying corrosion-related bond deterioration under a more representative load-transfer mechanism. However, further tests covering a wider range of corrosion levels are required to confirm the observed trends.

Abstract. The February 6, 2023 Kahramanmaraş earthquake sequence caused severe ground-motion demands in southern Türkiye, particularly in Hatay, where extensive structural damage was observed. This study evaluates acceleration, pseudo-spectral velocity, and spectral displacement response spectra of selected strong motion records obtained from AFAD stations in the Hatay region during the Pazarcık main shock. Thirteen stations and two horizontal components for each station were considered, resulting in 26 horizontal acceleration records. Five-percent-damped response spectra were calculated in MATLAB using the Newmark-β average acceleration method over a period range of 0.01–8.00 s. The horizontal components were evaluated separately and then combined to obtain resultant spectra. The mean resultant spectra were compared with DD-2 elastic design spectra generated according to the Turkish Building Earthquake Code 2018 for different local site classes, while the mean acceleration spectrum was also compared with DD-1 spectra. The results show significant period-dependent demands. The mean resultant pseudo-spectral acceleration reached approximately 1.9 g at about 0.5–0.7 s, while the mean pseudo-spectral velocity and spectral displacement reached about 380–390 cm/s and 320–325 cm, respectively. The spectra exceeded DD-2 design demands over a broad period range and approached or exceeded some DD-1 spectra in certain intervals. These findings indicate that PGA alone is insufficient for interpreting seismic demand in Hatay; velocity- and displacement-related demands should also be considered.

Keywords: Kahramanmaraş earthquakes; response spectra; Hatay region; local site class; spectral demand.

1 Introduction

On February 6, 2023, two major earthquakes occurred in southeastern Türkiye within approximately nine hours. The Pazarcık earthquake occurred at 04:17 local time with a moment magnitude of Mw 7.7, followed by the Elbistan earthquake at 13:24 local time with a moment magnitude of Mw 7.6. The earthquake sequence affected a wide region, including Kahramanmaraş, Hatay, Adıyaman, Gaziantep, Malatya, Osmaniye, and surrounding provinces, and caused extensive structural damage and significant loss of life [1,2].

Hatay was among the most severely affected regions. In addition to the intensity of the recorded ground motions, local geological and geotechnical conditions played an important role in the spatial variation of damage. Previous studies indicate that Antakya and İskenderun are largely underlain by Quaternary alluvial deposits consisting of clayey, sandy, silty, and gravelly

materials. Such local site conditions may significantly influence the amplitude, frequency content, and duration of ground motion, particularly in soft soil deposits [3].

The evaluation of earthquake demand only in terms of peak ground acceleration may not be sufficient to explain structural response. Ground motions with similar peak acceleration values may produce different demands depending on their frequency content, duration, velocity demand, displacement demand, and spectral characteristics. Therefore, spectral acceleration, pseudo-spectral velocity, and spectral displacement should be considered together, as they provide complementary information on force-related, velocity-related, and displacement-related seismic demands. Several post-earthquake studies reported that response spectra obtained from strong ground motion records during the Kahramanmaraş earthquakes exceeded the elastic design spectrum values of the Turkish Building Earthquake Code 2018 in certain locations and period ranges [4,5]. Recent site-response studies also emphasized that local site effects and site amplification may significantly influence the spectral characteristics of ground motions in the affected regions [6]. These findings highlight the need for a detailed spectral evaluation of recorded ground motions, especially in heavily affected regions such as Hatay.

This study evaluates acceleration, pseudo-spectral velocity, and spectral displacement response spectra of selected strong ground motion records obtained from AFAD stations in the Hatay region during the Pazarcık main shock. Thirteen stations and both horizontal components of each record are considered. The 5%-damped response spectra are computed in MATLAB using the Newmark-β average acceleration method and compared with TBDY 2018 elastic design spectra for different local site classes [7]. The main objective is to investigate how spectral demand in Hatay varies with period range and local site class, and to provide a preliminary basis for future seismic demand and performance-based assessments of reinforced concrete buildings affected by the 2023 earthquake sequence.

2 Strong Ground Motion Records Used in the Study

The strong ground motion records used in this study were obtained from the Turkish Strong Ground Motion Database operated by AFAD [1]. The record selection was limited to stations located in the Hatay region during the February 6, 2023 Pazarcık earthquake. The availability of two horizontal components, time-step suitability, and regional representativeness were considered in the selection process.

A total of 13 AFAD stations located in Antakya, Belen, Dörtyol, Hassa, and Kırıkhan districts and their surroundings were selected. For each station, the north-south and east-west horizontal components were evaluated separately, resulting in 26 horizontal acceleration records. The vertical components were not used in the response spectrum calculations, but their PGA values are listed in Table 1 for completeness.

The PGA values are given in cm/s², and the records were converted to m/s² before the numerical analyses. The VS30 values listed in Table 1 range from 271 m/s at station 3139 to 688 m/s at station 3137, indicating different near-surface stiffness conditions within the selected Hatay dataset.

The selected dataset includes stations with different source-to-site distances and local geological conditions within the Hatay region, allowing the evaluation of period-dependent acceleration, velocity, and displacement demands. The records were not modified by spectral matching or amplitude scaling; only unit conversion and basic preprocessing were applied to preserve their original spectral characteristics.

Table 1. Selected strong ground motion records used in the study.

No	Event	Station Code	Location	PGA-NS (cm/s²)	PGA-EW (cm/s²)	PGA-UD (cm/s²)	Rrup (km)	VS30 (m/s)
1	Pazarcık	3115	Hatay / Belen	286.72	241.50	214.81	38.53	424
2	Pazarcık	3123	Hatay / Antakya	655.57	593.94	867.58	72.58	469
3	Pazarcık	3124	Hatay / Antakya	572.63	638.32	578.08	69.66	283
4	Pazarcık	3134	Hatay / Dörtyol	246.11	203.91	141.51	16.71	374
5	Pazarcık	3137	Hatay / Hassa	428.37	670.17	448.37	18.44	688
6	Pazarcık	3138	Hatay / Hassa	888.73	746.66	1296.27	9.70	619
7	Pazarcık	3139	Hatay / Kırıkhan	577.13	504.82	378.62	28.54	271
8	Pazarcık	3141	Hatay / Antakya	961.12	868.82	722.66	54.20	338
9	Pazarcık	3142	Hatay / Kırıkhan	651.69	739.29	456.90	38.09	538
10	Pazarcık	3143	Hatay / Hassa	381.09	351.38	412.11	8.10	444
11	Pazarcık	3144	Hatay / Hassa	611.27	763.36	451.61	12.36	485
12	Pazarcık	3145	Hatay / Kırıkhan	591.88	692.29	609.73	21.68	533
13	Pazarcık	3146	Hatay / Belen	483.85	346.93	341.39	41.57	560

The spatial distribution of the selected stations is shown in Figure 1. The map values correspond to the maximum horizontal peak ground acceleration, PGAmax,h, calculated from the two horizontal components of each record. To relate the station distribution to the observed damage concentration, the Antakya district was highlighted on the map. Reported district-level damage figures indicate 6,369 collapsed, 3,734 emergency-demolition, and 21,830 heavily damaged buildings in Antakya, corresponding to 31,933 severely damaged buildings and approximately 35.9% of the severe-damage building count reported for Hatay province [9]. An official district list also documents heavily damaged buildings scheduled for demolition [10]. This information was included only as district-level damage context and was not used to establish a direct building-level damage correlation.

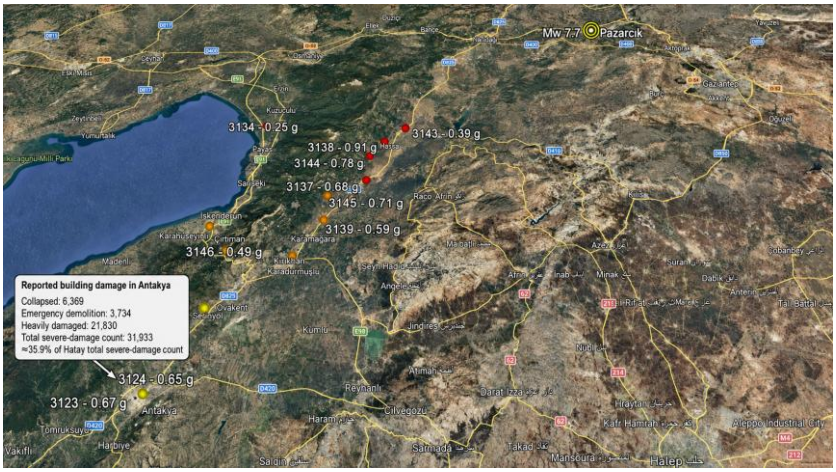

Fig. 1. Selected strong-motion stations, PGA values, and Antakya damage context. Base map: Google Earth. Strong ground motion data: AFAD Turkish Strong Ground Motion Database [1].

3 Methodology

The selected acceleration records were processed to compute 5%-damped response spectra and to compare the obtained spectra with code-based elastic design spectra for different local site classes. The north-south and east-west horizontal components were evaluated separately. The records, originally given in cm/s², were converted to m/s², and the mean value of each acceleration record was removed to reduce possible baseline offset effects. The response spectra were computed in MATLAB using the Newmark-β average acceleration method [8]. A damping ratio of 5% and a period range of 0.01–8.00 s were used. For each oscillator period, the maximum relative displacement response was obtained and used to calculate spectral displacement, pseudo-spectral velocity, and pseudo-spectral acceleration as follows:

$$S_d(T) = \max |u(t)|, \quad S_v(T) = \omega\, S_d(T), \quad S_a(T) = \omega^2\, S_d(T) \tag{1}$$

where $\omega = 2\pi/T$ is the circular frequency. The spectral acceleration values were expressed in terms of g, while pseudo-spectral velocity and spectral displacement were expressed in cm/s and cm, respectively.

For each station, a resultant spectrum was calculated from the two horizontal components as:

$$S_R(T) = \sqrt{[S_N(T)^2 + S_E(T)^2]} \tag{2}$$

The SRSS combination was applied to the spectral ordinates of the two horizontal components at each oscillator period. Since pseudo-spectral velocity and pseudo-spectral acceleration are derived from spectral displacement by multiplication with ω and ω² at the same period, the SRSS operation is mathematically consistent for Sd, Sv, and Sa. The resulting spectrum represents a component-wise resultant spectrum and should not be interpreted as a time-domain vector resultant or as a RotD50-type orientation-independent spectrum.

The mean resultant spectra were compared with elastic design spectra generated according to the Turkish Building Earthquake Code 2018 [7]. The mean ± one standard deviation range was also calculated at each oscillator period to represent record-to-record dispersion.

4 Design Spectra for Different Local Site Classes

Elastic design spectra were generated according to the Turkish Building Earthquake Code 2018 to evaluate the influence of local site class on spectral demand [7]. The reference spectral acceleration parameters were obtained for the selected location in the Hatay region, and the corresponding design parameters were calculated for local site classes ZA, ZB, ZC, ZD, and ZE. Both DD-1 and DD-2 earthquake ground motion levels were considered. DD-1 represents the maximum considered earthquake level, whereas DD-2 represents the design earthquake level. The short-period and 1.0-s spectral acceleration parameters, SDS and SD1, were calculated using the corresponding local site coefficients. The design spectra were computed over the same period range as the recorded spectra and used for direct comparison with the mean resultant spectra. Table 2 presents the parameters used to construct the elastic design spectra.

Table 2. TBDY 2018 design spectral acceleration parameters for different local site classes.

Level	Site class	SS	S1	Fs	F1	SDS	SD1

DD-1	ZA	2.067	0.560	0.800	0.800	1.654	0.448
DD-1	ZB	2.067	0.560	0.900	0.800	1.860	0.448
DD-1	ZC	2.067	0.560	1.200	1.440	2.480	0.806
DD-1	ZD	2.067	0.560	1.000	1.740	2.067	0.974
DD-1	ZE	2.067	0.560	0.800	2.080	1.654	1.165
DD-2	ZA	1.026	0.268	0.800	0.800	0.821	0.214
DD-2	ZB	1.026	0.268	0.900	0.800	0.923	0.214
DD-2	ZC	1.026	0.268	1.200	1.500	1.231	0.402
DD-2	ZD	1.026	0.268	1.090	2.064	1.118	0.553
DD-2	ZE	1.026	0.268	1.079	2.960	1.107	0.793

As shown in Table 2, the design spectral parameters vary depending on the local site class. In general, the short-period range is mainly controlled by S_{DS}, whereas medium- and long-period demands are more influenced by S_{D1}. Therefore, the recorded ground motions were evaluated not only in terms of spectral acceleration, but also in terms of pseudo-spectral velocity and spectral displacement.

5 Spectral Demand Evaluation

The calculated response spectra were evaluated in terms of pseudo-spectral acceleration, pseudo-spectral velocity, and spectral displacement to investigate the period-dependent seismic demand of the selected Hatay records. The individual resultant spectra were examined together with the mean resultant spectra and compared with TBDY 2018 elastic design spectra for different local site classes.

5.1 Evaluation of Resultant Response Spectra

Figures 2–4 present the individual resultant spectra, the mean spectrum, and the mean ± one standard deviation range, which illustrates the record-to-record dispersion of the selected Hatay ground motions.

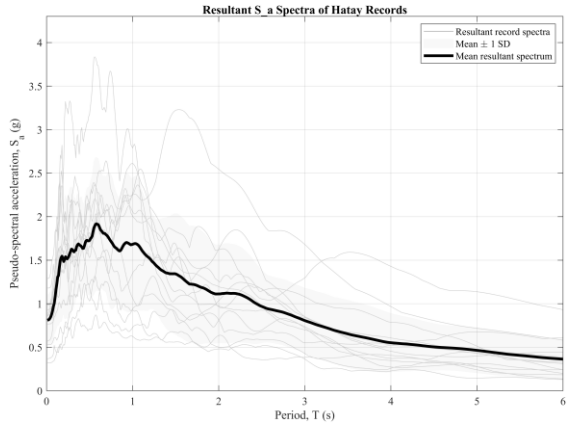

Fig. 2. Resultant S_a spectra with mean ± 1 SD.

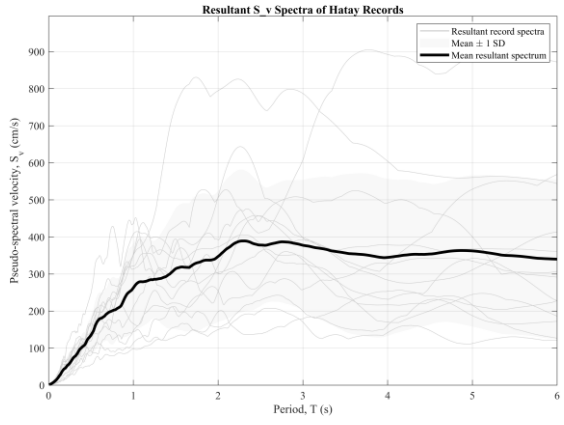

Fig. 3. Resultant Sv spectra with mean ± 1 SD.

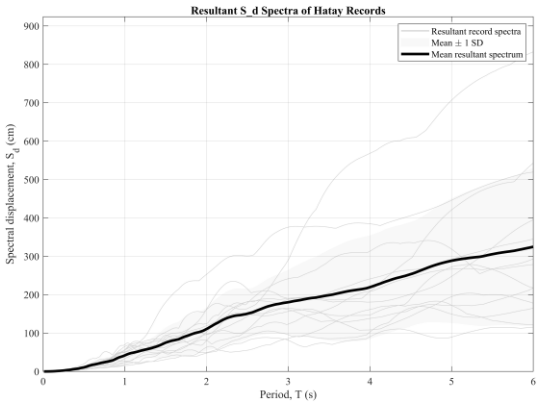

Fig. 4. Resultant Sd spectra with mean ± 1 SD.

Figure 2 shows the resultant pseudo-spectral acceleration spectra of the selected Hatay records together with the mean spectrum and the mean ± one standard deviation band. The mean Sa spectrum reaches approximately 1.9 g at about T = 0.5–0.7 s, while some individual records exceed 3.0 g in the short- and medium-period ranges. This period range is significant because it may correspond to the fundamental periods of mid-rise reinforced concrete buildings, depending on their height, stiffness, and structural configuration. Previous evaluations of earthquake-damaged buildings in Türkiye associated similar period ranges with multi-story reinforced concrete structures, while field observations after the February 6, 2023 earthquakes showed severe damage particularly in multi-story buildings in heavily affected areas [2,5]. Therefore, the high Sa demand in this range may be interpreted as an indicator of force-related demand on the reinforced concrete building stock in the Hatay region.

Figure 3 presents the resultant pseudo-spectral velocity spectra of the selected records. The mean Sv spectrum reaches approximately 380–390 cm/s around T = 2.2–2.8 s, with considerable record-to-record dispersion in the medium-period range. These high Sv values indicate that the selected records may impose significant velocity-sensitive and cyclic-deformation-related demands on reinforced concrete buildings. Repeated inelastic cycles may contribute to damage accumulation, stiffness degradation, and residual drift; therefore, the seismic demand should not be interpreted only as force-related, but also as velocity-sensitive and deformation-related.

Figure 4 presents the resultant spectral displacement spectra of the selected records. The mean Sd spectrum increases with period and reaches approximately 320–325 cm at T = 6 s, while some individual records produce much larger displacement demands at longer periods. The increasing width of the mean ± one standard deviation band also indicates considerable record-to-record variability in the long-period range. Large spectral displacement demand is directly related to deformation-sensitive structural response. In reinforced concrete buildings, increased displacement demand may lead to larger interstory drift ratios, stiffness degradation, concentration of deformation in weaker stories, and second-order P-Δ effects, particularly in buildings with vertical irregularities, insufficient lateral stiffness, or limited deformation capacity.

Overall, Figures 2–4 show that the selected Hatay records produced significant acceleration, velocity, and displacement demands over different period ranges. Therefore, the seismic demand in the Hatay region should not be evaluated only in terms of PGA. The combined assessment of Sa, Sv, and Sd provides a more comprehensive interpretation of the ground-motion characteristics.

Figure 5 provides a schematic interpretation of the structural mechanisms associated with different spectral demand ranges. Short-period acceleration demand may be related to force-controlled brittle damage mechanisms, while long-period displacement demand may be associated with drift-sensitive mechanisms such as soft-story response and P-Δ effects.

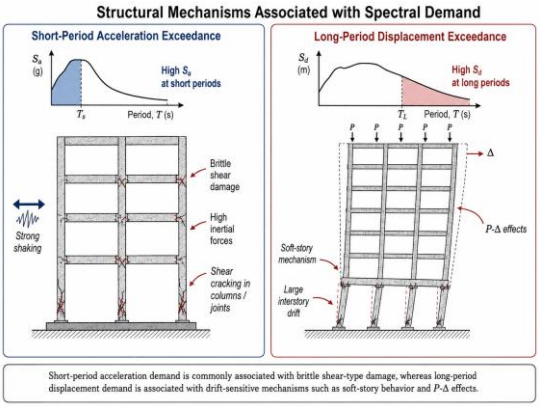

Fig. 5. Schematic illustration of spectral-demand-related damage mechanisms.

5.2 Comparison with TBDY 2018 DD-2 Design Spectra

Figures 6–8 compare the mean resultant Sa, Sv, and Sd spectra with the TBDY 2018 DD-2 spectra for different local site classes.

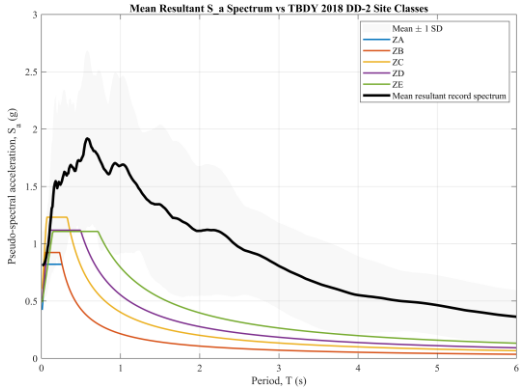

Fig. 6. Mean Sa and TBDY 2018 DD-2 spectra.

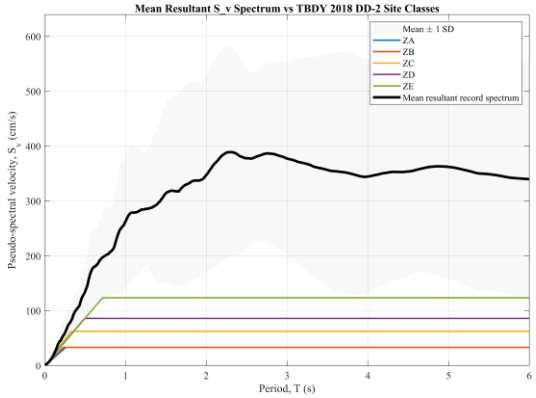

Fig. 7. Mean Sv and TBDY 2018 DD-2 spectra.

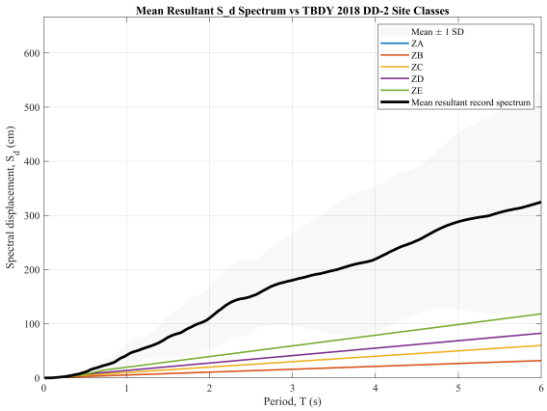

Fig. 8. Mean Sd and TBDY 2018 DD-2 spectra.

Figure 6 shows the mean resultant pseudo-spectral acceleration spectrum and its mean ± one standard deviation band with the TBDY 2018 DD-2 elastic design spectra for different local site classes. The mean recorded spectrum exceeds the DD-2 spectra over a broad period range, particularly in the short- and medium-period ranges where it remains above the code-based spectra for all considered local site classes. This indicates that the selected Hatay records produced acceleration demands higher than the design earthquake level represented by DD-2 spectra. The peak of the mean Sa spectrum occurs around T = 0.5–0.7 s, corresponding to the period range of many mid-rise reinforced concrete buildings depending on their stiffness, height, and structural configuration. Therefore, the high Sa demand in this range may be associated with significant force-related demand on the regional building stock.

However, the acceleration spectrum alone does not fully represent the destructive potential of the selected ground motions. Therefore, the Sa comparison in Figure 6 should be interpreted together with the Sv and Sd comparisons in Figures 7 and 8.

Figure 7 shows the mean resultant pseudo-spectral velocity spectrum with the TBDY 2018 DD-2 pseudo-spectral velocity spectra. The recorded Sv demand remains considerably higher than the code-based spectra over a wide period range for all local site classes, with the difference becoming especially pronounced in the intermediate- and long-period ranges. The high Sv demand is one of the important findings of this study. Pseudo-spectral velocity is not a direct measure of input energy; however, it is commonly used as an indicator of velocity-sensitive structural response and cyclic deformation demand. Large Sv values may therefore be associated with damage accumulation, stiffness degradation, residual drift potential, and increased ductility demand in reinforced concrete buildings.

Although PGV and pseudo-spectral velocity are not identical parameters, both highlight the importance of velocity-related demand in interpreting strong ground motion effects. Previous evaluations of the Kahramanmaraş earthquake sequence also emphasized the role of high PGV values, pulse-like velocity histories, and near-field ground-motion characteristics [13]. In this study, the mean resultant Sv spectrum reaches approximately 380–390 cm/s in the medium-period range, indicating substantial velocity-related demand that may be critical for medium- and longer-period reinforced concrete buildings.

Figure 8 presents the comparison of the mean resultant spectral displacement spectrum with the TBDY 2018 DD-2 spectral displacement spectra. The recorded Sd demand exceeds the code-based spectra for all considered local site classes, especially at medium and long periods, and the difference increases with period. This finding shows that the selected Hatay records produced considerable displacement-related demand in addition to high acceleration and velocity demands. Large Sd values are directly related to deformation-sensitive structural response and may lead to larger interstory drift ratios, concentration of deformation in weaker stories, stiffness degradation, residual drift, and second-order P-Δ effects in reinforced concrete buildings. The displacement-related interpretation is especially important for flexible and longer-period buildings. As the period increases, the response becomes less acceleration-sensitive and more influenced by velocity and displacement demand. This is consistent with the tripartite representation of response spectra, in which short-period response is mainly acceleration-sensitive, intermediate-period response is velocity-sensitive, and long-period response is displacement-sensitive [13].

Overall, the DD-2 comparisons indicate that the selected Hatay records produced spectral demands exceeding the design-level code spectra in terms of acceleration, velocity, and

displacement. The mean ± one standard deviation bands also show considerable record-to-record dispersion, indicating that individual records may impose substantially higher demands over specific period ranges. These results confirm that the seismic demand in the Hatay region cannot be explained by PGA or Sa alone; Sv and Sd should also be considered to capture velocity-sensitive and deformation-related demands, particularly in the medium- and long-period ranges. It should be emphasized that the mean resultant spectrum represents the average response of the selected Hatay records and is not a site-class-specific mean spectrum. The ZA–ZE comparisons were used as a parametric code-based reference to evaluate the influence of local site class on spectral shape. A fully site-consistent comparison would require site-class-based record grouping and station-specific site response analyses, which are beyond the scope of this study.

5.3 Comparison with TBDY 2018 DD-1 Design Spectra

Figure 9 compares the mean resultant pseudo-spectral acceleration spectrum with the TBDY 2018 DD-1 elastic design spectra. The comparison was included to evaluate whether the recorded acceleration demand approaches the maximum considered earthquake level. The mean recorded spectrum is generally lower than the upper DD-1 spectra in the short-period range; however, it approaches or exceeds some DD-1 site-class spectra in certain medium- and long-period intervals. This indicates that the selected Hatay records produced demands clearly above the DD-2 design level and locally comparable to the DD-1 level in some period ranges. The mean ± one standard deviation band also shows considerable dispersion, indicating that individual records may impose demands substantially higher than the mean response. The DD-1 comparison supports the need for a period-dependent interpretation of seismic demand. While acceleration demand is critical at shorter periods, longer-period response should also be interpreted together with velocity- and displacement-related quantities as part of a broader Sa–Sv–Sd assessment.

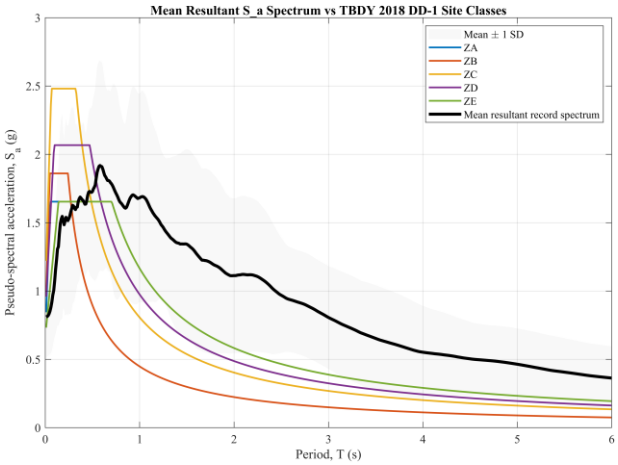

Fig. 9. Mean Sa and TBDY 2018 DD-1 spectra.

5.4 Case-Based Interpretation: Rönesans Residence

To provide an engineering interpretation of the calculated spectral demands, the Rönesans Residence in Antakya was considered as a representative collapsed reinforced concrete building case discussed in previous research [11]. The building complex was located in Ekinci Mahallesi, Antakya, and consisted of A1, A2, and A3 blocks separated by expansion joints. According to the available technical information, the A blocks had two basement stories, a

ground story, and 12 normal stories, with a total height of approximately 44 m from the foundation level. The structural system was reported as a reinforced concrete wall-frame system with C30 concrete and S420 reinforcing steel [12].

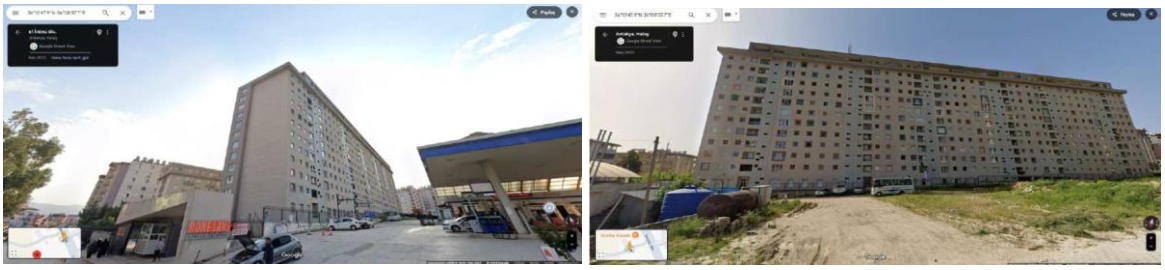

Fig. 10. Pre-earthquake Google Maps view of the Rönesans Residence, reproduced from [12].

The modal analysis results reported for the A blocks indicate first-mode periods of 2.1681 s, 2.2188 s, and 2.0036 s for A1, A2, and A3, respectively [12]. These periods were used to relate the calculated regional response spectra to the dynamic characteristics of an actual collapsed reinforced concrete building case in Antakya. It should also be noted that the reported modal periods correspond to linear elastic model properties and were used only as reference periods for spectral interpretation. Possible period elongation, stiffness degradation, and changes in effective damping during nonlinear response were not simulated in this study. The mean spectral ordinates corresponding to these first-mode periods were obtained by linear interpolation from the calculated mean resultant spectra, as summarized in Table 3.

Table 3. Fundamental periods of the Rönesans A-blocks and mean resultant spectral demands.

Block	Structural Condition	T_1 (s)	T_2 (s)	Mean $S_a(T_1)$ (g)	Mean $S_v(T_1)$ (cm/s)	Mean $S_d(T_1)$ (cm)
A1	Collapsed	2.1681	1.7802	1.12	379	131
A2	Collapsed	2.2188	1.7574	1.11	385	136
A3	Collapsed	2.0036	1.6840	1.11	348	111

Note: Spectral demands were obtained by linear interpolation from the calculated mean resultant spectra at the first-mode periods.

The interpolated values indicate that the first-mode periods of the Rönesans Residence A blocks correspond to mean pseudo-spectral acceleration values of approximately 1.11–1.12 g, mean pseudo-spectral velocity values of approximately 348–385 cm/s, and mean spectral displacement values of approximately 111–136 cm. These values show that the case-study building periods fall within a range where velocity- and displacement-related demands remain significant. To visually support this case-based interpretation, the fundamental periods of the Rönesans Residence A blocks were also marked on the mean resultant S_a, S_v, and S_d spectra, as shown in Figure 11. Previous research on the Rönesans Residence and similar post-2000 reinforced concrete buildings described this failure type as an uprooting collapse mechanism and emphasized that such collapses may occur when several adverse conditions act together, including high velocity demand, flexible load-bearing systems, improper structural member configuration, and high height-to-width ratio [11]. In the present study, the high S_v and S_d demands observed near the Rönesans A-block period range are therefore consistent with the need to evaluate not only acceleration-related demand, but also velocity- and displacement-related demand when interpreting the seismic performance of flexible reinforced concrete

buildings. This case-based interpretation does not aim to establish a direct collapse causality for the Rönesans Residence. Such a conclusion would require building-specific nonlinear analyses, detailed as-built information, construction quality assessment, soil-structure interaction evaluation, and complete damage observations. However, the spectral ordinates corresponding to the fundamental period range of the Rönesans Residence A blocks provide a practical connection between the regional spectral demand results of this study and an actual collapsed reinforced concrete building case in the Hatay region.

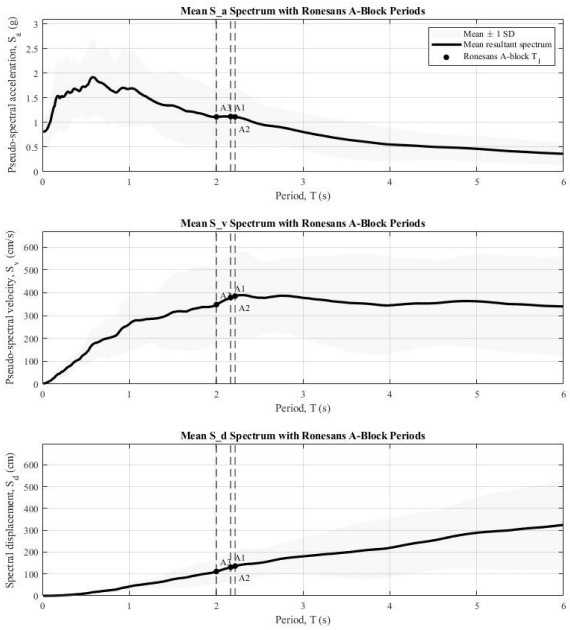

Figure 11. Rönesans Residence A-block periods marked on the mean resultant Sa, Sv, and Sd spectra.

5.5 Engineering Implications of Velocity- and Displacement-Related Demands

The results indicate that the selected Hatay records cannot be interpreted only through acceleration-related parameters. The Sv and Sd spectra show significant velocity-sensitive and deformation-related demands, including cyclic deformation, drift concentration, residual drift, and second-order P-Δ effects. This interpretation is consistent with the Rönesans Residence case; however, it does not establish direct collapse causality. The comparison with TBDY 2018 spectra should therefore be regarded as a code-based reference rather than a substitute for detailed site response or nonlinear structural performance analysis. Future studies should include station-specific geotechnical data, site response analyses, and nonlinear evaluations of representative reinforced concrete buildings.

6 Conclusions

In this study, acceleration, pseudo-spectral velocity, and spectral displacement response spectra were evaluated for selected strong ground motion records obtained from the Hatay region during the February 6, 2023 Pazarcık earthquake. Thirteen AFAD stations and both horizontal components of each record were considered, and the calculated spectra were compared with TBDY 2018 elastic design spectra for different local site classes. The following conclusions can be drawn from the study:

· The selected Hatay records produced significant spectral demands over a wide period range. The mean resultant pseudo-spectral acceleration spectrum reached approximately 1.9 g in the medium-period range, while some individual records produced considerably higher demands. This indicates that the ground-motion demand in the region was highly variable and dependent on station location and period range.

· The seismic demand was not limited to acceleration-related effects. The pseudo-spectral velocity and spectral displacement spectra remained high in the medium- and long-period ranges, indicating considerable velocity-sensitive and deformation-related demands. Therefore, velocity- and displacement-related spectral quantities should be evaluated together with acceleration-based parameters.

· The comparison with TBDY 2018 design spectra showed that the selected Hatay records produced demands clearly above the DD-2 design level over a broad period range and locally comparable to the DD-1 level in some intervals. This exceedance was observed not only in the acceleration spectrum but also in the velocity and displacement spectra.

· The comparison of different local site classes showed that soil-dependent design parameters significantly affect the spectral shape. While SDS mainly controls the short-period acceleration demand, SD1 becomes more influential in the medium- and long-period velocity and displacement demands. Therefore, local site effects should be considered together with Sa, Sv, and Sd when evaluating seismic demand.

· The case-based interpretation using the Rönesans Residence indicates that the fundamental period range of a collapsed reinforced concrete building in Antakya coincides with the period range where high velocity- and displacement-related demands were observed. However, since the present study is based on selected strong motion records and code-based local site class comparisons, future studies should include station-specific geotechnical data, detailed site response analyses, near-field ground motion characteristics, and nonlinear structural performance evaluations of reinforced concrete buildings in the Hatay region.

Abstract. This study summarizes the results of an experimental program conducted at the Laboratory of the National Centre for Applied Research in Earthquake Engineering (CGS)-ALGERIA, which examined the cyclic axial behavior of cold-formed steel studs. Three distinct specimen lengths (L = 2000 mm, L/2 = 1000 mm and L/4 = 500 mm) were used to determine specific buckling modes, such as local, distortional or global buckling. There were four specimens in each group. Each group underwent two cyclic axial loading tests, as well as two monotonic axial concentric loading tests (one compression and one tension). The cyclic loading protocol was modelled on FEMA 461, and the initial displacement was derived from the monotonic testing. The results showed that the slenderest specimens are more susceptible to localized geometric imperfections in the edge stiffeners due to their deformation capacity and behavior. As height decreases, the interaction between local buckling and global flexural buckling also decreases. These results provide valuable empirical evidence to inform the design of seismic codes, particularly with regard to predicting failure mechanisms and energy dissipation in thin-walled members. This study provides practicing engineers with a rational basis for optimizing stud slenderness ratios and stiffener detailing in earthquake-resistant, cold-formed steel framing, by quantifying instability modes under cyclic loads. It also provides researchers with a validated experimental benchmark for creating more accurate numerical models that capture interactive buckling under severe loading histories.

Keywords: Cold-formed steel column, Axial loading, Hysteretic load-deformation behavior, Buckling.

1 Introduction

Cold-formed steel (CFS) sections are becoming increasingly common in modern construction, particularly in low and medium-rise commercial, industrial and residential buildings. They have several advantages over hot-rolled steel sections, including a higher strength-to-weight ratio, faster fabrication, higher recycling rates and lower carbon emissions. However, the thin walls of CFS sections make them prone to instability, including local and global buckling modes [1, 2, 5, 7]. These buckling interactions become much more complex under seismic loading conditions, so a thorough understanding of the cyclic axial behavior of the CFS structural members is required. Understanding the hysteretic behavior and energy dissipation capacity of these sections is essential for performance-based seismic design.

Unlike hot-rolled steel sections, CFS members exhibit complex buckling interactions that can significantly influence their deformation and failure modes under cyclic loading [5,7]. Cold-formed steel lipped channel sections are commonly used as studs in shear wall panel systems. They are prone to three main types of buckling modes: local buckling (local instability of the flange or web), distortional buckling (distortion of flange and lip relative to web), and

global buckling -flexural or flexural-torsional buckle of the entire member [1,7]. The combination of these buckling behaviors has been recognized as a key factor in determining the ultimate strength and post-buckling behavior of a CFS member [7,9].

Recent investigations have indicated that the slenderness of CFS studs has a considerable influence on the buckling behavior of CFS studs [1, 10,11]. Thin sections with larger web-height-to-thickness ratios are more susceptible to local geometric imperfections, particularly in the edge stiffener regions [1]. Moreover, the interaction between local and global buckling modes depends strongly on the member length, with shorter specimens exhibiting less interaction between local and global buckling [1,7,11]. The cyclic axial behavior of bare CFS studs has been studied and several researches has been done on the monotonic axial behavior of CFS columns [6,8,9,10,11,12,13].

Although substantial progress has been made in understanding the behavior of CFS under monotonic loading [6, 9, 14], there is limited experimental data available on the cyclic axial behavior of bare CFS studs, particularly in relation to the effect of specimen length on the interaction of buckling modes under reversed cyclic loading. Most of the existing cyclic studies have concentrated on sheathed wall panels [3,4] or beam-column members under combined loading [8], which has left a gap in understanding the fundamental cyclic axial behavior of bare studs.

This work intends to fill this gap by an experimental investigation of the behavior of cold-formed steel studs under cyclic axial loading. The specific objectives are:

1.To identify the influence of specimen length on the activation of local, distortional, and global buckling modes under cyclic axial loading;

2.To characterize the deformation capacity and failure mechanisms of CFS studs with varying slenderness ratios;

3.To investigate the interaction between local and global buckling modes as a function of member height.

Three different specimen lengths (L=2000mm, L/2=1000mm, and L/4=500mm) were selected to capture distinct buckling modes. Each group comprised four specimens, subjected to monotonic compression, monotonic tension, and two cyclic axial loading. The cyclic loading protocol was adapted from FEMA 461, with initial displacement amplitudes derived from monotonic test results.

2 Experimental program

2.1 Specimen's dimensions and materials properties

Twelve cold-formed steel section specimens were used in the experiment. As illustrated in Fig.1, the cross-section used for each specimen is 600s200-68, which was chosen from the standard sizes listed in the Structural Stud Manufacturers Association (SSMA) catalog [15].

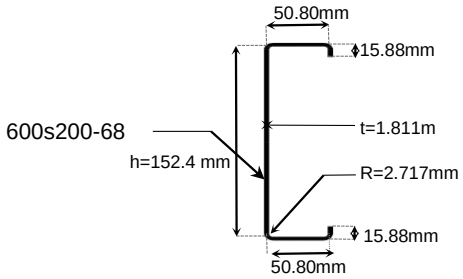

Fig. 1. Cross-section geometry 600-S200-68

Tensile tests were performed in accordance with the ASTM A370-12a 2012 criteria to determine the basic mechanical properties of the CFS utilized in the test specimens, as illustrated in Fig.2. The yield strength and ultimate tensile strength had average values of 281.62 MPa and 311.22 MPa, respectively. The elasticity modulus was assumed to be 203400 MPa in accordance with AISI S100-2012 [16].

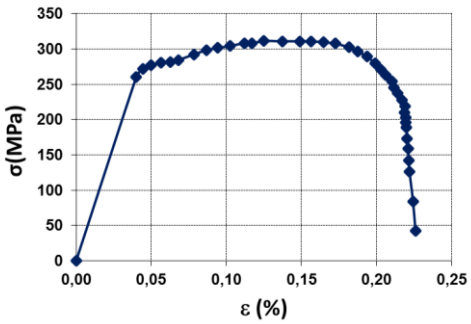

Fig. 2. Stress-strain relationship for CFS (Tensile test) [2].

The specimen's Length was varied to isolate each buckling limit state (global buckling, local buckling, and distortional buckling), Three different lengths were considered (L=2000mm, 1/2L=1000mm and 1/4L=500mm). The test program includes two specimens subjected to monotonic axial displacement (compression and tension) and two specimens subjected to quasi-static cyclic axial displacement per specimen length.

The representative load-deformation envelope and the ultimate displacement were estimated using the monotonic tests. Cyclic experiments were conducted. to ascertain the hysteretic energy dissipation and axial hysteretic response, Specimen's nomenclature is summarized in Table 1. As implemented in the real field, boundary conditions were taken to be fixed-fixed.

Table 1. Specimen's dimensions and nomenclature

Length (mm)	**Specimens**	**Test**	**Loading rate (mm/s)**
L= 2000 mm	LWOWM	Monotonic compression	0.02
	LWOWMT	Monotonic Tension	0.02
	LWOWC1	Cyclic 1	0.5
	LWOWC2	Cyclic2	0.5
1/2L= 1000 mm	1/2LWOWM	Monotonic compression	0.02
	1/2LWOWMT	Monotonic Tension	0.02
	1/2LWOWC1	Cyclic 1	0.5
	1/2LWOWC2	Cyclic2	0.5
1/4L= 1000 mm	1/4LWOWM	Monotonic compression	0.02
	1/4LWOWMT	Monotonic Tension	0.02
	1/4LWOWC1	Cyclic 1	0.5
	1/4LWOWC2	Cyclic2	0.5

2.2 Test setup and instrumentation

A loading frame was used to test the studs vertically at the National Center of Applied Research in Earthquake Engineering Laboratory (CGS)-Algeria, as shown in Fig.3(a). To transfer axial load, end plates were attached to both ends of the specimens. All out-of-plane displacements were prohibited by lateral braces.

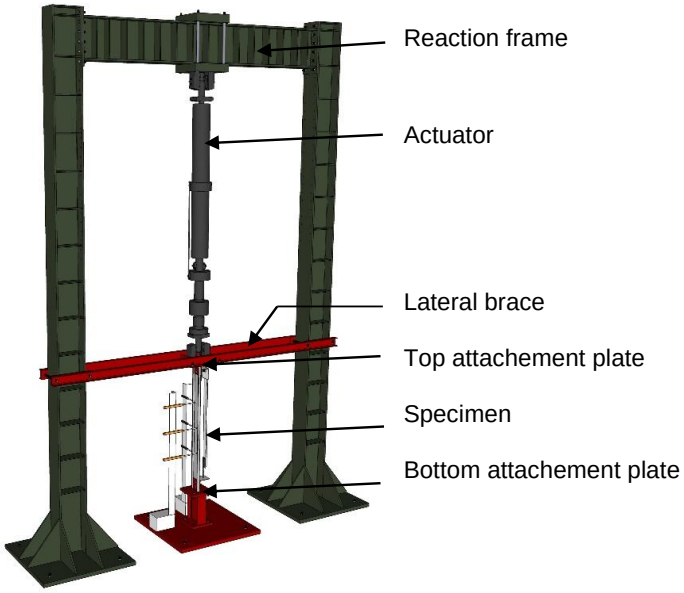

Fig. 3. Test setup.

2.3 Loading protocol

During the monotonic tests, an increasing displacement-controlled load was supplied at a rate of 0.02 mm/s until the specimen failed in tension or compression.

The approach for quasi-static cyclic loading was adapted from FEMA461. This procedure is suited for hysteretic testing, also known as racking testing, which quantifies all damage states that require the development of fragility functions [17].

Iterative cycles with increasing deformation amplitudes constitute the FEMA reversed cyclic protocol. Each amplitude consists of two cycles. The beginning amplitude is δ_0, and the final projected amplitude is δ_m. δ_i is the amplitude of the cycles as they grow in magnitude. δ_m is defined as the displacement observed when the post-peak resistance is reduced to 80% of the ultimate resistance, and it is estimated from the monotonic test. The protocol consists of six modest-amplitude δ_0=0.018 δ_m initiation cycles. The amplitude δ_{i+1} of the step i+1 (not of each cycle, since each step has two cycles) is given by the equation δ_{i+1}=1.4 δ_i where δ_i is the amplitude of the preceding step. Fig.4. shows the reversed cyclic loading history applied during the tests [17].

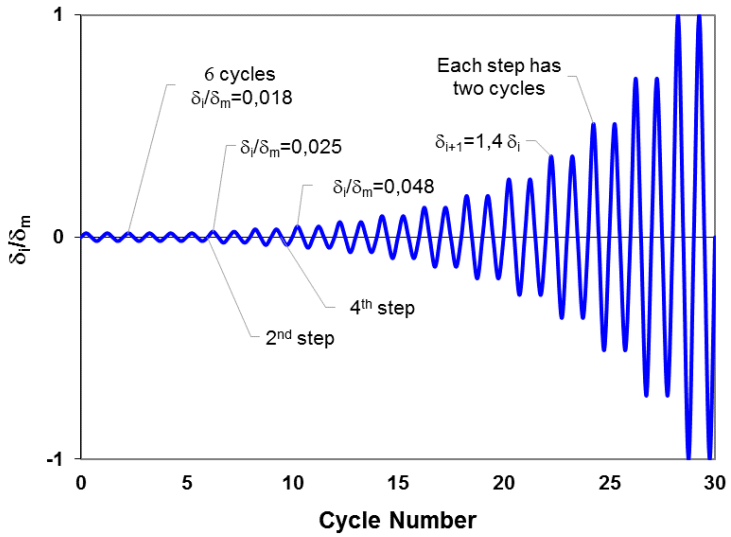

Fig. 4. Loading path [17].

3 Experimental program

3.1 Monotonic response

The LWOW specimens exhibited a monotonic response with flexural buckling of the weak axis first, followed by a few waves of local buckling when the maximum compressive load was attained (see Fig.5a). Following that, the compressive strength and stability of the LWOWs gradually declined upon unloading, with compressive damage accumulating in the mid-height (see Fig.5b).

From here on, "compression" is represented by positive displacement and "tension" by negative displacement.

(a) LWOWM- maximum compressive load (b) LWOWM-End test

Fig. 5. Deformed shape-Monotonic test-LWOW specimens

The 1/2LWOW specimens had a monotonic reaction, with many waves of local buckling occurring across the entire height of the web. This happened when the maximum compressive load was met, as illustrated in Fig.6a. The web of the part near the top end of the flanges suffered significant damage. However, as seen in Fig.6b, web deformations were more obvious than flange openings.

(a) 1/2LWOWM- maximum compressive load (b) 1/2LWOWM-End test

Fig. 6. Deformed shape-Monotonic test-1/2LWOW specimens

The 1/4LWOW specimens' monotonic response was marked by web buckling, with buckling waves occurring before reaching the maximum compressive load. After reaching the maximum load, one of the waves got stuck in mid-height, resulting in damage accumulating at this point

(see Fig.7). As indicated in Fig.8, compressive strength and unloading stiffness declined rapidly.

(a) 1/4LWOWM- maximum compressive load (b) 1/4LWOWM-End test

Fig. 7. Deformed shape-Monotonic test-1/4LWOW specimens

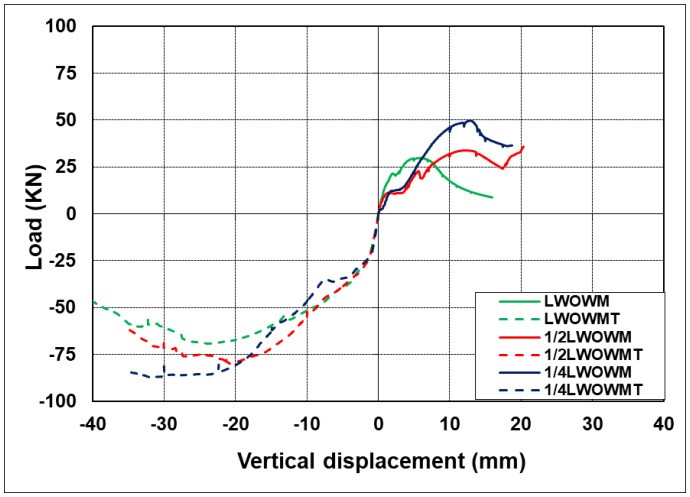

Fig. 8. Monotonic behavior

The monotonic tensile response of the specimens exhibited modest linearity in their monotonic tensile response up to 30% of the maximum tensile load, which corresponds to the onset of plastic deformation in the web, followed by nonlinearity corresponding to deformation propagating around the cross-section.

3.2 Cyclic response

Based on general test results, all specimens showed global buckling deformation about the minor axis, which interacted with local buckling.

Once the maximum compressive load was attained, the compressive strength declined faster due to the accumulation of local damage. Figs 9,10 and 11 show the deformations.

Fig.9 displays the more slender LWOW specimens, where the local-global interaction is more evident. Furthermore, it was discovered that the slendernest specimens had a capacity and deformation behavior that was more susceptible to localized geometric imperfections in the edge stiffeners. As the height reduces, there is less interaction between local buckling and global flexural buckling.

The cyclic response of the LWOW specimens was represented by buckling about the minor axis, as well as edge stiffener opening, flange bending, and section tearing at mid-height (Fig 9).

Fig. 9. Deformed shape-Cyclic test-LWOW specimens

The cyclic response of the 1/2LWOW specimens was marked by flexural buckling around the weak axis, with the flanges bending at mid-height. As well, inelastic buckling caused by warping occurred near the supports as damage accumulated at the upper end's bent flanges, which was the final failure mode, as illustrated in Fig.10.

Fig. 10. Deformed shape-Cyclic test-1/2LWOW specimens

Fig.11 indicates the cyclic response of the 1/4LWOW specimens, which included buckling along the weak axis and warping of the web and flanges at mid-height.

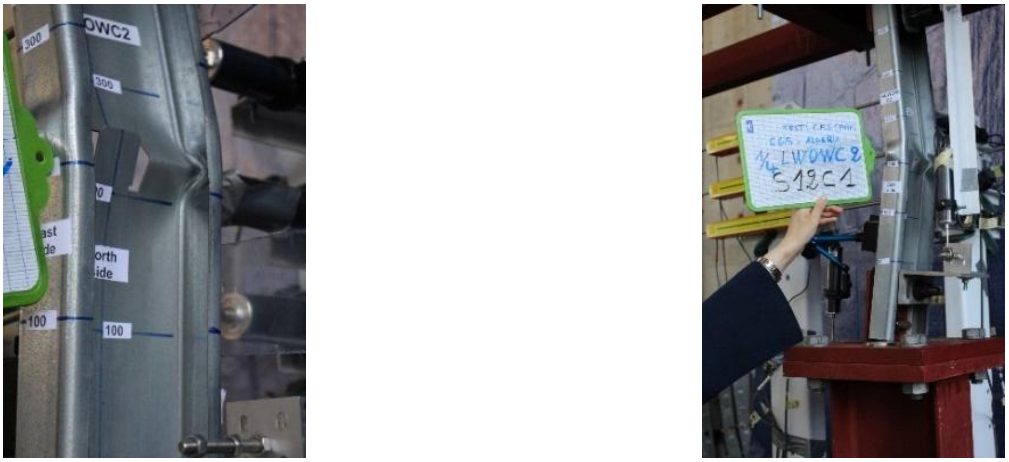

Fig. 11. Deformed shape-Cyclic test-LWOW specimens

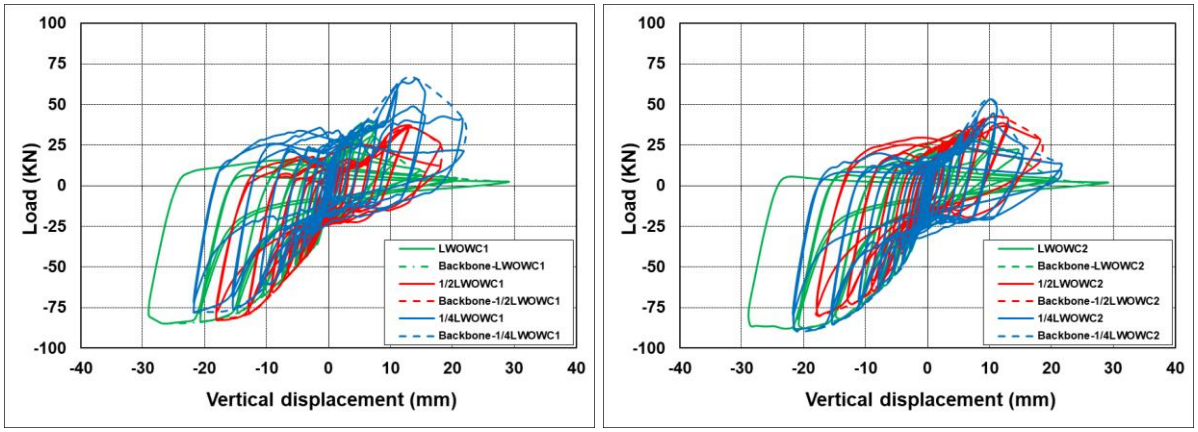

Fig. 12. Cyclic behavior

3.3 Hysteretic energy dissipation

By determining the area enclosed by a single-cycle hysteresis loop, the specimen's hysteretic energy dissipation can be determined.

Fig. 13 displays the energy dissipation time history. The findings demonstrated that, for low cycle numbers, the energy dissipation of the slendernest specimens is the most significant, and it rapidly increased for the highest number of cycles.

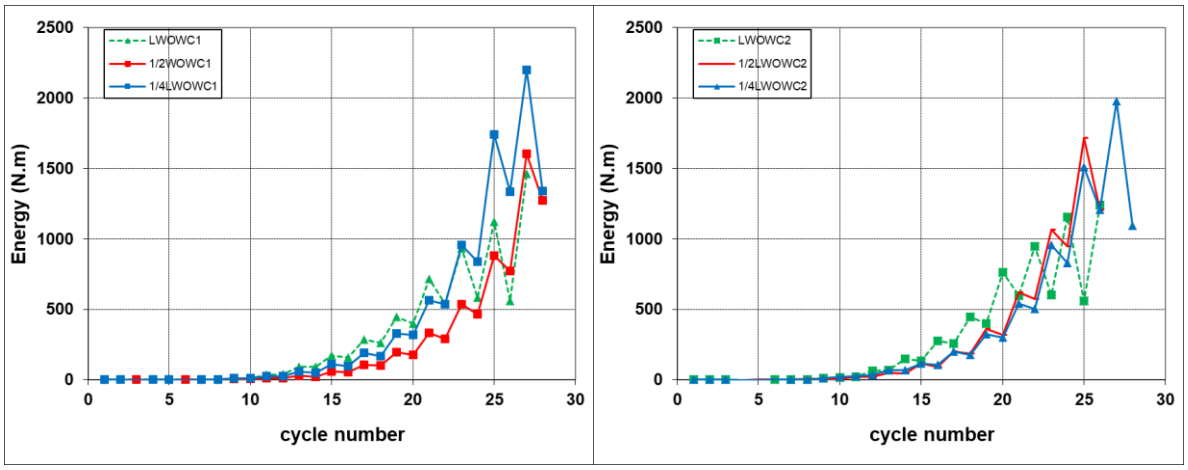

Fig. 13. Hysteretic energy dissipated

4 Conclusion

A parametric experimental investigation was conducted on cold-formed steel specimens of various heights to determine the effect of height on cyclic axial behavior and energy dissipation capacity, based on twelve monotonic and cyclic tests.

Under monotonic loading, the LWOW specimens failed in a combination of buckling and local warping, with damage accumulating at mid-height by the end of the test. Cyclic loading also caused opening of the edge stiffeners, bending of the flanges and tearing of the section at mid-height

The monotonic response of the 1/2LWOW specimens was highlighted by multiple waves of local buckling throughout the whole height, as well as considerable damage to the section's web

toward the top end. This was related to the deformation of the mid-height flanges, which was the ultimate failure mode under cyclic loads.

The 1/4LWOW specimens were distinguished by a combination of buckling and local warping of the web and flanges, with damage accumulating at mid-height by the end of the test under monotonic and cyclic loads.

It has been noticed that the slenderest specimens have a higher deformation capacity and are more sensitive to local geometric imperfections in the edge stiffeners. As the height decreases, the interaction between local and global flexural buckling becomes less pronounced.

Acknowledgments
The technical support of the National Center of Applied Research on Earthquake Engineering (CGS) for carrying this research is greatly acknowledged. As well as many thanks for the financially support by Frame-metal and Blida University.

Abstract. The continuous expansion of contemporary urban infrastructure necessitates the design of highly resilient and material-efficient cable-stayed footbridge (CSFB) structures. In this paper, an optimization framework is established by coupling the metaphor-free Rao-2 metaheuristic algorithm with finite element modeling via MATLAB and the SAP2000 OAPI environment. The central aim is to achieve a lightweight cable arrangement alongside appropriate PTF distributions while strictly satisfying all allowable stress and displacement limits under varied static and dynamic loading scenarios. Demonstrated on a numerical model of a twin-pylon steel CSFB with a modified fan cable arrangement, the proposed approach achieved a significant stay-cable weight reduction of nearly two-thirds while fully preserving structural integrity. Consequently, the results highlight the efficacy and practical applicability of the Rao-2 algorithm for multi-variable optimization in cable-stayed pedestrian bridges.

Keywords: Cable-stayed footbridge; Stay-cable optimization; Post-tensioning force; Cable cross-sectional area; SAP2000 OAPI; Rao-2 algorithm.

1 Introduction

Cable-stayed bridges have become one of the most effective and visually appealing structural solutions for medium- to long-span projects, relying on a self-anchored system in which inclined stay cables transfer deck loads directly to the pylons and thereby enable slender, elegant bridge forms whose global performance and serviceability are fundamentally governed by the intensity and allocation of prestressing loads applied to the stay cables. Consequently, determining the ideal initial prestressing forces represents a vital phase in both bridge design and erection. These forces are essential to establishing a viable equilibrium state wherein the completed bridge matches its intended profile under permanent dead loading, minimizes girder and pylon bending moments, and ensures a balanced stress distribution within safe deflection thresholds. Nevertheless, identifying such optimal forces is exceptionally challenging due to system nonlinearities, high dimensional complexity, and strong structural component coupling.

As modern bridge layouts often feature scores or even hundreds of individual cables, the resulting design space expands substantially, making conventional trial-and-error techniques and manual iterative calculations impractical and excessively labor-intensive. To overcome this difficulty, five main categories of methods have been introduced. The trial-and-error method, the most conventional and instinctive approach, relies primarily on the engineer's experience and skill, manually adjusting cable forces through repeated structural analyses until a satisfactory, though not necessarily optimal, solution is reached, and is widely recognized as time-consuming, costly, and almost impossible to apply to large and complex bridges. The zero-

displacement method of Wang et al. [1] identifies the cable tensions that return the deck and pylons to their specified design geometry under permanent dead load, minimizing vertical deck drop and horizontal pylon displacement while accounting for important nonlinearities such as cable sag and large-displacement (P-Delta) effects, although it proves computationally intensive and thus less effective for modern long-span bridges. The force equilibrium method of Chen et al. [2] instead concentrates on the internal force state, computing initial cable tensions that produce a predefined distribution of bending moments along the deck girder, an approach proclaimed easier and more powerful for practical design, particularly of prestressed concrete bridges, but one that usually assumes linear elastic, force-based equilibrium and may not account for the considerable geometric nonlinearities that develop during construction and service. The unit load method of Janjic et al. [3] offers a more complete framework that employs influence matrices to relate small variations in cable forces to variations in internal forces and displacements, enabling the structured incorporation of construction sequence, nonlinear geometric behavior, and time-dependent effects such as concrete creep, shrinkage, and steel relaxation, though it may not always yield a perfectly balanced and optimal distribution of cable forces and girder bending moments for super long-span bridges. Finally, optimization methods, as formulated by Boyd and Vandenberghe [4], systematically select the best possible solution by minimizing or maximizing an objective function while satisfying all equality and inequality constraints, allowing engineers to express design, control, and resource-allocation problems as mathematical programs and thereby find solutions with the best performance, least cost, or maximum reliability within specified limits.

Within an optimization-oriented approach, this study addresses the concurrent sizing and prestress force determination of stay cables by coupling the Rao-2 metaheuristic algorithm with MATLAB [5] and the SAP2000 [6] Open Application Programming Interface (OAPI). The primary objective is to achieve a lightweight cable system subject to stress and displacement boundaries under multiple static and dynamic load combinations. Through this strategy, the study seeks to characterize load-sharing mechanisms among structural components and clearly identify the dominant constraints—specifically differentiating between stress-governed and displacement-controlled bridge responses.

2 Structural Model Description of the bridge

The selected case study shown in *Fig. 1* is a double-pylon, modified fan-type cable configuration steel footbridge [7], chosen to investigate the application of the Rao-2 optimization algorithm in determining the optimal cable forces and cable dimensions. The footbridge, adopted from [7], spans a total of 61.30 m, with a 32.70 m central section supported by two 12.95 m steel pylons of hollow rectangular section, each carrying a modified fan-type arrangement of 14 stay cables per pylon connected to the deck. With a deck width of 4.20 m, the hybrid system integrates longitudinal and transverse steel I-shaped beams with a 12 cm concrete slab and lateral steel bracing, while the stay cables attach to the girder at mean intervals of 4.0785 m. Following the parameters established in [7], *Table 1* presents the material and geometrical properties: 28 stay elements made of nine-strand Grade 270 tendons are configured in a modified fan layout and divided into seven symmetrical groups (A_1–A_7), carrying initial prestressing force levels between −0.0001 and −0.0014. Because its structural stiffness is disregarded during computational modeling, the 12 cm concrete deck slab functions exclusively as applied dead load.

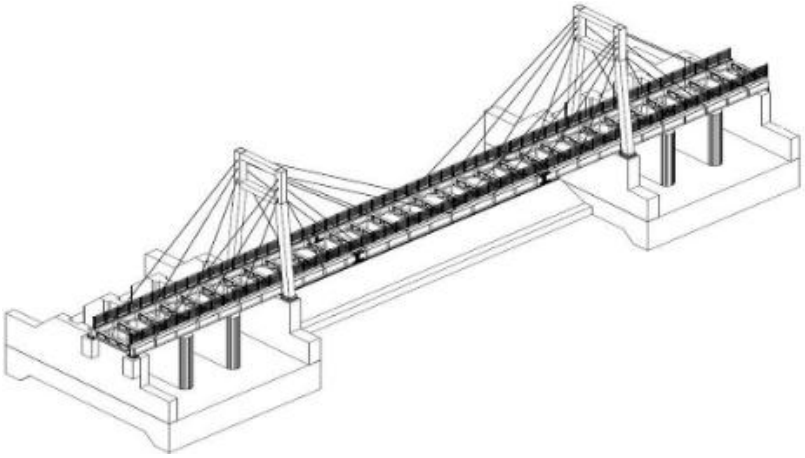

Fig. 1. Selected footbridge elevation [7].

Table 1. Stay-cable properties.

Property	Description	Value / Specification
Cable type	-	9-strand Grade270 low-relaxation prestressing steel
Ultimate tensile strength	f_{pu}	1862 MPa
Allowable stress	σ_{all}	1395 MPa (0.75 ×f_{pu})
Strand cross-sectional area	A_{strand}	140 mm²
Total cross-sectional area per cable	A_{total}	1260 mm²
Number of cables	-	28
Cable groups	-	A_1, A_2, A_3, A_4, A_5, A_6, A_7
Young's modulus	E	195 GPa
Post-tensioning strain	ε	–0.0001 to –0.0014

3 Load Combinations

Throughout this study, the load types considered in the structural analysis are identified by standard notation. Self-weight of the structural and non-structural members is captured by the dead load G, whereas the pedestrian live load Q is applied as a uniformly distributed load representing foot traffic across the deck. Wind action is treated in both principal directions, with *Wx* and *Wy* denoting the wind pressure acting along the longitudinal and transverse axes, respectively. Cable pre-stress is simulated by introducing the post-tensioning force (PTF) P as an initial strain, and seismic effects are likewise accounted for in both directions, with Ex and Ey representing earthquake excitation in the longitudinal and transverse directions, respectively. In accordance with the loading strategy defined by [7] for this bridge geometry, 14 load cases were implemented, consisting of eight static combinations (Comb1–Comb8) alongside six earthquake combinations (Comb9–Comb14); the detailed load categories and sign arrangements are detailed in *Table 2.*

Table 2. Load-combination sign patterns.

Load Combinations	Load zone on deck				Pylon-1		Pylon-2		Earthquake		Load Patterns
	1	2	3	4	W_x	W_y	W_x	W_y	U_x	U_y	
Comb1	+	+	+	+	+	+	+	+			$1.35G+1.5Q+0.9W_y+0.3W_x+P$
Comb2	+	+	+	+	+	+	+	+			$1.35G+1.5Q+0.3W_y+0.9W_x+P$
Comb3	+	-	+	-	-	+	+	+			$1.35G+1.5Q+0.9W_y+0.3W_x+P$
Comb4	+	-	+	-	-	+	+	+			$1.35G+1.5Q+0.3W_y+0.9W_x+P$
Comb5	-	+	+	-	+	+	+	+			$1.35G+1.5Q+0.9W_y+0.3W_x+P$
Comb6	-	+	+	-	+	+	+	+			$1.35G+1.5Q+0.3W_y+0.9W_x+P$
Comb7	+	-	-	+	-	+	+	+			$1.35G+1.5Q+0.9W_y+0.3W_x+P$
Comb8	+	-	-	+	-	+	+	+			$1.35G+1.5Q+0.3W_y+0.9W_x+P$
Comb9	+	+	+	+					+	+	$G+Q+0.3E_X+E_Y+P$
Comb10	+	+	+	+					+	+	$G+Q+E_X+0.3E_Y+P$
Comb11	+	+	+	+					+	-	$G+Q+0.3E_X+E_Y+P$
Comb12	+	+	+	+					-	+	$G+Q+E_X+0.3E_Y+P$
Comb13	+	+	+	+					-	-	$G+Q+0.3E_X+E_Y+P$
Comb14	+	+	+	+					-	-	$G+Q+E_X+0.3E_Y+P$

4 Methodology

A twin-pylon, modified fan-type steel cable-stayed footbridge (CSFB) was selected as the numerical model for the optimization study. The stay cables represent the main design variables of the optimization problem. Their cross-sectional areas and PTFs were simultaneously optimized to minimize the total cable weight while satisfying the required structural performance criteria. The optimization was performed by coupling the Rao-2 optimization algorithm with the finite element analysis software SAP2000 through its Open Application Programming Interface (OAPI). MATLAB was used as the main programming environment to control the optimization procedure and communicate with the SAP2000 model.

The main objective of the optimization was to minimize the total weight of the stay cables, expressed as:

$$W_{min} = \sum_{i=1}^{n_{sc}} \rho \, L_i \, A_i \tag{1}$$

Here W is the objective function defining the total weight of the cable system, ρ indicates the material density, L_i signifies the length of the i-th stay cable, A_i denotes its respective cross-sectional area, while n_{sc} represents the total number of stay cables in the bridge model.

In addition to minimizing cable weight, the optimized design was required to satisfy cable stress, deck displacement, and pylon displacement constraints. The constraint functions were defined as:

$$\mathrm{g}_i = \frac{\sigma_i}{\sigma_u} - 1 \leq 0 \; \mathrm{i} = 1, \ldots, nsc \tag{2}$$

$$\mathrm{g}_i = \frac{\delta_j}{\delta_{u-deck}} - 1 \leq 0 \; \mathrm{j} = 1, \ldots, npd \tag{3}$$

$$\mathrm{g}_k = \frac{\delta_k}{\delta_{u-pylon}} - 1 \leq 0 \; \mathrm{k} = 1, \ldots, npp \tag{4}$$

$$\text{If } \mathrm{g} > 0 \; \mathrm{c} = \mathrm{g} \text{ else } \mathrm{c} = 0 \tag{5}$$

In these expressions, σ_i and σ_u denote the computed axial stress and allowable stress limit for the cables, respectively, with nsc indicating the total number of stay cables. The terms npd and npp represent the number of nodes on the slab and towers, δ_j and δ_{u-deck} correspond to the computed and allowable vertical displacements of the deck, and δ_k and $\delta_{u-pylon}$ denote the computed and allowable horizontal displacements of the tower. When a constraint is satisfied,

the corresponding penalty parameter remains zero; otherwise, a non-zero violation value is assigned. The cumulative penalty value (C) for the entire optimization system is then determined via the following relation.

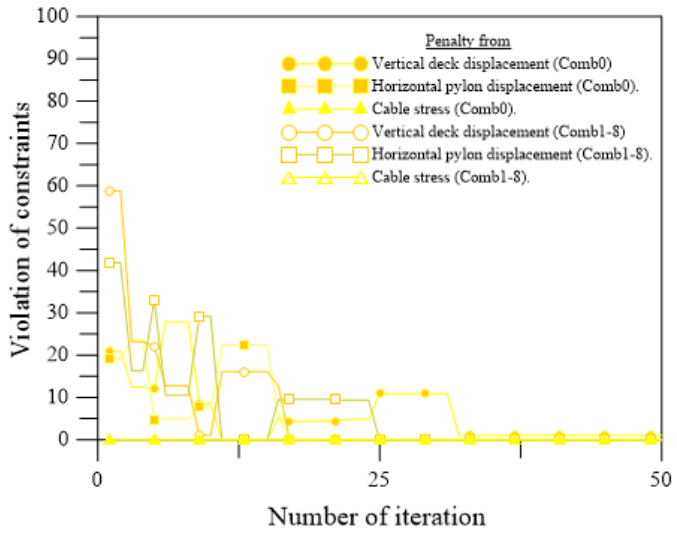
$$C = \sum_{i\,1}^{nsc} c_i \; + \sum_{j\,1}^{npd} c_j + \sum_{k=1}^{mpp} c_k \tag{6}$$

The Rao-2 algorithm is a simple, metaphor-free population-based optimization technique designed to solve complex optimization problems with a limited number of algorithm-specific parameters [8]. It improves candidate solutions by utilizing information from the best and worst solutions while also considering a randomly selected solution within the population.
The Rao-2 algorithm was employed to optimize the cross-sectional areas and PTFs of the stay cables. During each iteration, the candidate solutions are updated using the best and worst solutions of the current population, together with a randomly selected solution. Two random numbers, (r_1) and (r_2), within the range [0,1] are used in the updating process. In this study, a population size of 30 and a maximum of 1000 iterations were considered. The updated design variables were evaluated through SAP2000 using the MATLAB–OAPI interface, and the optimization continued until the maximum number of iterations was reached. The Rao-2 update equation is given as follows:

$$X'_{j,k,i}=X_{j,k,i} + r_{1,j,i}\left(X_{j,best,i} - X_{j,worst.i}\right) + r_{2.j.i}\left(\left|X_{j,k,i} or\ X_{j,l,i}\right| - \left|X_{j,l,i} or\ X_{j,k,i}\right|\right) \tag{7}$$

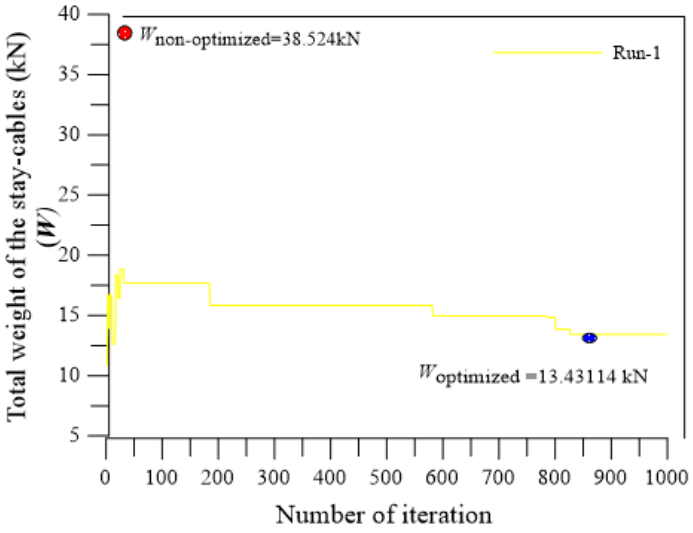
where is $X_{j,k,i}$ the value of the (j)-th design variable of the (k)-th solution at iteration (i), ($X_{j,best,i}$) and ($X_{j,worst.i}\}$) represent the corresponding variables of the best and worst solutions, respectively, and ($X_{j,l,i}$) denotes a randomly selected solution. The “or” terms are determined according to the objective-function values of the current and randomly selected solutions.

5 Numerical Results



To assess the effectiveness of the developed optimization framework, a single independent execution of the Rao-2 algorithm was carried out based on the established problem parameters. The optimization was performed to determine whether the algorithm could obtain a feasible design while satisfying the prescribed stress and displacement constraints. The evolution of constraint violations throughout the optimization process is presented in *Fig. 2(a)*.

As shown in *Fig. 2(a),* the initial design contains several constraint violations, with the most significant violations associated with the displacement responses of the deck and pylons. In particular, the vertical deck displacement under Comb1–8 represents one of the dominant violations at the beginning of the optimization, while violations in the horizontal pylon displacement are also observed. In contrast, the cable stress violation remains very small compared with the displacement-related penalties. As optimization progresses, the constraint violations generally decrease as the cable cross-sectional areas and PTFs are continuously updated by the Rao-2 algorithm. Some fluctuations can be observed during the intermediate iterations, reflecting the search process of the algorithm. The remaining displacement violations are gradually reduced, and all constraint-violation curves eventually converge to zero. This indicates that the final optimized design satisfies the required stress and displacement limits for the considered load combinations. Overall, the results demonstrate that the optimization process was primarily governed by the deck and pylon displacement constraints, whereas the cable stress constraint was comparatively less critical.



One independent optimization run was conducted using the Rao-2 algorithm to evaluate the optimization performance and determine the final optimized weight of the stay-cable system. *Fig. 2(b)* presents the variation of the total weight of the stay-cables with the number of

iterations. The initial unoptimized design had a total stay-cable weight of approximately 38.524 kN. During the initial iterations, the total cable weight showed some fluctuations as the algorithm searched for more efficient combinations of cable cross-sectional areas and PTFs. The objective function then gradually stabilized as the optimization progressed, indicating convergence toward an optimum solution. The final optimized stay-cable weight was 13.43114 kN at the 828th iteration, after which no significant improvement was observed. Compared with the initial design, this represents a substantial reduction in the total stay-cable weight while satisfying the imposed structural constraints. Overall, the convergence history demonstrates the ability of the Rao-2 algorithm to efficiently reduce cable weight and obtain a stable optimized solution.

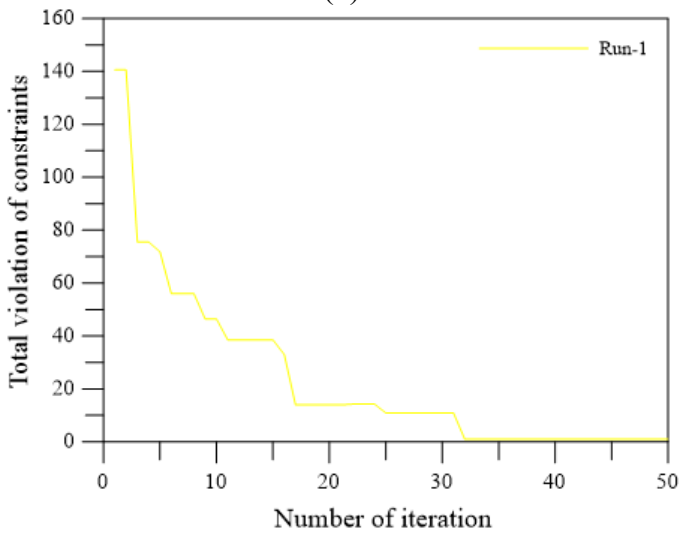


Fig. 2(c) illustrates the variation of the total constraint violation with the number of iterations for Run-1. At the beginning of the optimization process, the total constraint violation is approximately 140, indicating that the initial design does not satisfy the imposed structural constraints. As the number of iterations increases, the total violation decreases progressively, although several small fluctuations can be observed during the early and intermediate stages of the optimization. These changes reflect the adjustment of the cable cross-sectional areas and PTFs as the Rao-2 algorithm searches for a feasible solution. The total constraint violation continues to decrease throughout the optimization process and reaches zero at approximately the 34th iteration. A zero value indicates that all imposed stress and displacement constraints are satisfied. After reaching zero, the constraint violation remains at zero, confirming that the optimized solution remains within the required constraint limits. Overall, the convergence history demonstrates that the Rao-2 algorithm successfully guided the initial infeasible design toward a feasible solution within a relatively small number of iterations.

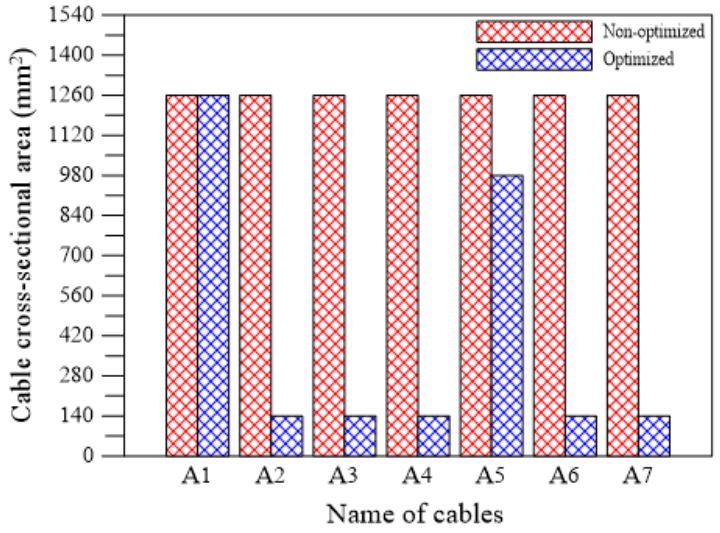
(b)



(c)

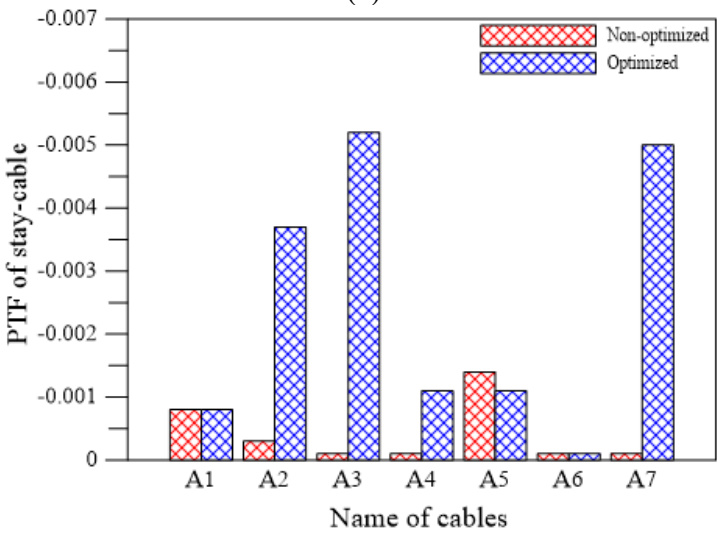


Fig. 2. Convergence of the Rao-2 optimization process: (a) individual constraint violation curves, (b) stay-cable weight across iterations, and (c) total violation of constraints.

Fig. 3(a) compares the cross-sectional areas of the stay-cable groups before and after optimization using the Rao-2 algorithm. In the non-optimized design, all cable groups have an identical cross-sectional area of 1260 mm², indicating a uniform initial cable configuration. Following optimization, the cable areas are redistributed according to the structural requirements of each cable group. The cross-sectional area of A1 remains relatively close to its initial value, decreasing slightly to approximately 1120 mm², while the areas of A2, A3, A4, A6, and A7 are significantly reduced to approximately 140 mm². In contrast, A5 retains a considerably larger cross-sectional area of approximately 980 mm², indicating that this cable group requires greater capacity to satisfy the structural constraints. This non-uniform distribution demonstrates that the Rao-2 algorithm effectively identifies cable groups where material can be reduced while maintaining sufficient capacity in the more critical cable groups. Overall, the optimized configuration results in a substantially more efficient distribution of cable material compared with the initial uniform design, contributing to the reduction in the total stay-cable weight from 38.524 kN to 13.43114 kN, corresponding to an overall reduction of approximately 65.14%.

Fig. 3(b) compares the PTFs applied to the stay-cable groups before and after optimization using the Rao-2 algorithm. The non-optimized configuration shows a relatively limited and uneven distribution of PTF among the cable groups. Following optimization, the PTF values are redistributed considerably between the different cable groups rather than being modified uniformly. The optimized solution maintains a similar PTF for A1, while noticeable increases in the magnitude of PTF are observed for A2, A3, A4, and A7. In contrast, A5 shows a slight reduction in the magnitude of the applied PTF, while A6 remains approximately zero. This redistribution indicates that the optimization process adjusts the prestressing forces according to the structural response of each cable group. The optimized PTF distribution works together with the optimized cable cross-sectional areas to satisfy the imposed displacement and stress constraints while reducing the overall cable weight. Therefore, the results demonstrate that the Rao-2 algorithm does not simply minimize the cable size but simultaneously determines a more suitable distribution of prestressing forces among the stay-cables.

6 Conclusion

This study presents a numerical optimization framework for determining the optimum cross-sectional areas and post-tensioning forces (PTFs) of stay-cables in a cable-stayed footbridge

(CSFB). The Rao-2 algorithm was integrated with MATLAB and SAP2000 through the OAPI interface to minimize the total stay-cable weight while satisfying the prescribed stress and displacement constraints. A twin-pylon, modified fan-type steel CSFB was used as the numerical model to demonstrate the applicability of the proposed optimization approach. Based on the results obtained, the following conclusions can be drawn:

- The Rao-2 optimization reduced the total stay-cable weight from 38.524 kN to 13.43114 kN, corresponding to an overall reduction of approximately 65.14% while satisfying the imposed structural constraints.
- The optimized cable cross-sectional areas were redistributed according to the structural requirements of each cable group, resulting in a more efficient allocation of cable material compared with the initial uniform configuration.
- The optimization process successfully determined suitable PTF for the individual stay-cables, contributing to the satisfaction of the required displacement and stress limits.
- The convergence results indicate that deck and pylon displacement constraints were more critical than cable stress constraints, while all imposed constraints were ultimately satisfied by the optimized design.

Abstract. This study presents a comparative assessment of the original and optimum designs of a real-world large-span steel truss roof system in terms of cost efficiency and compliance with key design constraints, including demand-to-capacity (D/C) ratios and maximum displacements. The truss system has plan dimensions of 94.25 m × 64.00 m, corresponding to a total covered area of 6032 m². Structural weight was adopted as a cost proxy, and both designs were evaluated on the same basis (i.e., identical code provisions, loading, load combinations, member grouping, and section catalog) so that they differ only in the sizing decision. The optimization was carried out using a recently developed, design-driven technique called the Capacity Controlled Search (CCS) algorithm. To mitigate run-to-run variability, 15 independent runs were performed, each capped at 500 structural analyses. The minimum-weight feasible design across all runs was selected as the optimum solution and yielded a structural weight reduction of 16.4% relative to the original engineering-office design. Notably, the heaviest design across all runs was still 11.9% lighter than the original, so that a single overnight run (10 h 33 min on a notebook PC) is sufficient in a design-office setting. Beyond direct material savings, this weight reduction translates into lower fabrication, transportation, and erection costs, as well as a reduced environmental footprint. These findings illustrate that design-driven optimization can be integrated into real engineering workflows, offering a practical and computationally affordable pathway to cost-efficient, sustainable structural design.

Keywords: Large-Span Steel Truss Roof System, Structural Design Optimization, Design-Driven Optimization, Real-World Structures, Sustainable Structural Design

1 Introduction

In modern civil engineering practice, large-span steel truss roof systems are frequently preferred for covering wide, column-free spaces such as those in sports arenas, shopping malls, and industrial facilities. They are also unusually favorable targets for optimization: they comprise hundreds of members, are highly redundant, are priced by tonnage, and are assembled from a limited number of repeated member groups, so that an improvement obtained for one group propagates across the entire roof. These structures are typically designed via iterative, trial-and-error procedures driven by engineering judgment, with member sizes selected from a discrete catalog of commercially available sections. Since designers can manually explore only a fraction of a vast design space, the resulting structures are often over-designed, leading to unnecessarily inflated material costs, which in turn cascade into higher fabrication, transportation, and erection costs, as well as a larger overall environmental footprint.

A systematic search of the design space to identify economically optimal solutions can be automated via structural optimization. Early optimization methods (e.g., mathematical programming, optimality criteria) relied on gradient information to determine search directions

[1–3]. These approaches, however, are largely impractical for real-world steel design problems characterized by discrete cross-sectional variables and nonlinear, non-convex constraints. Consequently, metaheuristic algorithms have gained significant research interest [4]. While metaheuristics can easily handle discrete variables without requiring gradient calculations, thousands of structural analyses are typically required before converging to a high-quality feasible design due to their stochastic nature. Moreover, multiple independent runs must be performed before any reported design can be trusted. This computational cost becomes especially prohibitive in practical applications, where even a single analysis can be computationally expensive owing to large models, numerous load combinations, and the nonlinear procedures increasingly required by modern codes [5].

This computational burden was largely overcome with the development of design-driven (guided) optimization methods [6–9]. These algorithms substantially accelerate the search process by leveraging structural response information obtained in previous iterations. The present study employs one such method: the Capacity Controlled Search (CCS) algorithm [10]. CCS is deliberately adopted here for its algorithmic simplicity, robustness, and fast convergence, which make it well suited to practical project schedules. CCS uses maximum demand-to-capacity (D/C) ratios to rapidly direct the search toward lighter yet highly utilized designs, while employing probabilistic rules to manage global displacement constraints and to retreat from infeasible regions.

Despite these algorithmic advances, the adoption of optimization in professional practice remains limited. One reason is that academic research is dominated by simplified or idealized benchmark structures on which algorithms are compared against one another rather than against an actual design produced by an engineering office. Applications to real structures do exist [4, 11], but they remain few relative to the benchmark literature, and differ in structural type, design code, and comparison basis. Therefore, the savings margin available within any given typology cannot yet be regarded as established; what is needed, then, is not a further demonstration that optimization is feasible on a real structure, but the accumulation of same-basis, code-compliant comparisons across practical typologies, each reported together with the analysis budget it consumed. The remaining barriers to adopting optimization in practice are largely non-technical: limited familiarity with advanced techniques, the misconception that heavier structures are inherently safer, and an underappreciation of optimization's broader benefits among stakeholders [11].

This study presents a comparative assessment of a real-world large-span steel truss roof system covering 6032 m² (94.25 m × 64.00 m). The original engineering-office design was compared against a minimum-weight code-compliant design generated by the CCS algorithm under identical code provisions, loading, load combinations, member grouping, and section catalog, so that the two designs differ only in the sizing decision. Through this comparison, this study ultimately aims to (1) quantify the material savings achievable through optimization relative to a conventional design-office solution for the given typology; and (2) demonstrate the practical viability of design-driven optimization for real-world engineering applications in terms of computational cost and time.

The rest of this paper is organized as follows. Section 2 outlines the mathematical formulation of the structural optimization problem. Section 3 provides a brief summary of the CCS algorithm. Section 4 presents the real-world large-span truss roof system, detailing the comparative analysis between the original engineering-office design and the optimum design. Finally, Section 5 summarizes the conclusions drawn from this study.

2 Optimum Design Problem Formulation

In steel design, member sections are selected from a predefined pool of standard profiles. These available sections are ordered from the smallest to the largest and assigned index numbers

accordingly. Since using too many different section types is generally undesirable from a fabrication and erection standpoint, structural members are usually grouped, and all members within the same group are assigned the same section. Based on this approach, the discrete sizing optimization problem for a steel structure can be formulated as follows:

$$\mathbf{I^T} = \left[I_1, I_2, \dots, I_{N_g}\right] \tag{1}$$

$$W = \sum_{i=1}^{N_g} \gamma_i A_i \sum_{j=1}^{N_{m,i}} L_{j,i} \tag{2}$$

$$g_k \leq 0, \quad k = 1, 2, \dots, N_c \tag{3}$$

where $\mathbf{I}$ is the vector of section indices assigned to the N_g member groups; γ_i and A_i are the unit weight and cross-sectional area of group i, respectively; $N_{m,i}$ is the number of members in group i; $L_{j,i}$ is the length of member j in group i; g_k is the $k-th$ normalized design constraint; and N_c is the total number of constraints.

A design is considered feasible only if it satisfies the relevant code requirements. In this study, the strength and serviceability constraints are defined according to the Turkish Structural Steel Design Specification [12]. The following constraints are considered.

For doubly and singly symmetric members under combined axial force and bending moment:

$$\left(\frac{P_r}{P_c}\right)_j \geq 0.2, \qquad g_1 = \left(\frac{P_r}{P_c}\right)_j + \frac{8}{9}\left(\frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}}\right)_j - 1.0 \leq 0 \tag{4}$$

$$\left(\frac{P_r}{P_c}\right)_j < 0.2, \qquad g_1 = \left(\frac{P_r}{2P_c}\right)_j + \left(\frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}}\right)_j - 1.0 \leq 0 \tag{5}$$

For members subjected to shear force:

$$g_2 = \left(\frac{V_r}{V_c}\right)_j - 1 \leq 0 \tag{6}$$

For tubular and box-section members subjected to the combined effects of torsion, shear, bending, and axial force:

$$\left(\frac{T_r}{T_c}\right)_j \geq 0.2, g_3 = \left(\frac{P_r}{P_c} + \frac{M_{rx}}{M_{cx}} + \frac{M_{ry}}{M_{cy}}\right)_j + \left(\frac{V_{\mathrm{rx}}}{V_{\mathrm{cx}}} + \frac{V_{\mathrm{ry}}}{V_{\mathrm{cy}}} + \frac{T_r}{T_c}\right)_j^2 - 1 \leq 0 \tag{7}$$

Here, g_1, g_2, and g_3 denote the strength constraints for members under axial force and bending, shear, and combined axial force-bending-shear-torsion effects, respectively. P_r, M_{rx}, M_{ry}, V_{rx}, V_{ry}, and T_r represent the required axial force, bending moments, shear forces about the x- and y-axes, and torsional moment, respectively. P_c, M_{cx}, M_{cy}, V_{cx}, V_{cy}, and T_c are the corresponding available strengths defined by the design code. The x and y subscripts refer to the major and minor axes.

For large-span steel roof systems, serviceability requirements are also important. Therefore, the displacement constraint for the roof trusses is defined as:

$$g_4 = \frac{\Delta_i^{max}}{\Delta_i^a} - 1 \leq 0 \tag{8}$$

Here, Δ_i^{max} is the maximum displacement of truss i under the governing load combinations, and Δ_i^a is the allowable displacement limit.

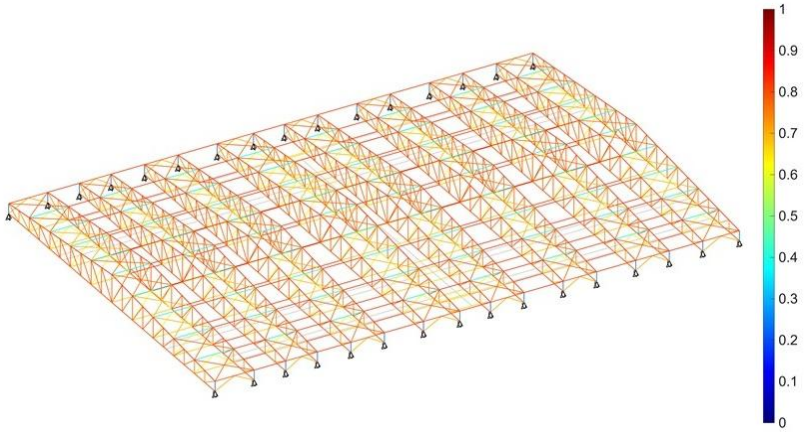
In this study, an exterior penalty function approach [13] is used to handle constraint violations. Designs violating one or more constraints (i.e., infeasible designs) are penalized through the following expression:

$$\phi = W[1 + Penalty(\mathbf{I})] = W\left[1 + r_o\left(\sum_{k=1}^{N_c} \max(0, g_k)\right)\right] \tag{9}$$

where ϕ is the penalized objective function, g_{k} is the $k-th$ normalized constraint, N_c is the total number of constraints, and r_o is the penalty coefficient, taken as 1.0 in this study. At the end of the optimization process, the lightest feasible design obtained during the search is selected as the optimum solution.

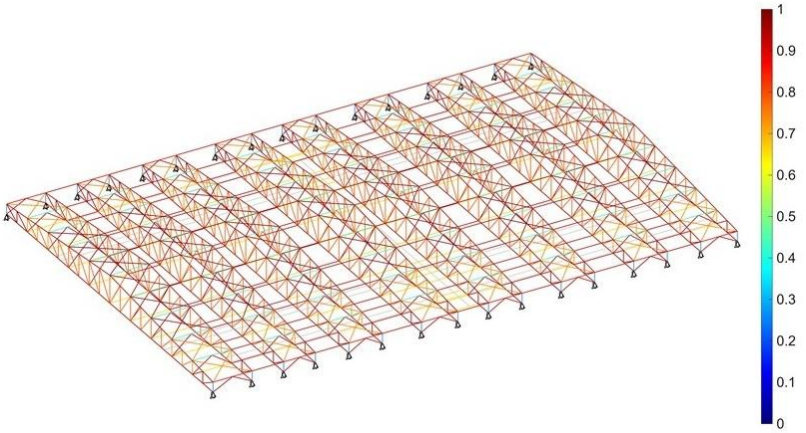
3 Optimization Algorithm

The optimization was performed using CCS algorithm [10], a design-driven optimization method that uses maximum D/C ratios to quickly guide the search toward near-optimal solutions. The search process is initialized with the largest available sections for each member group. The penalized weight and the group-wise maximum D/C ratios are then evaluated. Next, a candidate design is generated by perturbing member groups, where modification likelihoods and adaptive step sizes are determined based on corresponding D/C ratios. Similarly, displacement constraints are handled with D/C ratio-based probabilistic rules to retreat from infeasible regions. Candidate solutions are first screened using a pre-analysis objective function, and only promising designs undergo full structural analysis. A candidate replaces the current elite design only if it yields a lower objective function value. In case of a prescribed number of non-improving iterations, a stagnation escape period (SEP) is activated. During SEP, limited uphill moves are temporarily allowed to escape from a local optimum. The search is terminated when a stopping criterion is satisfied. Full details regarding the implementation steps of the CCS algorithm are provided in Eser and Hasançebi [10].



4 Real-World Design Case: 1941-Member Large-Span Steel Truss Roof System

In this study, a large-span steel truss roof consisting of 1941 steel truss members is optimized (Fig. 1). The roof has plan dimensions of 94.25 m × 64.00 m, and the maximum truss depth is 5 m. In line with the problem formulation of the original design, the members are divided into 17 sizing groups and assigned sections from two distinct S355 profile lists: H-sections and CHS (tube) sections. In the design, 121 load combinations are considered, including 115 for strength checks and 6 for deflection control, with the maximum vertical truss displacement limited to L/300 (21.3 cm). The analysis and design of the structure were performed on SAP2000 [14], whereas the optimization algorithm was coded to run in MATLAB [15].



To mitigate run-to-run variability, 15 independent runs were executed, each capped at 500 structural analyses, and the minimum-weight feasible design obtained across all runs was adopted as the optimum. All runs terminated feasible, with design weights ranging from 296.41 t to 308.47 t. The optimum design weighs 296.41 t, resulting in a reduction of 48.62 t (16.4%) relative to the original design, which weighs 345.03 t. These designs are tabulated in Table 1. The group-based D/C ratios in Fig. 1 reveal that the members are utilized more efficiently in the optimum design than in the original design. Both designs satisfy the deflection limit, the

maximum vertical displacement increasing from 13.4 cm to 15.6 cm (73% of the allowable value), which indicates that the optimum design is governed by strength rather than serviceability.

Regarding computational cost, the best run was initialized with the largest available cross-sections and located optimum design at 273rd analysis, after 5 h 45 min of computation on a notebook PC with an Intel i7-12700H processor and 32 GB DDR5-4800 RAM; the run then continued to the cap of 500 analyses, requiring 10 h 33 min in total. Since even the heaviest of the 15 designs remains 11.9% lighter than the original engineering-office design, a single run would suffice in a design-office setting, placing the computational demand at one overnight job for a structure of this size.

(b) Optimum Design

Fig. 1. Group-based D/C ratios of original and optimum designs for 1941-member truss roof system

5 Conclusion

In this study, a real-world large-span steel truss roof system with a total covered area of 6032 m² was designed for minimum weight using the Capacity Controlled Search algorithm. The results show that a 16.4% (48.62 t) reduction in structural weight relative to the original engineering-office design can be achieved while satisfying all design constraints. A lighter structure translates into lower material, fabrication, transportation, and erection costs as well as a reduced environmental footprint, thus promoting sustainable construction. Since the heaviest design across 15 independent runs is 11.9% lighter than the original design, even a single overnight run (10 h 33 min on a notebook PC) is sufficient in a design-office setting. Therefore,

design-driven optimization is practically suitable for integration into real-world engineering workflows.

Progressive Collapse of Reinforced Concrete Buildings with Ground-Floor Slab Discontinuity: Effectiveness of the Tie Force Method and the Role of Column Orientation

Alaaddin ALJUNEED[1], Temel TÜRKER[1]

1 Department of Civil Engineering, Karadeniz Technical University, 61080 Trabzon, Türkiye
aljuneed@ktu.edu.tr · temelturker@ktu.edu.tr

Abstract. Diaphragm discontinuity is treated by current seismic codes purely as an in-plane force-transfer problem, and the indirect tie force (TF) design route of UFC 4-023-03 presumes that internal ties run uninterrupted across the floor and that peripheral ties form a closed ring. A large slab opening violates that premise geometrically, yet no provision addresses it. This study examines, through 60 nonlinear dynamic column-removal analyses in LS-DYNA, how a ground-floor slab opening of constant area but varying position affects progressive collapse response, and whether the TF method remains effective when the diaphragm is interrupted. A three-storey 4×3-bay reinforced concrete frame-slab building is used as the regular reference; three opening layouts of equal area (corner, central and full-row) are generated, and all four buildings are then redesigned according to UFC 4-023-03, giving four matched pairs that differ only in tie reinforcement. The numerical model reproduces the full-scale corner-column removal test of Adam et al. (2020) with 0.0% error in peak and +5.6% in residual displacement. Peak displacements range from 15.1 to 30.0 mm and chord rotations remain below 40% of the UFC acceptance limit, placing the entire response in the flexural regime: compressive arch action is not even reached. The effect of the discontinuity varies between −0.9% and +37.8% depending on the scenario, governed by whether the opening interrupts the alternate load path at the position of the removed column rather than by its area. Tie reinforcement reduces peak displacement by 7.5–8.7%, but the measured rotations are only 1.6–3.1% of the 0.20 rad on which the method relies; three independent observations show the gain to be a flexural stiffness effect rather than the intended catenary action. Tied buildings with openings do not reach the performance of the untied regular building. Finally, column orientation emerges as an independent governing parameter: two long-edge columns carrying loads within 0.3% of each other produce peak displacements 41% apart depending on which axis the remaining bridging supports bend about.

Keywords: Progressive collapse; Diaphragm discontinuity; Tie force method; Alternate path method; Nonlinear dynamic analysis; LS-DYNA

1. Introduction

Progressive collapse is the propagation of an initial local failure from element to element until a portion of the structure — or the whole of it — is lost, and the final damage is disproportionate to the triggering event (Starossek, 2014). Since the Ronan Point and Alfred P. Murrah Federal Building failures, design guidance has converged on two complementary routes. The indirect route prescribes minimum continuity, ductility and redundancy through tie forces, without requiring any removal analysis. The direct route, the Alternate Path (AP) method, removes a load-bearing element and verifies that the remaining structure can bridge over the resulting gap. GSA (2016) and UFC 4-023-03 (DoD, 2016) are the two documents most widely used for both, and their application to reinforced concrete framed buildings has been examined in detail by Helmy et al. (2012).

The tie force (TF) method of UFC 4-023-03 rests on a specific mechanical premise: that under a column loss the floor system develops tensile membrane and catenary action, and that the tie reinforcement is able to sustain its design force at a rotation of 0.20 rad (McKay et al., 2012). Equally important, and more often overlooked, is a geometric premise: internal ties must run uninterrupted from one edge of the floor to the other, and peripheral ties must close a continuous

ring around it. A large opening in the floor slab — an atrium, a stairwell and lift core, a double-height void — breaks both continuities at the ground floor, precisely where the consequences of a column loss are most severe.

Current codes do not address this. Diaphragm discontinuity is classified as an irregularity only in relation to seismic in-plane force transfer: TBDY-2018 defines type A2 irregularity when the total opening area exceeds one third of the gross floor area, and ASCE 7-16 sets the corresponding limit at one half. Both are area-ratio criteria, and neither carries any requirement for the case of vertical element loss. Whether an area ratio is an adequate descriptor of progressive collapse vulnerability has not been tested.

The importance of modelling the slab itself is now well established. Pang et al. (2021), Cheng et al. (2024) and Mohieldin et al. (2026) all show that frame-only models substantially misrepresent the alternate load path, because the slab supplies both flexural continuity and, at large displacement, tensile membrane action. Yu and Tan (2013) quantified the displacement thresholds at which the successive resisting mechanisms are mobilised, and their results remain the standard reference for deciding which regime a given response belongs to. Studies of irregular buildings (Yavari et al., 2019; Azim et al., 2020) have concentrated on plan and vertical irregularity rather than on diaphragm openings, and where openings are considered the opening area rather than its position is the variable.

This study addresses that gap. Three slab opening layouts of identical area but different position are compared against a regular reference building, each with and without UFC tie reinforcement, under GSA-compliant column removal scenarios. The objectives are to quantify (i) how strongly the position of an equal-area opening governs the response, (ii) whether the TF method remains effective, and through which mechanism it actually works, when the diaphragm is interrupted, and (iii) an effect that emerged during the analyses and proved larger than expected — the orientation of the rectangular columns that support the bridging frame.

2. Numerical modelling

2.1. Solution scheme and material models

All analyses were carried out in LS-DYNA using the explicit central-difference solver. Concrete was represented by *MAT_CSCM_CONCRETE (MAT 159), a continuous surface cap model developed and calibrated for impulsive loading (Murray, 2007), with f'c = 30 MPa, ρ = 2380 kg/m³, maximum aggregate size 19 mm, strain-rate effects active (IRATE = 1), element erosion at ERODE = 1.05 and a maximum compressive strain of 0.08. Reinforcement was modelled with *MAT_PIECEWISE_LINEAR_PLASTICITY (MAT 24) with fy = 420 MPa, E = 200 GPa, ν = 0.3, failure strain 0.12 and Cowper–Symonds rate parameters C = 40 s^{-1} and p = 5. Reinforcement was represented by beam elements coupled to the concrete solid mesh through *CONSTRAINED_LAGRANGE_IN_SOLID, which permits an independent mesh for the bars while enforcing displacement compatibility. The mesh size was 100 mm in plane and 50 mm through the slab thickness.

The analysis followed the sequence prescribed by GSA (2016). Gravity loads under the combination wF = 1.2(D + Sw) + 0.5L were applied from zero in at least ten increments until full static equilibrium was reached. The target column was then removed with *LOAD_REMOVE_PART over a period shorter than one tenth of the vertical vibration period of the bays above it, so that the removal is effectively instantaneous. The dynamic response was followed for 1.5 s, approximately ten oscillation cycles, so that both the peak and the settled position could be read from the same record.

2.2. Validation

The model was validated against the full-scale sudden corner-column removal test reported by Adam et al. (2020), which remains one of the few experiments performed on a complete real-scale reinforced concrete building rather than a subassemblage (Yu and Tan, 2013; Qian and

Li, 2015) or an isolated flat-plate specimen (Peng et al., 2017). The comparison is given in Table 1. The peak vertical displacement is reproduced exactly; the residual value is 5.6% larger than measured, a deviation attributable to the incomplete representation of post-cycle stiffness recovery in concrete and well within the range normally accepted for this class of problem.

Table 1. Validation against the full-scale corner-column removal test of Adam et al. (2020).

	Peak vertical displacement (mm)	**Residual vertical displacement (mm)**
Test (Adam et al., 2020)	48.1	42.8
Present numerical model	48.1	45.2
Deviation	**0.0%**	**+5.6%**

2.3. Building models and removal scenarios

The reference building is a three-storey reinforced concrete frame-slab structure with 4×3 bays of 4.8 m and a storey height of 3.2 m, designed to TBDY-2018. The slab is 150 mm thick, beams are 300×500 mm and all columns are 300×600 mm with 12Ø14 longitudinal bars and Ø8/8/10/13 ties. Superimposed dead load is 2.0 kN/m² and live load 2.5 kN/m²; cladding load is 11.0 kN/m on exterior beams and 7.0 kN/m on interior beams. The rectangular columns are placed in a checkerboard pattern, with each column rotated 90° relative to its neighbours — a common arrangement in practice, and one whose consequences are examined in Section 3.3.

Three ground-floor opening layouts were generated from this reference, each removing four bay panels, i.e. approximately one third of the floor area: a corner opening (P2), a central opening (P3) and a full-row opening extending along the whole A–B band (P4). Each of the four buildings was then redesigned according to the UFC 4-023-03 tie force method, producing a second group (P5–P8) in which geometry, materials, loading and analysis settings are identical and the only difference is the tie reinforcement. The eight models therefore form four matched pairs, so that any observed difference within a pair can be attributed to the ties alone.

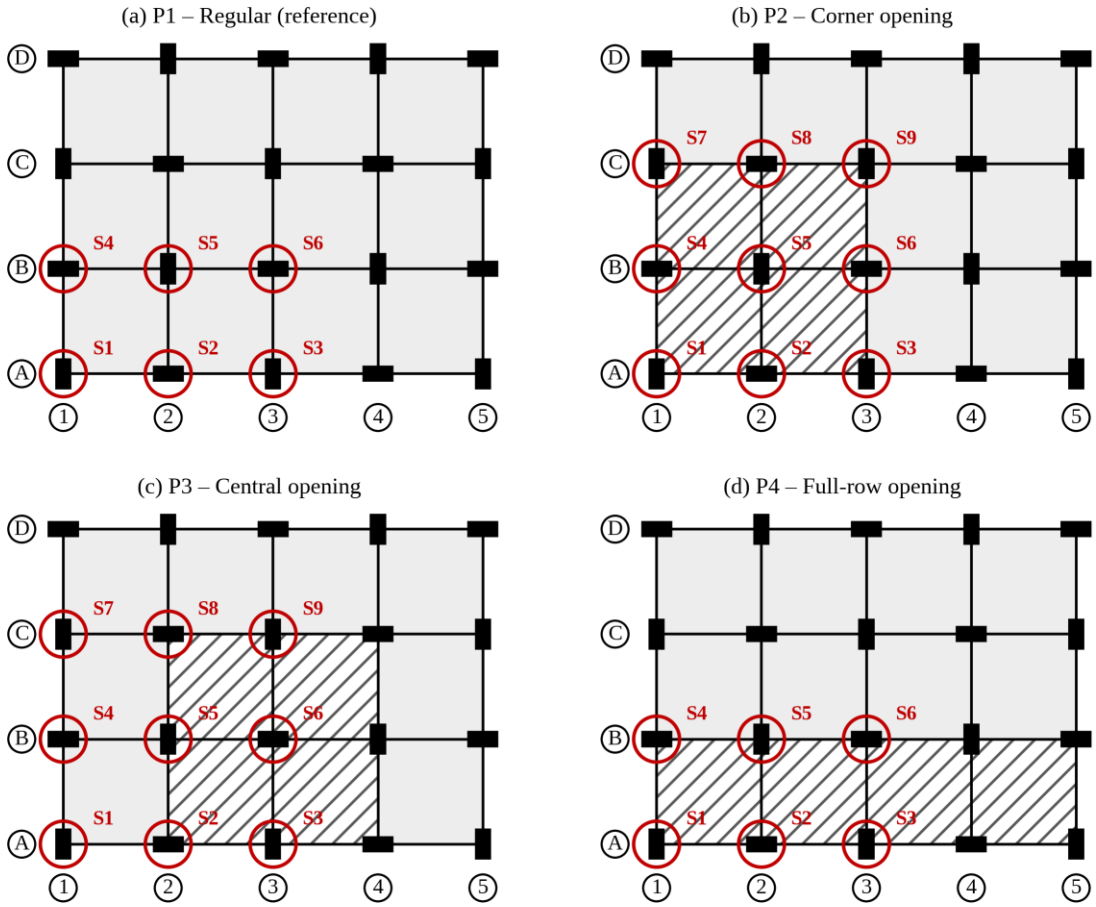

Fig. 1. Ground-floor layouts and column removal scenarios. Hatching marks the slab opening; the 300×600 mm columns are drawn to scale to show the checkerboard orientation.

Column removal scenarios follow GSA (2016), which requires the corner, long-edge, short-edge and interior positions to be examined. The scenarios S1–S9 correspond to columns A1, A2, A3, B1, B2, B3, C1, C2 and C3 (Figure 1). In the regular buildings P1 and P5, axes B and C are mirror images including column orientation, so scenarios S1–S6 represent all distinct positions. In the full-row models P4 and P8 the opening lies in the A–B band, this symmetry does not hold, and the C-axis scenarios were excluded as being remote from the opening. In the corner and central models the opening destroys both symmetries and all nine scenarios were analysed. In total 60 nonlinear dynamic analyses were performed. So that the four slab layouts are always compared on identical ground, every cross-comparison reported below is made on the common S1–S6 basis.

2.4. Tie force design

Required tie strengths were computed from the UFC 4-023-03 expressions with wF = 8.15 kN/m² and a span of 4.8 m; reinforcement areas follow from As = F / (φ · 1.25 · fy) with φ = 0.75. The results are summarised in Table 2. Internal ties were spaced at not more than 0.2L and anchored into the peripheral ties, and the peripheral ties were placed within a 1.0 m edge strip. The vertical tie requirement was satisfied by making half of the existing column longitudinal reinforcement continuous through the joints.

Table 2. Required tie forces and reinforcement according to UFC 4-023-03.

Tie type	Expression	Required force	Required As	Provided
Internal tie (both directions)	Fi = 3wF L	117.4 kN/m	2.98 cm²/m	2Ø14/m
Peripheral tie – exterior	Fp = 6wF L + 3Wc,e	287.8 kN	7.31 cm²	5Ø14
Peripheral tie – interior	Fp = 6wF L + 3Wc,i	273.4 kN	6.94 cm²	5Ø14
Vertical tie (per column)	Fv (one storey)	304.4 kN	7.73 cm²	6Ø14 cont.

2.5. Numerical reliability checks

Because the explicit scheme does not enforce energy conservation, every analysis was checked after the fact against the energy database. The hourglass energy remained below 0.9% of the internal energy and the kinetic energy below 0.4% of it during the gravity stage, confirming that the preload phase is quasi-static. The internal energy immediately before removal was identical to within 0.3% across all scenarios of a given building and 7% lower in the models with openings, consistent with the four missing slab panels. Total base reactions were 12,838–12,886 kN for the regular buildings and 11,938–12,070 kN for those with openings. In every analysis the reaction at the removed column fell to zero, and the sum of the reaction changes at the remaining columns recovered 99.7% of the removed load, confirming the redistribution calculations.

3. Results and discussion

3.1. Displacement level and the resisting regime

Peak vertical displacements at the node above the removed column are given in Table 3 for all eight buildings. They range from 15.1 mm (P5, A3 removal) to 30.0 mm (P4, A2 removal). Chord rotations were evaluated as $\theta = \Delta/L$ with L = 4800 mm. Because the mid-span stirrup spacing of 200 mm exceeds d/3 = 150 mm, the beams were conservatively classified as non-conforming, for which UFC 4-023-03 permits $\theta_{lim} = 0.0157$ rad. The computed rotations lie between 0.0031 and 0.0063 rad, the largest being 40% of the limit. No collapse mechanism formed in any model.

Table 3. Peak vertical displacement (mm) above the removed column, and maximum chord rotation for each building.

Scenario	Column	Position	P1	P2	P3	P4	P5	P6	P7	P8
S1	A1	Corner	22.9	29.0	23.7	29.2	20.8	26.0	20.8	26.0
S2	A2	Long edge	23.0	27.8	26.1	30.0	21.2	25.6	23.3	27.4
S3	A3	Long edge	16.3	17.5	22.4	19.9	15.1	16.2	20.7	18.4
S4	B1	Short edge	21.9	26.2	24.0	22.2	19.8	23.6	21.4	20.4
S5	B2	Interior	18.0	19.7	19.6	17.8	17.0	18.9	18.5	16.8
S6	B3	Interior	16.1	16.9	16.5	17.2	15.2	15.7	15.7	16.2
Mean	–	–	**19.7**	**22.8**	**22.1**	**22.7**	**18.2**	**21.0**	**20.1**	**20.9**
θmax, rad	–	–	**0.0048**	**0.0060**	**0.0054**	**0.0063**	**0.0044**	**0.0053**	**0.0049**	**0.0057**
θmax/θlim	–	–	**31%**	**38%**	**35%**	**40%**	**28%**	**34%**	**31%**	**36%**

This displacement level determines how every other result must be read. Yu and Tan (2013) located compressive arch action capacity at 0.18–0.46 times the beam depth, the onset of catenary action at approximately one beam depth and catenary capacity beyond two beam depths. For the 500 mm beams used here these thresholds correspond to 90–230 mm, 500 mm and 1000 mm respectively. The largest displacement obtained in the whole series, 30.0 mm, is one third of the lower bound for compressive arch action and 3% of the catenary threshold. The

alternate load path in these buildings is therefore established entirely in the flexural (Vierendeel) regime: compressive arch action is not even reached, and neither catenary action nor tensile membrane action of the slab is mobilised.

Two conclusions follow. First, for this class of building — regularly framed, three storeys, designed to a modern seismic code, with the slab modelled in three dimensions — the loss of a single column produces limited local damage rather than collapse, and the acceptance criterion is met with a wide margin. Second, and consequently, an assessment reduced to pass/fail conveys very little. The differences produced by the discontinuity all lie inside that margin, so they can only be seen through relative performance.

3.2. Position dependence of the discontinuity

Although the three opening layouts have identical area, the increase in peak displacement relative to the regular building varies from −0.9% to +37.8% depending on the scenario (Figure 2). What governs is not the area of the opening but the position of the removed column and whether the opening interrupts the alternate load path at that particular position.

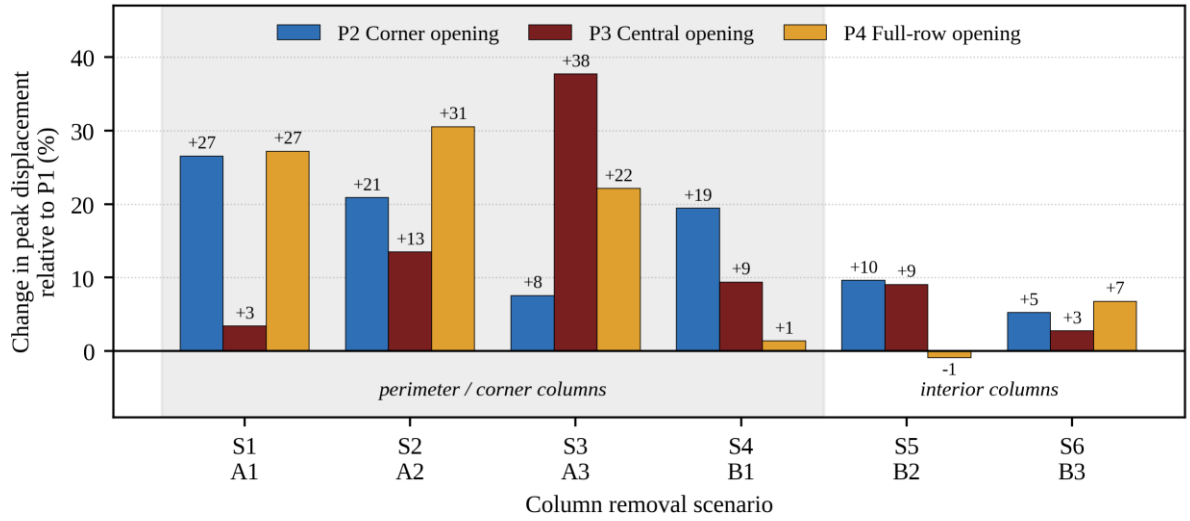

Fig. 2. Change in peak vertical displacement relative to the regular building P1, by scenario.

The full-row model illustrates this most clearly. Removing A2 raises the peak displacement from 23.0 mm to 30.0 mm (+30.5%), whereas removing B2 lowers it from 18.0 mm to 17.8 mm (−0.9%). Both columns sit on the boundary of the same opening, whose geometry, area and position are identical in the two cases. The difference is that A2 is a perimeter column: with the slab removed on one side and the building edge on the other, the alternate load path is reduced to the axis-A frame alone. B2 is an interior column; the A–B band is missing but the B–C band is intact, and four-way beam continuity is preserved. Averaged over the three layouts, perimeter scenarios show increases of +15.9% to +20.3% and interior scenarios of +2.9% to +7.4%. When the removed column is one bay away from the opening, the effect falls to the limit of measurability.

The discontinuity also makes the building sensitive to which column is lost. The spread between the most and least severe scenario within a single building is 40–43% for the regular models but reaches 48–75% for those with openings. A building with an opening is therefore not merely weaker on average; its worst case is further from its average, which is the more important property for a hazard whose location cannot be predicted.

This has a direct bearing on how irregularity limits are drawn. The opening ratio studied here sits at the TBDY-2018 type A2 threshold and below the ASCE 7-16 limit, so these buildings would not be classified as irregular under ASCE 7. Yet three layouts of identical area behave very differently from one another. An area-ratio criterion cannot distinguish between them, because the quantity that matters is whether the internal and peripheral tie paths are severed, not how much slab is missing.

3.3. The effect of column orientation

The clearest opportunity to isolate this effect is provided by two adjacent scenarios on the long edge. Columns A2 and A3 are of the same position type — perimeter, long edge — and in the regular building they carry practically the same load, 587 and 589 kN, a difference of 0.3%. Their removal nevertheless produces markedly different responses: 23.0 mm for A2 against 16.3 mm for A3, a difference of 41% (Figure 3). Repeating the comparison in the tied regular building P5 gives 40%. Since load, position type and slab layout are identical, the difference can only be attributed to column orientation.

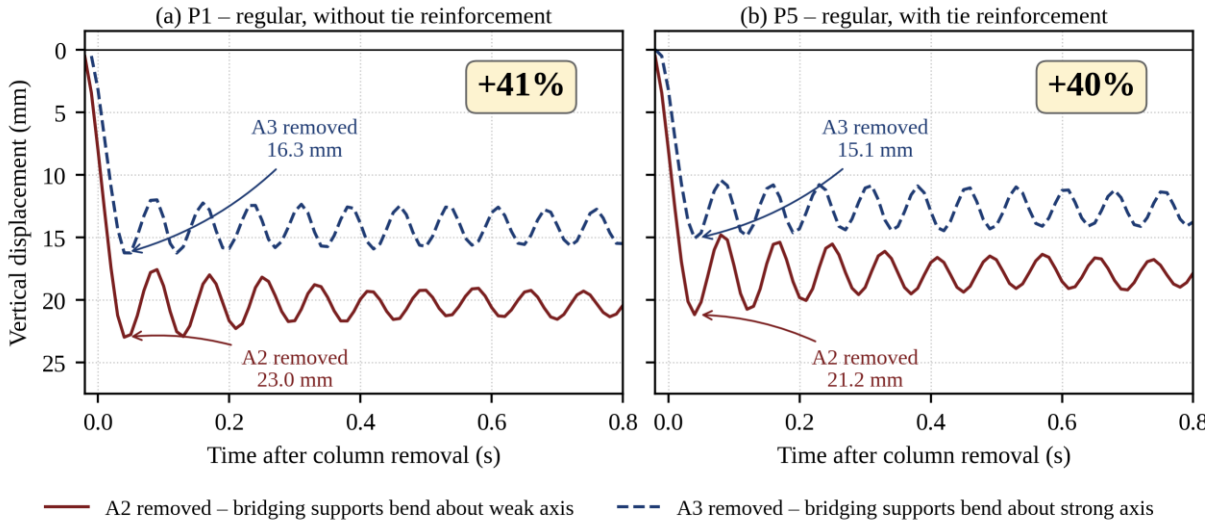

Fig. 3. Displacement histories for the removal of two long-edge columns carrying loads within 0.3% of one another, in the regular building without (a) and with (b) tie reinforcement.

The mechanism is the checkerboard arrangement. When A2 is lost, the bridging frame spans between A1 and A3, whose 300 mm dimension is parallel to the span, so both supports bend about their weak axis. When A3 is lost, the supports are A2 and A4, whose 600 mm dimension is parallel to the span. The same comparison between the interior columns B2 and B3 gives only 12%, because an interior loss develops bridging in two directions at once and the orientation of any single support matters much less.

The practical consequence is that identifying the critical removal scenario from position type and axial load alone — which is what the code scenario lists effectively do — can be wrong by 40% in a building of entirely ordinary layout. Where rectangular columns are placed in alternating orientation, the scenario set should include the perimeter column whose neighbours bend about their weak axis.

3.4. Effectiveness and actual mechanism of the tie force method

Tie reinforcement reduced the peak displacement in all four pairs, by 7.5% to 8.7% on average (Figure 4). Taken at face value this confirms the method. The difficulty is that the rotations at which it was achieved are 1.6–3.1% of the 0.20 rad on which the method is founded. At that

level the tie reinforcement is working at a very small fraction of its tensile capacity, and the improvement cannot be the catenary contribution the method intends to provide.

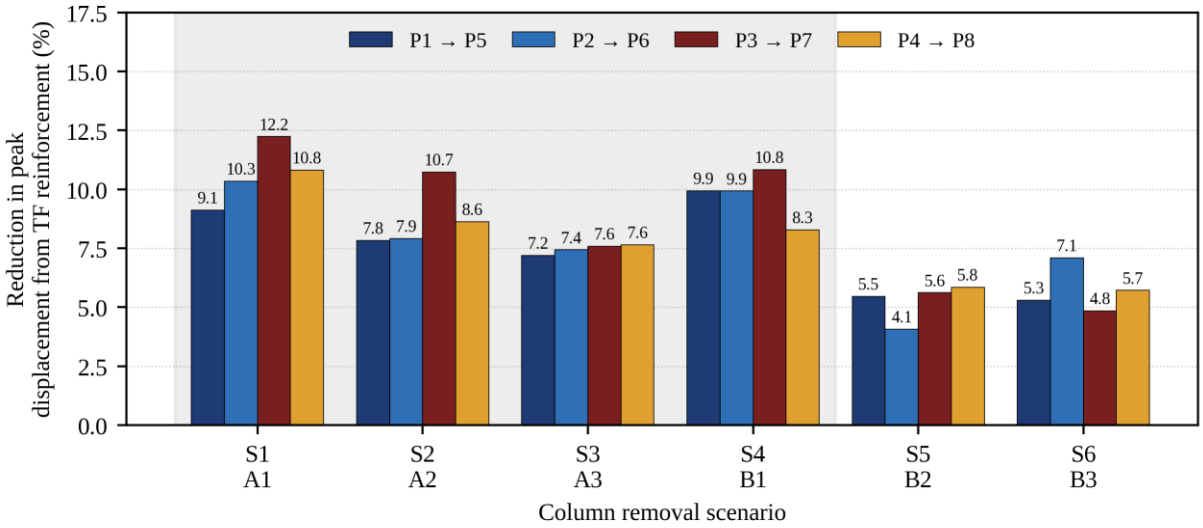

Fig. 4. Reduction in peak vertical displacement produced by UFC 4-023-03 tie reinforcement, by scenario and slab layout. Shaded band: perimeter and corner scenarios (mean 9.2%); unshaded: interior scenarios (mean 5.5%).

Three independent observations identify the mechanism as flexural instead. First, the reduction in the mean displacement at the end of the analysis (10.5–11.6%) is 1.34 to 1.47 times the reduction in the peak. The ties do not merely damp the first excursion; they raise the position at which the structure settles, which is the signature of a permanent stiffness gain rather than a transient dynamic effect. Second, the reduction at perimeter and corner scenarios (9.2%) is 1.68 times that at interior scenarios (5.5%). This follows directly from the ties lying in the top reinforcement plane of the slab, where they raise the hogging capacity and the cracked-section stiffness over the supports — the governing component of the load path precisely when the subsystem cantilevers, as it does at a perimeter or corner loss. Third, adding ties makes the redistribution more local, not less: the share taken by adjacent columns rises while that of remote columns is unchanged. A tensile chain would be expected to carry load across the opening to more distant frames; the observed trend is the opposite.

The consequences for discontinuous diaphragms are direct. Buildings with openings that have been tied according to UFC 4-023-03 do not reach the performance of the untied regular building: their mean peak displacement is 20.1–21.0 mm against 19.7 mm for P1. The penalty imposed by the discontinuity is barely changed by tying — it is +12.6% to +14.8% in the untied group and +11.2% to +14.5% in the tied group. Most tellingly, at the opening-boundary scenarios S1 and S2, which are the critical ones, no tied model with an opening falls below the untied regular reference. The tie force method reduces the loss caused by the discontinuity but does not remove it, and the assumption that it implicitly covers diaphragm discontinuity fails exactly where it matters most.

One consequence is favourable. Because the redistribution stays local, adding ties to an existing building does not require capacity re-checks on remote columns: no column in any analysis exceeded a load amplification factor of 1.56.

3.5. Load redistribution

The load released by the removed column is taken up almost entirely in its immediate neighbourhood. Adjacent columns absorb 118–142% of it — the figure exceeds unity because some columns in the ring unload — while columns three bays away or further change by only 4–7%. The distribution among the adjacent columns follows connection continuity rather than distance. When A2 is removed, the interior column B2, continuous in four directions, takes 70% of the released load, whereas the corner column A1, connected by only two beams, takes 18%. Across all scenarios, four-way continuous interior columns take 40–70% and perimeter or corner columns 14–19%.

4. Conclusions

1. Under single column loss, all eight buildings satisfied the UFC 4-023-03 acceptance criterion with a wide margin: peak displacements of 15.1–30.0 mm and chord rotations below 40% of the limit. The alternate load path formed entirely in the flexural regime; compressive arch action was not reached and catenary action was never mobilised.

2. A ground-floor slab opening of approximately one third of the floor area changes the peak displacement by −0.9% to +37.8% depending on the scenario. What governs is the position of the removed column and whether the opening severs the alternate load path there, not the area of the opening. Perimeter scenarios show mean increases of +15.9% to +20.3% against +2.9% to +7.4% for interior ones.

3. The discontinuity also widens the scatter between scenarios, from 40–43% in the regular buildings to 48–75% in those with openings, so that the worst case moves further from the average.

4. Because three layouts of identical area behave very differently, an irregularity classification based on the opening area ratio is not a sufficient indicator of progressive collapse vulnerability. The criterion should be whether the internal and peripheral tie paths are interrupted.

5. UFC 4-023-03 tie reinforcement reduced the peak displacement by 7.5–8.7%. However, the measured rotations reached only 1.6–3.1% of the 0.20 rad on which the method relies, and three independent observations — the larger reduction in the settled position, the 1.68-fold concentration of the benefit at perimeter and corner scenarios, and the increased locality of redistribution — show that the gain comes from added flexural stiffness, not from the intended catenary mechanism.

6. Tied buildings with openings did not reach the performance of the untied regular building, and the discontinuity penalty was essentially unchanged by tying. At the critical opening-boundary scenarios no tied model fell below the untied regular reference. For discontinuous diaphragms the tie force method should not be relied upon alone; the scenarios at the opening boundary warrant direct Alternate Path analysis.

7. Column orientation is an independent governing parameter. Two long-edge columns carrying loads within 0.3% of each other produced peak displacements 41% apart, according to whether the remaining bridging supports bend about their weak or strong axis. The effect falls to 12% for interior columns, where bridging develops in two directions. Scenario selection based on position type and axial load alone can therefore miss the critical case.

8. Load redistribution is strongly local: adjacent columns take 118–142% of the released load and remote columns 4–7%. The share follows connection continuity — 40–70% for four-way

continuous interior columns against 14–19% for perimeter and corner columns — and no column exceeded a load amplification of 1.56.

The results are limited to vertical-load response under single column loss; soil–structure interaction, infill contribution, multi-column loss (Parisi and Scalvenzi, 2020) and the initiating event itself were outside the scope. Because the response never approached the rotation at which the tie force method is meant to operate, the performance of that method in the catenary regime remains untested here and is the natural subject of a pushdown study on the critical scenarios.

Abstract. Rapid and reliable prediction of the nonlinear behavior of reinforced concrete elements is critical in performance-based earthquake engineering. This study develops a digital twin-based framework for machine-learning prediction of the initial stiffness, yield displacement and post-yield stiffness ratio of reinforced concrete columns and shear walls. The methodology comprises numerical model calibration in OpenSeesPy, synthetic data generation by Latin Hypercube Sampling, and a comparison of column-specific, wall-specific and unified models. The column model was calibrated on two real specimens from the PEER Structural Performance Database. For a specimen whose properties are precisely documented, the base shear capacity was predicted with a 2.9 % error; for a specimen with unverified properties, the deviation was 53.9 %. A sensitivity analysis then back-calculated the section size that reproduces the measured capacity, illustrating a diagnostic use of the digital twin: a physically plausible back-calculated value implicates a single misestimated parameter. Calibration of the wall model against experimental wall tests remains for future work. The synthetic data pipeline was verified at small scale (N = 25 per element type; 24/25 column and 25/25 wall runs converged; mean $R^2 > 0.95$). The study establishes the framework required to quantify the accuracy-practicality trade-off between component-specific and unified surrogate models in future work.

Keywords: Digital twin, Machine learning, Reinforced concrete, Seismic behavior, OpenSeesPy.

1 Introduction

Performance-based earthquake engineering requires an accurate characterization of the nonlinear behavior of structural elements. The conventional method for determining the stiffness, yield strength and deformation capacity of reinforced concrete (RC) columns and shear walls is finite-element-based pushover analysis. These analyses, however, impose a significant computational burden when large building inventories or many design alternatives must be evaluated, since each element and building configuration requires separate modeling and analysis.

Combining the digital twin concept with machine learning (ML) has recently emerged as a promising route around this bottleneck. Bárkányi et al. examined the role of surrogate models in digital twin applications and showed that such models can substantially reduce the computational cost of complex physical systems [1].

Kuria and Kegyes-Brassai developed a Random Forest-based digital twin framework using pushover curves from two hundred layered-shell models and reported coefficients of determination of 0.996, 0.995 and 0.925 for the initial stiffness, yield displacement and post-yield stiffness ratio of RC shear walls [2]. Angarita et al. predicted the pushover curves of low-rise RC frame buildings with ML models at a fraction of the computation time of nonlinear OpenSeesPy analyses [3]. At the element scale, Huang et al. proposed an XGBoost-based model for the shear strength of flexure-shear type columns [4], and Kaveh and Amiri developed a physics-informed, region-specific approach for the seismic demand of RC frames [5].

Although these studies demonstrate high accuracy and significant computational gains, the majority address a single element type. Whether a generalized architecture spanning different element types is feasible — and what accuracy is sacrificed for that generality — has not been sufficiently addressed. This study therefore proposes a digital twin-ML approach covering both RC columns and shear walls, and presents (i) parametric synthetic data generation calibrated in OpenSeesPy, (ii) a comparison of component-specific and unified models, and (iii) practical recommendations for digital twin architecture design derived from pilot calibrations on real experimental data.

2 Methodology

The proposed methodology follows a hybrid approach combining experimental data with parametric numerical modeling in OpenSeesPy. The workflow consists of five steps (Fig. 1): data collection, numerical model calibration, synthetic data generation, feature extraction, and ML model training with comparative evaluation.

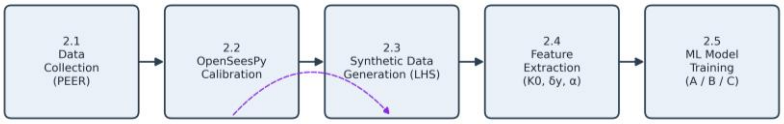

Fig. 1. Workflow of the proposed digital twin–machine learning methodology.

2.1 Data Collection

Column behavior is taken from the PEER Structural Performance Database [6], which covers rectangular- and spiral-reinforced column tests. Experimental wall data will be compiled from a separate wall test database in the next stage of the study. For every specimen the geometry, material strengths, reinforcement ratios, axial load level and the complete measured force-displacement history are compiled.

2.2 Numerical Model Calibration

Columns are modeled with fiber-section **forceBeamColumn** elements using the Concrete02 and Steel02 material models (Fig. 2). Shear walls are modeled with the MVLEM (Multiple-Vertical-Line-Element Model) formulation (Fig. 3), which keeps the computational cost low enough for the large parametric sweeps required in Section 2.3.

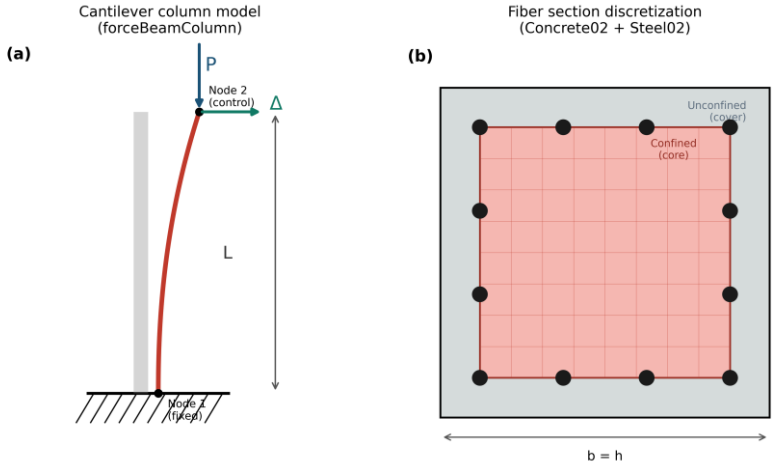

Fig. 2. RC column model: (a) cantilever elevation and (b) fiber section discretization.

```
ops.section('Fiber', sec_tag, '-GJ', GJ)
ops.patch('rect', mat_conf, n_fibers_core, n_fibers_core,
          -core_half_b, -core_half_h, core_half_b, core_half_h)
ops.layer('straight', mat_steel, n_bars_x, bar_area,
          -core_half_b, core_half_h, core_half_b, core_half_h)
```

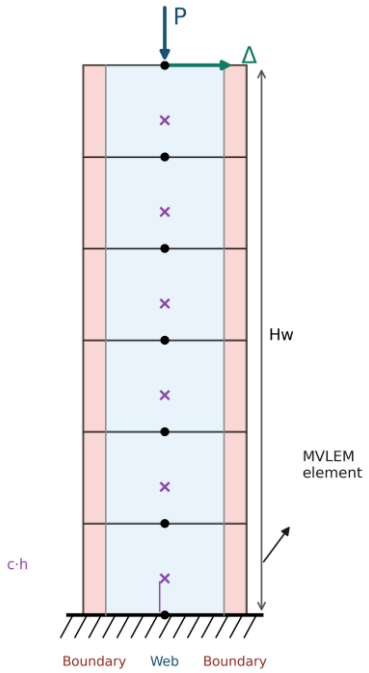

Fig. 3. Shear wall MVLEM model

```
ops.element('MVLEM', ele_tag, 0.0, i+1, i+2, m_fibers, c,
    '-thick', *thick, '-width', *widths, '-rho', *rho,
    '-matConcrete', *mat_concrete_tags,
    '-matSteel', *mat_steel_tags, '-matShear', mat_shear_tag)
```

A common analysis driver applies a constant axial load followed by displacement-controlled lateral loading. Adaptive step-size control combined with alternative solver algorithms (**Newton, ModifiedNewton, KrylovNewton, NewtonLineSearch, Broyden**) substantially reduced convergence difficulties in the softening region of the force-based column formulation.

2.3 Synthetic Data Generation

A separate parameter space was defined for each element type (Table 1) and sampled by Latin Hypercube Sampling [7], which limits clustering in a multi-dimensional space and thereby represents parameter interactions better than random sampling. The column section depth range (200–500 mm) was chosen to cover approximately 80 % of the rectangular-reinforced columns in the PEER Structural Performance Database, whose mean depth is 319 mm [6].

```
sampler = qmc.LatinHypercube(d=len(names), seed=seed)
unit = sampler.random(n=n_samples)
scaled = qmc.scale(unit, bounds[:, 0], bounds[:, 1])
```

Table 1. Parameter ranges used for Latin Hypercube Sampling.

Element	Parameter	Range
Column	b = h	200–500 mm
	L/b	2.5–6.0
	Bar diameter	16–32 mm
	fc / fy	20–40 / 350–500 MPa
	Axial load ratio	0.05–0.35
Wall	Hw	1.5–4.0 m
	Hw/Lw	1.2–3.0
	tw	100–250 mm
	ρv (web / boundary)	0.15–0.50 / 1.0–3.0 %
	fc / fy	20–40 / 350–500 MPa
	Axial load ratio	0.02–0.15

2.4 Feature Extraction

The pushover curve from each run is reduced to a bilinear idealization defined by the initial stiffness K0, the yield displacement δy and the post-yield stiffness α, fitted by least squares. The peak base shear Vmax is recorded separately as a validation quantity.

```
def _bilinear_model(d, K0, dy, alpha):
    Vy = K0 * dy
    return np.where(d <= dy, K0*d, Vy + alpha*(d - dy))
```

2.5 Model Training and Comparison Strategy

Three models will be trained on the resulting feature-target dataset: Model A (column-specific), Model B (wall-specific) and Model C (unified, with element type as a categorical feature). Performance will be evaluated with Random Forest and XGBoost under nested cross-validation, reported through R^2, MAE, RMSE and 95 % confidence intervals. Comparing Model C to Models A and B quantifies the accuracy cost of a single generalized architecture.

3 Preliminary Implementation and Interim Findings

3.1 Pilot Calibration of Column Models

Two shear-critical column specimens with different levels of input verification were used: Sezen and Moehle Specimen 1 [8], whose geometry and material properties are precisely documented, and Wight and Sozen Specimen WS033AE [9], modeled with approximate values because the source report could not be accessed directly. Although both specimens are archived

in the same database, they originate from independent experimental programs. The complete measured histories (2384 and 349 points, respectively) were obtained and the positive envelope curves extracted.

For the Sezen specimen the model predicted V_{max} with a 2.9 % error against the reported value of 303 kN. A known deviation appeared in the yield displacement (6.7 mm against 13.9 mm estimated with the method of [10]), because the fiber formulation represents neither bar slip nor shear deformation; these components can account for a substantial share of the total drift in shear-critical columns [11, 12]. For the Wight and Sozen specimen the model underestimated the measured V_{max} of 98.8 kN by 53.9 % (the database summary table lists 94 kN for this specimen). Fig. 4 compares both models against their experimental envelopes.

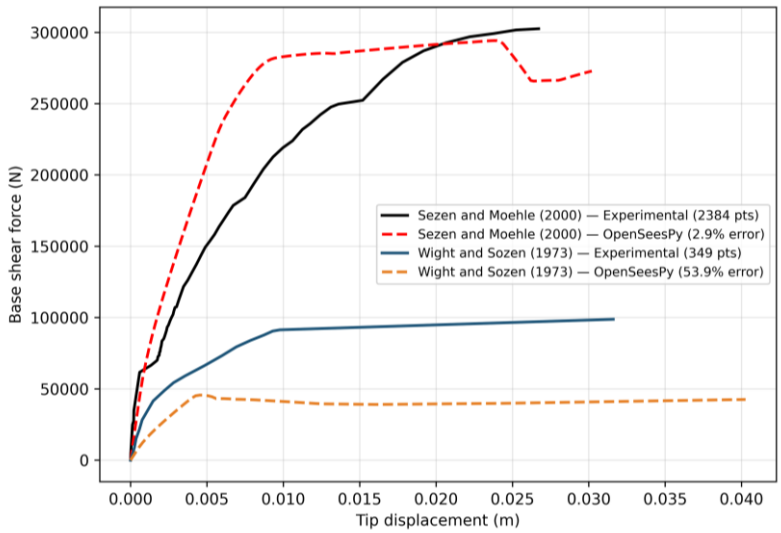

Fig. 4. OpenSeesPy pushover curves compared with the measured envelope curves for Sezen and Moehle Specimen 1 [8] and Wight and Sozen Specimen WS033AE [9].

3.2 Status of the Shear Wall Model

An initial wall pilot based on the file labeled Thomsen and Wallace 1994, A1 has been withdrawn. Inspection of the PEER Structural Performance Database showed that this specimen (Test 200, peak shear 44 kN) belongs to the rectangular-reinforced column dataset rather than to a wall test, so a comparison with a slender-wall MVLEM model is not meaningful. Consequently, the MVLEM wall formulation has so far been exercised only in the synthetic runs of Section 3.4, and its calibration against genuine experimental wall tests is deferred to future work.

3.3 Sensitivity Analysis and Calibration Guidance

The two column pilots show a consistent pattern (Table 2): the error is small where the inputs are documented and large where they are assumed. This section uses the digital twin in reverse — as a diagnostic tool — by sweeping the most uncertain input and back-calculating the value that reproduces the measured capacity.

Table 2. Effect of input verification level on the accuracy of the predicted base shear capacity.

Specimen	Input verification	Vmax error
Sezen and Moehle [8]	Precise literature values	+2.9 %
Wight and Sozen [9]	Approximate, unverified	−53.9 %

For the Wight and Sozen specimen, all parameters except the section size were held fixed and b = h was swept from 140 to 225 mm (Fig. 5). Reproducing the measured capacity requires a section of approximately 222 mm, 46 % larger than assumed. Because this value remains physically plausible, the deviation can plausibly be attributed to a single misestimated parameter that can be settled by consulting the source report.

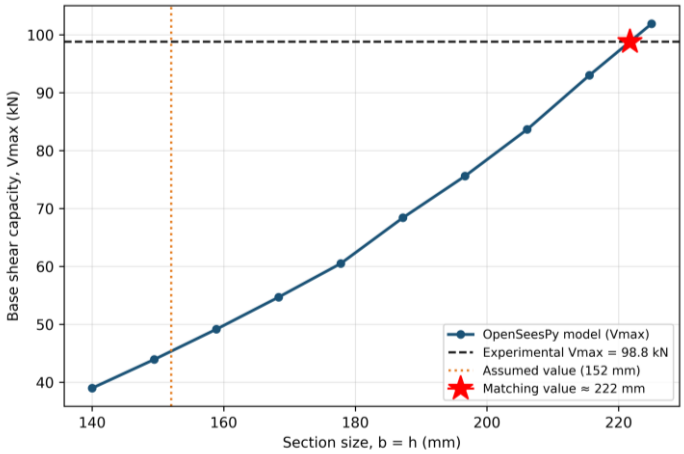

Fig. 5. Sensitivity of Vmax to section size for the Wight and Sozen specimen [9]

The Wight and Sozen sweep suggests a reusable calibration guide. First, when a model deviates from measurement, sweep the single most uncertain input. Second, if the back-calculated value is physically plausible, treat it as evidence of one misestimated parameter and verify that quantity at its source. Third, if the back-calculated value is implausible, conclude that the deviation arises from the combined effect of several parameters and move to a multi-parameter verification; this branch has not yet been demonstrated on a real specimen and will be tested once verified specimen data are available. The framework is thus usable in the reverse direction, from behavior to input, as well as the forward direction.

3.4 Pilot Synthetic Data Generation

The sampling pipeline of Section 2.3 was run at small scale, N = 25 per element type, over the ranges in Table 1. All 25 wall runs and 24 of the 25 column runs converged (the single failure was a short, thick column, L/b ≈ 2.5, in the softening range), and the bilinear fit quality reached a mean R^2 above 0.95 for both element types (Table 3), indicating that the pipeline is ready to be executed at the scale of thousands of runs required for model training.

Table 3. Summary of the pilot Latin Hypercube sampling run.

Criterion	Column (N = 25)	Wall (N = 25)
Successful convergence	24/25	25/25
Mean R^2 (bilinear fit)	0.959	0.963
R^2 range	0.712–0.999	0.730–0.998
Vmax range	78–571 kN	91–1072 kN

4 Conclusions and Future Work

A digital twin-machine learning framework for predicting the seismic behavior of RC columns and shear walls has been presented, and its calibration, feature extraction and synthetic

data generation components have been implemented; the column components were verified on two real specimens together with a small-scale sampling study. The pilot with documented input properties reproduced the measured shear capacity to within 2.9 %, whereas the pilot with assumed properties deviated by 53.9 %. A sensitivity analysis converted this deviation into diagnostic information by back-calculating the section size that reproduces the measurement, and yielded a three-step calibration guide. The wall formulation has so far been verified only on synthetic runs.

Future work will (i) verify the geometry and material properties of the Wight and Sozen column specimen at its primary source, (ii) calibrate the wall model against experimental wall tests from a dedicated wall database, (iii) convert the back-calculation logic into an automated calibration module, (iv) expand the sampling run to thousands of cases, (v) train and compare the component-specific and unified models, and (vi) translate the outcome into practical recommendations for digital twin architecture design.

Abstract. This study presents a three-dimensional elasticity-based state-space differential quadrature formulation for the buckling analysis of functionally graded sandwich (FGS) plates resting on a full three-parameter Kerr elastic foundation. The plate is modeled directly within three-dimensional elasticity, while the in-plane derivatives are discretized using the differential quadrature method and the through-thickness equations are written in state-space form. The resulting equations are assembled by a scaled Global Matrix Method. The formulation is first assessed against available buckling solutions for unsupported and elastically supported FGS plates. A concise parametric study is then carried out for a simply supported Type A plate under uniaxial compression to examine the independent effects of the upper spring stiffness, lower spring stiffness, and intermediate shear-layer stiffness of the Kerr model. The results show that all three foundation components increase the critical buckling load within the investigated ranges, with the upper spring stiffness producing the most pronounced variation. The proposed formulation provides a three-dimensional framework for evaluating the stability response of FGS plates supported by a full Kerr foundation.

Keywords: Functionally graded sandwich plate; buckling; three-dimensional elasticity; Kerr foundation; differential quadrature method; state-space method.

1 Introduction

Functionally graded sandwich (FGS) plates combine the structural efficiency of sandwich construction with a continuous variation of material properties through the thickness. This gradual material distribution can reduce abrupt interfacial property changes while allowing the stiffness distribution to be tailored for structural requirements. Buckling under in-plane compression is an important design consideration for such plates because the critical load is influenced by material gradation, layer arrangement, plate geometry, and support conditions. Various reduced-order formulations, including first-order, higher-order, and quasi-three-dimensional plate theories, have therefore been developed for the stability analysis of FGS plates [1-3].

Although reduced-order plate theories provide computationally efficient models, their accuracy depends on the assumed through-thickness kinematics. Three-dimensional elasticity formulations avoid a predefined displacement variation and retain transverse normal and shear effects directly in the governing equations. State-space approaches are particularly suitable for layered and functionally graded structures because the variation of the field variables through the thickness can be treated explicitly. Alibeigloo and Alizadeh [4] combined the state-space method with the differential quadrature method (DQM) for three-dimensional analyses of FGS plates, providing a useful basis for extending the formulation to stability problems.

The interaction between a plate and an elastic supporting medium can also modify its buckling response. Most available buckling studies on FGS sandwich plates have considered Winkler or Pasternak foundations [5-8]. The Kerr model provides a more general representation by introducing an intermediate shear layer between upper and lower spring layers [9,10]. The three foundation stiffness components can therefore be specified independently. While Kerr-type foundations have been considered in vibration studies of functionally graded plates, their use in three-dimensional buckling analyses of FGS plates remains comparatively limited.

In this study, a three-dimensional elasticity-based state-space differential quadrature method (SSDQM) formulation is employed to investigate the buckling behavior of FGS plates resting on a full Kerr elastic foundation. The upper spring stiffness, lower spring stiffness, and intermediate shear-layer stiffness are retained as independent foundation parameters. The numerical model is first checked against available buckling solutions, after which the individual influence of the Kerr foundation parameters on the critical buckling load is examined for a representative simply supported Type A FGS plate under uniaxial compression.

2 Theoretical Formulation

2.1 FGS plate and material model

A rectangular Type A FGS plate with length a, width b, and total thickness h, resting on a full Kerr elastic foundation, is considered as shown in Fig. 1. The plate consists of two functionally graded face sheets and a homogeneous ceramic core, with perfect bonding assumed at the layer interfaces. The material variation in the face sheets is described by a power-law distribution. For the ceramic volume fraction,

$$V_c(z) = \begin{cases} \left(\frac{z-z_0}{z_1-z_0}\right)^p, & z_0 \le z \le z_1 \\ 1, & z_1 \le z \le z_2 \\ \left(\frac{z_3-z}{z_3-z_2}\right)^p, & z_2 \le z \le z_3 \end{cases} \tag{1}$$

where p is the power-law index.

The effective Young's modulus is obtained from the rule of mixtures as

$$E(z) = E_m + (E_c - E_m)V_c(z) \tag{2}$$

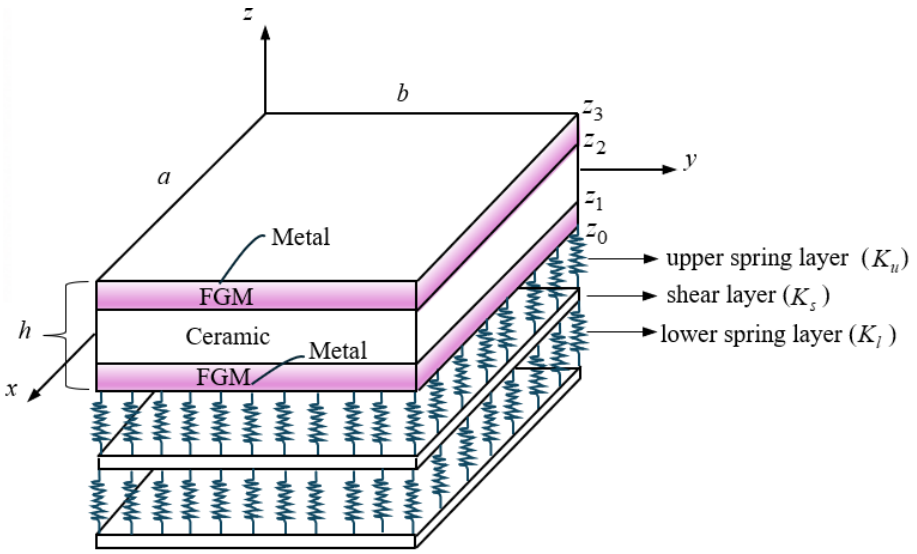

Fig. 1. Geometry and material configuration of the Type A functionally graded sandwich plate resting on a full Kerr elastic foundation.

where the subscripts m and c denote the metal and ceramic constituents, respectively. Poisson's ratio is assumed to remain constant through the thickness.

2.2 Three-dimensional buckling formulation and Kerr foundation

The stability problem is formulated within three-dimensional linear elasticity without introducing a predefined through-thickness displacement field. The displacement components are denoted by u, v, and w, and the constitutive relation is written in compact form as

$$\boldsymbol{\sigma} = \mathbf{C}(z)\boldsymbol{\varepsilon} \tag{3}$$

For the present study, uniform uniaxial compression is applied in the x-direction,

$$N_x = -\lambda, \qquad N_y = N_{xy} = 0 \tag{4}$$

where λ is the buckling load parameter. The corresponding initial in-plane stresses are included in the linearized three-dimensional equilibrium equations. The transverse equilibrium equation can be expressed as

$$\tau_{xz,x} + \tau_{yz,y} + \sigma_{z,z} + \sigma_x^0 w_{,xx} + \sigma_y^0 w_{,yy} = 0 \tag{5}$$

The full Kerr foundation consists of an upper spring layer with stiffness K_u, a lower spring layer with stiffness K_l, and an intermediate shear layer with stiffness K_s [9,10]. Introducing w_f as the displacement of the intermediate layer, the foundation reaction is

$$q_f = K_u\left(w - w_f\right) \tag{6}$$

while the equilibrium of the intermediate layer is written as

$$K_u\left(w - w_f\right) = K_l w_f - K_s\left(\frac{\partial^2 w_f}{\partial x^2} + \frac{\partial^2 w_f}{\partial y^2}\right) \tag{7}$$

At the plate-foundation interface, the transverse normal stress is balanced by the foundation reaction, while the transverse shear tractions vanish.

2.3 State-space differential quadrature solution

The displacement components and transverse stresses are selected as the state variables. For the *r*-th layer,

$$\mathbf{S}^{(r)} = [U \quad V \quad W \quad \sigma_z \quad \tau_{xz} \quad \tau_{yz}]^T, \qquad r = 1,2,3 \tag{8}$$

where *r* denotes the layer number and the governing equations are transformed into the first-order state-space form

$$\frac{d\mathbf{S}^{(r)}}{dz} = \mathbf{A}^{(r)}(z,\lambda)\mathbf{S}^{(r)}, \qquad r = 1,2,3 \tag{9}$$

Perfect bonding is imposed by enforcing the continuity of all state variables across the layer interfaces. The in-plane derivatives are discretized by DQM using Chebyshev-Gauss-Lobatto grid points [4]. The simply supported boundary conditions, surface conditions, interface continuity equations, and discretized Kerr-foundation equations are assembled simultaneously

using the scaled Global Matrix Method (GMM). The resulting homogeneous system is written as

$$\mathbf{G}(\lambda)\mathbf{d} = \mathbf{0} \tag{10}$$

where $\boldsymbol{G}(\lambda)$ is the parameter-dependent global matrix and $\mathbf{d}$ collects the layer-boundary state vectors and the discrete foundation variables. A non-trivial solution exists when

$$det[\,\boldsymbol{G}(\lambda)] = 0 \tag{11}$$

The smallest positive value of λ satisfying Eq. (11) is taken as the critical buckling parameter λ_{cr}. For reporting the numerical results, the critical buckling load and the Kerr foundation stiffness parameters are expressed in nondimensional form as

$$\overline{N}_{cr} = \frac{N_{cr}a^2}{100E_0h^3} \tag{12}$$

$$\overline{K}_u = \frac{k_u h}{E_0}, \overline{K}_l = \frac{k_l h}{E_0}, \overline{K}_s = \frac{k_s}{E_0 h} \tag{13}$$

where E_0 = 1 GPa is the reference Young's modulus used for nondimensionalization, h is the total plate thickness, and k_u, k_l, and k_s denote the dimensional upper spring, lower spring, and intermediate shear-layer stiffness parameters, respectively.

3 Numerical Results

3.1 Validation

The present formulation is first validated for a simply supported (SSSS) Type A FGS plate without an elastic foundation. To keep the comparison concise, the 2-1-2 thickness scheme is selected, and the dimensionless critical buckling loads are compared with the hyperbolic shear deformation theory (HSDT), sinusoidal shear deformation theory (SSDT), third-order shear deformation theory (TSDT), and first-order shear deformation theory (FSDT) solutions available in the literature for several power-law indices under uniaxial compression.

Good agreement is obtained over the considered range of the power-law index. The present 3D SSDQM results follow the same variation as the reference solutions, and the maximum relative difference between the present results and the reference solutions listed in Table 1 remains below approximately 0.8%. To further assess the implementation of the elastic-foundation terms, a second validation is performed for the same Type A FGS configuration resting on a Pasternak foundation.

Table 1. Comparison of dimensionless critical buckling loads for the SSSS Type A FGS plate with the 2-1-2 thickness scheme under uniaxial compression.

Method	p **= 0**	p **= 1**	p **= 5**	p **= 10**
HSDT, El Meiche et al. [2]	13.0055	5.8394	3.0414	2.7450
SSDT, Zenkour [1]	13.0061	5.8412	3.0441	2.7484
TSDT, Zenkour [1]	13.0050	5.8401	3.0426	2.7463

Table 2. Representative validation of the dimensionless critical buckling load for the Type A FGS plate with the 2-1-2 thickness scheme (p = 2) on a Pasternak foundation under uniaxial compression.

Method	$K_w = K_s = 0$	$K_w = K_s = 10$	$K_w = K_s = 100$
Akavcı [11]	2.8455	5.6690	31.0244
Van and Hieu [8]	2.9113	5.8178	32.1766
Present 3D SSDQM	**2.8823**	**5.7463**	**31.2998**

Table 2 compares the present results with the solutions of Akavcı [11] and Van and Hieu [8] for three foundation-stiffness levels. The present predictions remain between the two reference solutions throughout the range investigated and show good agreement with both sets of results. These comparisons support the accuracy of the three-dimensional buckling formulation and the implementation of the elastic-foundation terms before application to the full Kerr model.

3.2 Effect of Kerr foundation parameters

The effects of the three Kerr foundation parameters are examined separately for a simply supported Type A FGS plate with the 2-1-2 thickness scheme and (p = 2) under uniaxial compression. In each analysis, one foundation parameter is varied while the remaining parameters are kept at their reference values. This procedure allows the individual sensitivity of the critical buckling load to each component of the Kerr foundation to be evaluated.

Fig. 2 shows a monotonic and nonlinear increase in the dimensionless critical buckling load with increasing upper spring stiffness. As $\bar{K}_u$ increases from 0.01 to 100, $\bar{N}_{cr}$ rises from approximately 2.9789 to 5.7382. The increase becomes particularly pronounced over the intermediate stiffness range, whereas the curve progressively flattens at larger values of $\bar{K}_u$.This trend indicates that the critical buckling load becomes less sensitive to further increases in the upper spring stiffness once the foundation response is sufficiently stiff.

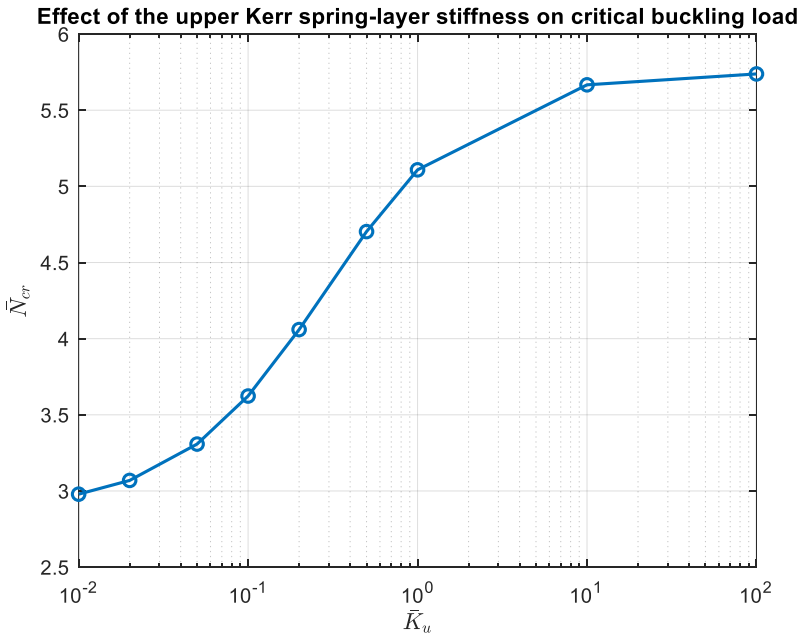

Fig. 2. Effect of the upper Kerr spring-layer stiffness on the dimensionless critical buckling load.

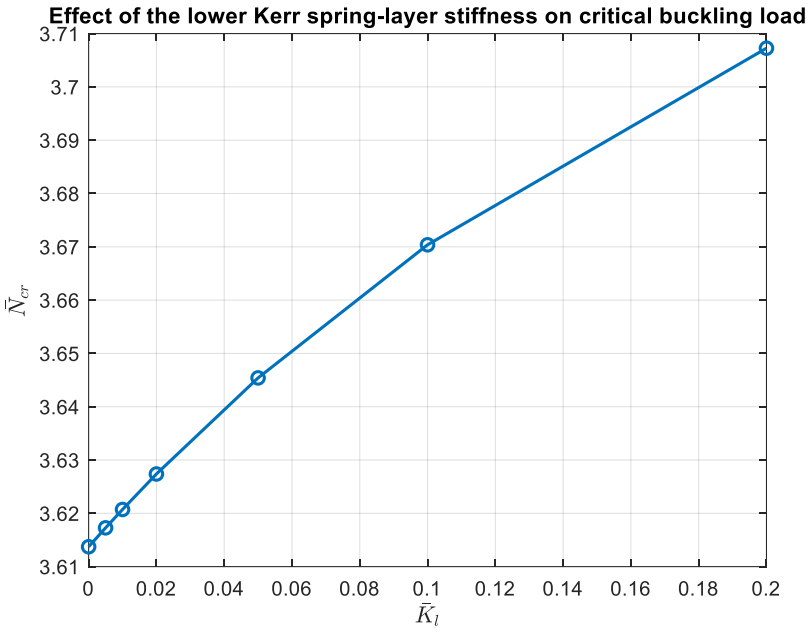

Fig. 3. Effect of the lower Kerr spring-layer stiffness on the dimensionless critical buckling load.

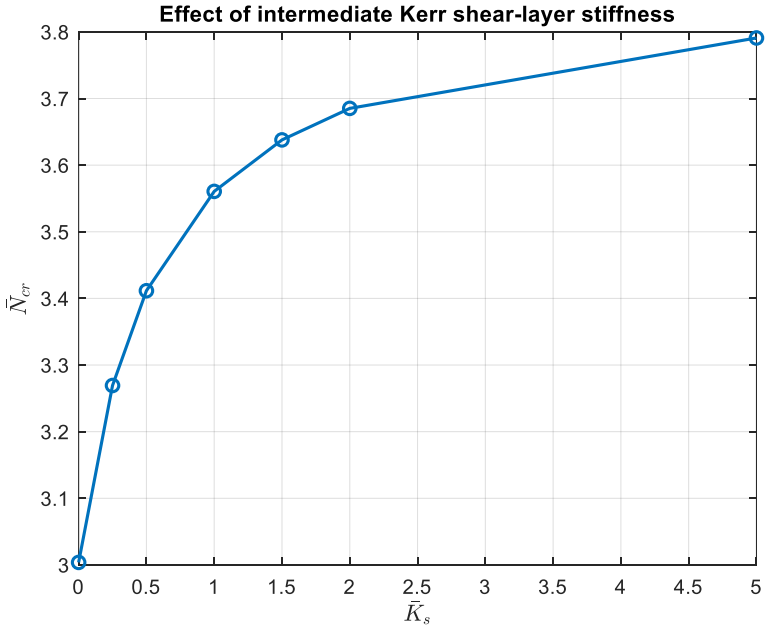

Fig. 4. Effect of the intermediate Kerr shear-layer stiffness on the dimensionless critical buckling load.

Fig. 3 illustrates the effect of the lower spring stiffness on the stability response. The dimensionless critical buckling load increases monotonically from approximately 3.6137 to 3.7073 as $\bar{K}_l$ varies from 0 to 0.2. Compared with the variation observed for the upper spring layer, the change is relatively small, indicating a lower sensitivity of the critical buckling load to $\bar{K}_l$ for the reference configuration considered. The response is also nearly linear over the investigated interval.

As shown in Fig. 4, increasing the intermediate shear-layer stiffness also enhances the buckling resistance. The dimensionless critical buckling load increases from approximately 3.0038 to 3.7909 as $\bar{K}_s$ varies from 0 to 5. The response is relatively steep at low stiffness levels

and gradually becomes flatter as $\overline{K}_s$ increases, indicating diminishing increments in the critical load at higher shear-layer stiffnesses. Thus, the intermediate shear layer has a clear stabilizing effect, although its influence becomes progressively less pronounced as the layer becomes stiffer.

Taken together, Figs. 2–4 show that the three Kerr parameters influence the buckling response with different sensitivities. Within the nondimensional parameter ranges considered, the upper spring stiffness produces the largest variation in the critical buckling load, the shear-layer stiffness has an intermediate effect, and the lower spring stiffness produces the smallest change. This comparison is specific to the adopted reference configuration and parameter ranges.

4 Conclusions

A three-dimensional elasticity-based state-space differential quadrature formulation was employed to investigate the buckling behavior of functionally graded sandwich plates resting on a full Kerr elastic foundation. The formulation showed good agreement with available reference solutions for both unsupported and Pasternak-supported FGS plates, supporting the accuracy of the buckling formulation and the implementation of the elastic-foundation terms. For the representative Type A plate considered, increasing each Kerr foundation parameter increased the dimensionless critical buckling load within the investigated ranges. The upper spring stiffness $\overline{K}_u$ produced the most pronounced variation, with the response becoming less sensitive at higher stiffness levels. The intermediate shear-layer stiffness $\overline{K}_s$ also provided a clear stabilizing effect with diminishing increments as its stiffness increased, whereas the lower spring stiffness $\overline{K}_l$ produced a comparatively smaller change. These findings show that the individual components of the full Kerr foundation influence the stability response with different sensitivities and highlight the importance of retaining the three foundation parameters independently.

Abstract. The use of nano silica (NS) in high-performance concrete has increased considerably in recent years due to its filler effect and high pozzolanic reactivity. However, agglomeration of nano-sized particles may limit the expected performance improvement. Therefore, the dispersion method of nano silica is an important parameter affecting concrete performance. In this study, the effects of different nano silica mixing methods on the mechanical and physical properties of fly ash-based high-performance concrete mixtures were investigated. Within the scope of the study, concrete series containing nano silica and fly ash were evaluated. In the reference mixtures, nano silica was directly incorporated into the dry binder before concrete production. The same mixtures were also produced by mechanically dispersing nano silica in the mixing water together with the superplasticizer prior to mixing. In addition, the same concrete series were also produced using ultrasonic dispersion to enable a comparative evaluation of the three nano-silica dispersion methods. The experimental program includes compressive strength tests, flexural strength tests, unit weight and slump flow measurements. Results indicated that mechanically dispersed nano silica provided higher compressive strength compared to the dry-mixing method under similar workability conditions. The obtained findings indicate that the dispersion quality of nano silica may have a significant effect on the mechanical and physical performance of high-performance concrete.

Keywords: dispersion method; nano silica; high performance concrete; ultrasonic dispersion.

1 Introduction

High-performance and reactive powder concrete matrix systems represent innovative cementitious composites engineered to exhibit exceptional mechanical strength and superior durability characteristics. To further optimize the efficiency of these high-performance materials, the incorporation of nanoparticles—most notably nano-silica (NS)—has attracted profound scientific interest due to its extremely fine particle size and massive specific surface area. Nanomaterials fundamentally enhance the cementitious matrix through physical and chemical pathways; while they act as ultra-fine pore fillers that structurally occupy nano scale voids to enhance particle packing density, they also exhibit high pozzolanic reactivity that accelerates cement hydration and promotes the formation of supplementary calcium silicate hydrate (C-S-H) gels [1,2]. This collaborative mechanism significantly densifies the microstructure, refines the pore distribution and improves the overall interfacial transition zone (ITZ) [3].

Due to their exceptionally high specific surface area, NS particles exhibit a strong tendency to agglomerate in cementitious systems. This agglomeration hinders the homogeneous

distribution of NS, critically affecting both the mechanical properties and workability of the concrete matrix. A significant portion of the contradictory results regarding NS application in the literature can be attributed to inadequate dispersion [4-5]. Proper dispersion is essential to maximize the positive effects of nanoparticles and minimize their drawbacks, which is crucial for developing high-performance composite materials [6].

To achieve effective dispersion, various physical and chemical methods have been explored, including high-speed mechanical mixing, ultrasonication, and the use of dispersion agents like superplasticizers. Mechanical and ultrasonic methods aim to separate particles through high shear forces and cavitation, respectively. While ultrasonication is highly effective in breaking down agglomerates through cavitation and enhancing hydration, prolonged exposure to high-frequency sound waves can generate excessive heat within the aqueous medium. This intensive acoustic energy can alter the structural and morphological properties of the nanoparticles [6]. Alternatively, chemical modification using polycarboxylate-based superplasticizers (PCE) provides physical or steric hindrance on the NS surface, significantly improving particle distribution and preventing rapid re-agglomeration in the cement pore solution [5].

Previous studies have highlighted that dispersion efficiency directly depends not only on the NS dosage but also on the mixing sequence, form of NS and the type of dispersion technique applied. In high performance concrete (HPC) formulations, where supplementary cementitious materials like fly ash are utilized, the interaction between nanoparticles and the binder matrix becomes even more critical. Incorporating dry NS powder directly into the mix often leads to poor dispersion and subsequent performance reductions [7-8]. Conversely, pre-dispersing NS in an aqueous solution with a superplasticizer has been proven to optimize the matrix microstructure and enhance early age properties [9-10].

To address these challenges, this study investigates the effects of different nano-silica mixing methodologies on the mechanical and physical properties of fly ash-based high-performance concrete mixtures. Within the scope of the experimental program, concrete series containing a fixed 2% NS replacement were evaluated. The investigation primarily compares a reference dry-mixing approach, in which nano silica was directly incorporated into the dry constituents, with mechanical pre-dispersion of nano silica in the mixing water containing the superplasticizer. Additionally, ultrasonic dispersion method was included in the experimental matrix for comparative analysis. The performance of the mixtures was comprehensively evaluated through slump flow, unit weight, compressive strengths, and flexural strength tests. Based on findings, this paper delineates how dispersion quality fundamentally dictates the physical and mechanical efficiency of NS-modified high-performance composites.

2 Materials and Methods

2.1 Materials

Ordinary Portland cement (CEM I 42.5 R) conforming to TS EN 197-1 [11] was used as the primary binder material. Class F fly ash (FA) was incorporated as a supplementary cementitious material at a replacement level of 10% by weight of cement. Nano silica (NS) (Fig. 1), consisting of amorphous silicon dioxide (SiO_2) nanoparticles with a particle size ranging from 15 to 35 nm, was utilized as a mineral additive due to its high pozzolanic activity and filler effect.

Fig. 1. Nano silica (NS) used in this study.

A polycarboxylate ether-based superplasticizer was employed to maintain adequate workability at a low water-to-binder ratio. Fine aggregate consisted of quartz powder (0-100 μm) and two silica sand fractions (100-300 μm and 300-700 μm) with different particle size distributions selected according to an optimized particle packing design. As steel fiber reinforcement, recycled steel fibers (Fig. 2) recovered from end-of-life tires were used in all mixtures. The fibers had an average length of approximately 13 mm and were incorporated to improve the mechanical performance of the concrete matrix. Potable tap water was used for mixing and curing.

Fig. 2. Recycled steel fibers (RSF).

2.2 Mixture Proportions

The concrete mixtures investigated in this study were derived from a previously developed high-performance concrete mixture [12]. A constant water-to-binder ratio of 0.25 was adopted for all series. Fly ash and nano-silica contents were fixed at 10% and 2% of the binder, respectively. While recycled steel fibers were incorporated at a constant dosage of 2.0 vol.%, throughout the study.

To isolate the effect of the nano-silica dispersion technique, all mixture parameters, including binder composition, aggregate content, fiber dosage, and curing conditions, were kept constant. The detailed mixture proportions are presented in Table 1.

Table 1. Mix proportions normalized by cement mass (cement=1.0).

Cement	Water	Superplast.	Quartz Powder	Silica Sand (100–300 μm)	Silica Sand (300–700 μm)	FA	NS	Recycled Steel Fiber (RSF)
1.0	0.284	0.045	0.247	0.238	0.366	0.114	0.023	2% (by total volume)

2.3 Nano-Silica Dispersion Procedures

Three different nano-silica incorporation techniques were evaluated. In the dry-mixed mixture (DM), NS powder was directly added to the dry constituents and mixed together prior to water addition. This method represents the simplest and most commonly applied incorporation technique in practice.

In the mechanically dispersed mixture (MD), NS was first dispersed in the mixing water containing the superplasticizer using a high-speed mechanical mixer before being introduced into the concrete mixture. This procedure was intended to improve particle distribution and reduce agglomeration.

In the ultrasonically dispersed mixture (UD), NS was dispersed in a water–superplasticizer solution using a probe-type ultrasonic processor for 30 min before being incorporated into the concrete mixture.

2.4 Specimen Preparation and Curing

All mixtures were produced using a laboratory mortar mixer following a standardized mixing sequence. Depending on the dispersion method, nano-silica was either directly incorporated into the dry constituents prior to mixing, mechanically dispersed in the mixing water containing the superplasticizer, or ultrasonically dispersed in the same solution before concrete production. Fresh concrete properties were evaluated immediately after mixing through slump-flow measurements.

Subsequently, 50×50×50 mm cubic specimens and 40×40×160 mm prism specimens were cast into steel molds and manually compacted by rodding under laboratory conditions for compressive and flexural strength testing, respectively.

After approximately 24 h, the specimens were demolded and cured in lime-saturated water at 20±2 °C in accordance with EN 12390-2 [13] until the designated testing ages of 28 days. Identical curing conditions were maintained for all mixtures to ensure that any observed differences in performance could be attributed solely to the nano-silica dispersion method.

2.5 Test Methods

The influence of the NS dispersion technique on the fresh, physical, and mechanical properties of high performance concrete was evaluated through slump-flow, bulk density, compressive strength, and flexural strength tests.

Slump-flow measurements were conducted in accordance with ASTM C1611/C1611M-21 [14] to assess the workability of fresh concrete mixtures. The bulk density of hardened concrete specimens was determined following EN 12390-7 [15]. Compressive strength tests were performed on 50×50×50 mm cube specimens following the loading procedure specified in ASTM C109/C109M-20B [16]. Flexural strength tests were performed at 28 days using 40×40×160 mm prism specimens following the procedures specified in ASTM C348-14 [17].

The obtained results were used to evaluate the effectiveness of the different NS dispersion methods and their influence on the physical and mechanical performance of fly ash-based high-performance concrete.

3 Result and Discussion

3.1 Workability

Fig. 3 presents the slump-flow results of the concrete mixtures prepared using different nano-silica dispersion methods. Both the dry-mixed (DM) and ultrasonically dispersed (UD) mixtures showed a slump flow of 34 cm, while the mechanically dispersed mixture (MD) exhibited a slump flow of 31 cm.

Although the MD mixture exhibited a slightly lower slump-flow value, all mixtures provided adequate workability for high-performance concrete production. The reduced flowability of the MD mixture may be attributed to the more uniform dispersion of nano-silica particles, which increases their effective surface area and consequently the water demand of the mixture. In contrast, the relatively higher slump-flow values observed for the DM mixture may be associated with particle agglomeration, which decreases the effective surface area of nano-silica and limits its interaction with the mixing water. The identical slump-flow values obtained for the DM and UD mixtures indicate that, under the conditions investigated, ultrasonic dispersion did not produce a noticeable change in the workability of the fresh concrete.

Since all mixtures exhibited relatively similar workability, any differences observed in the subsequent mechanical properties are likely to be associated with the effectiveness of the nano-silica dispersion rather than with variations in fresh concrete consistency.

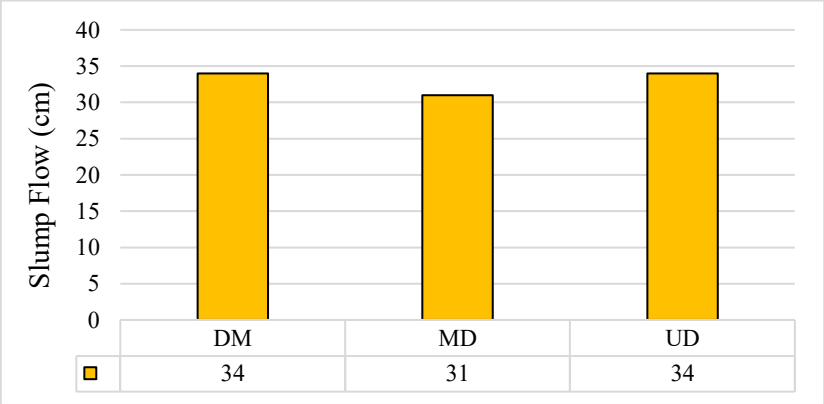

Fig. 3. Slump-flow results of the concrete mixtures.

3.2 Bulk Density

Fig. 4 presents the bulk density results of the concrete mixtures prepared using different NS dispersion methods. The average unit weights of the DM, MD and UD mixtures were 2.26, 2.29 and 2.33 kg/dm³, respectively. Among the investigated mixtures, the UD mixture exhibited the highest unit weight, whereas the DM mixture showed the lowest value.

The relatively lower unit weight of the DM mixture may be attributed to the agglomeration of nano-silica particles, which reduces their filler efficiency by causing them to behave as larger clusters rather than uniformly dispersed nanoparticles. Consequently, particle packing becomes less efficient, leading to the formation of locally less dense regions within the cementitious matrix. In contrast, the higher unit weights obtained for the MD and UD mixtures suggest that improved nano-silica dispersion promoted more efficient particle packing and a denser internal structure.

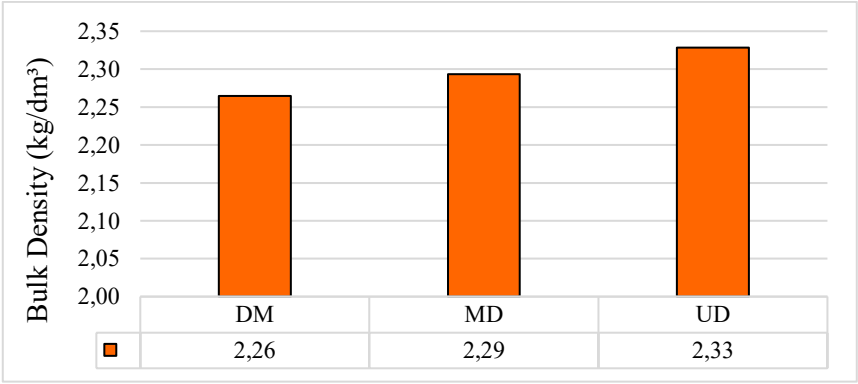

Fig. 4. Bulk density results of the concrete mixtures.

3.3 Compressive Strength

Fig. 5 presents the compressive strength results of the concrete mixtures prepared using different nano-silica dispersion methods. The average 28-day compressive strengths of the 50 × 50 × 50 mm cube specimens were 76.96 MPa, 112.73 MPa and 94.01 MPa for the DM, MD, and UD mixtures, respectively. Among the investigated mixtures, the MD mixture exhibited the highest compressive strength, whereas the DM mixture produced the lowest 28-day compressive strength. Compared with the dry mixing method, mechanical dispersion increased the 28-day compressive strength by approximately 46%, demonstrating the significant influence of nano-silica dispersion method on the mechanical performance of high-performance concrete.

The superior performance of the MD mixture may be attributed to the more effective dispersion of nano-silica particles within the cementitious matrix. A more homogeneous distribution of nano-silica increases its effective reactive surface area, enhancing both the filler effect and the pozzolanic reaction. In contrast, direct incorporation of nano-silica in dry form may promote particle agglomeration, reducing its efficiency and limiting its contribution to strength development. Similar observations have been reported by Elkady et al. [9] and Du et al. [10], who demonstrated that pre-dispersion of nano-silica is more effective than direct dry incorporation.

Following the flexural strength test, compressive strength tests were also carried out on the prism halves (40 × 40 × 40 mm). The average compressive strengths of the DM, MD and UD mixtures were 107.19 MPa, 125.84 MPa and 125.72 MPa, respectively. Similar to previous studies [18-19], the compressive strengths obtained from the prism halves were higher than those measured on the 50 × 50 × 50 mm cube specimens, which can be attributed to the specimen size effect [20]. Since the surface layer constitutes a larger proportion of the total cross-sectional area in smaller specimens, its beneficial influence on mechanical performance becomes more pronounced. In addition, according to Weibull's statistical size effect theory, smaller specimens have a lower probability of containing critical flaws, leading to higher measured compressive strengths [12]. Accordingly, the compressive strengths of the 40 × 40 × 40 mm specimens were approximately 12% to 39% higher than those of the 50 × 50 × 50 mm cube specimens, confirming the influence of specimen size on the measured strength values. The MD and UD mixtures exhibited nearly identical compressive strengths, while the DM mixture again produced considerably lower strength. These findings indicate that both mechanical and ultrasonic dispersion methods were similarly effective in improving the compressive performance of the investigated high-performance concrete. In contrast, direct dry incorporation of nano-silica resulted in consistently lower compressive strength, highlighting the importance of achieving adequate nano-silica dispersion.

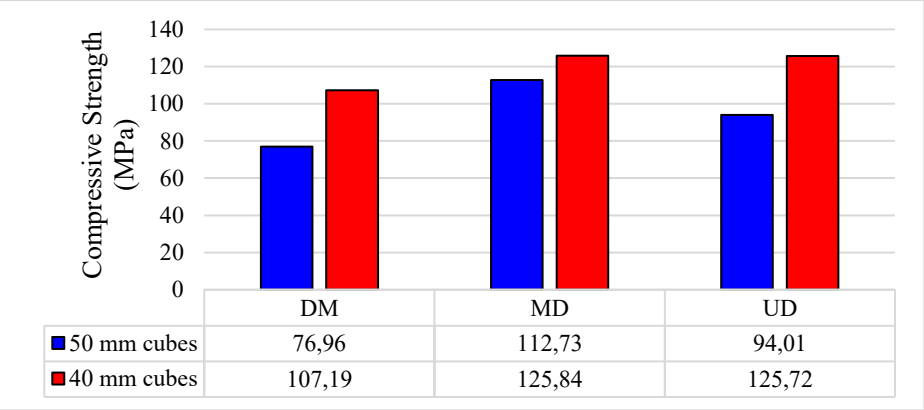

Fig. 5. Compressive strength results of the concrete mixtures.

3.4 Flexural Strength

Fig. 6 presents the flexural strength results of the concrete mixtures prepared using different nano-silica dispersion methods. The average flexural strengths of the DM, MD and UD mixtures were 18.58 MPa, 19.95 MPa and 15.17 MPa, respectively. Accordingly, the MD mixture exhibited the highest flexural strength, followed by the DM mixture, while the UD mixture produced the lowest value. Furthermore, the flexural strength of the MD mixture was approximately 7.4% higher than that of the reference dry-mixed (DM) mixture.

The differences in flexural strength may be associated not only with the dispersion of nano-silica but also with the distribution and orientation of recycled steel fibers within the specimens. While improved nano-silica dispersion is expected to enhance matrix densification, flexural performance of fiber-reinforced concrete is governed largely by the effectiveness of fiber bridging across the crack plane. Examination of the fractured cross-sections (Fig. 7) revealed that the MD and DM mixtures contained a higher concentration of fibers near the tensile region, whereas the UD mixture exhibited a more uniform fiber distribution throughout the cross-section. Since flexural cracks initiate from the tensile face, the higher local fiber concentration in this region likely enhanced crack-bridging capacity, delayed crack propagation, and resulted in higher flexural strengths for the MD and DM mixtures. This observation also explains why the UD mixture, despite exhibiting considerably higher compressive strength than the DM mixture, produced the lowest flexural strength among the investigated mixtures.

4 Conclusions

This study investigated the influence of different nano-silica dispersion methods on the fresh, physical, and mechanical properties of fly ash-based high-performance concrete. Based on the experimental findings, the following conclusions can be drawn:

- The nano-silica dispersion method had only a limited influence on the workability of the mixtures, as all concretes exhibited comparable slump-flow values.

- Improved nano-silica dispersion enhanced the compactness of the concrete matrix. Accordingly, the ultrasonically dispersed mixture exhibited the highest bulk density, whereas the dry-mixed mixture produced the lowest value.
- Mechanical dispersion produced the highest 28-day compressive strength in the 50 mm cube specimens and increased compressive strength by up to approximately 46% compared with direct dry mixing. Although the mechanically and ultrasonically dispersed mixtures exhibited nearly identical compressive strengths in the 40 mm cube specimens, both methods clearly outperformed the dry-mixing approach. These findings demonstrate that selecting an appropriate nano-silica dispersion technique can improve compressive strength by up to 46%, emphasizing the importance of proper nano-silica dispersion for enhancing the performance of high-performance concrete.
- The highest flexural strength was obtained in the mechanically dispersed mixture, while the ultrasonically dispersed mixture exhibited the lowest flexural strength. This behavior was associated with differences in the distribution of recycled steel fibers within the specimens, with the MD and DM mixtures exhibiting a higher concentration of fibers near the tensile region than the UD mixture.

Overall, the results demonstrate that the nano-silica dispersion technique is a key parameter governing the performance of high-performance concrete. Among the investigated methods, mechanical dispersion provided the most balanced overall performance, combining the highest compressive and flexural strengths with satisfactory physical properties. Although ultrasonic dispersion produced comparable compressive strength in the 40 mm specimens and the highest bulk density, these improvements did not translate into a clear overall performance advantage considering its additional processing time and specialized equipment requirements. Therefore, mechanical dispersion can be considered a more practical and efficient technique for incorporating nano-silica into high-performance concrete, while direct dry incorporation proved to be the least effective approach. Further microstructural investigations are recommended to better explain the relationship between nano-silica dispersion, fiber distribution, and the resulting mechanical behavior.

Abstract. This study presents a performance-based comparison of fly ash (FA) and recycled glass powder (GP) as partial cement replacements in concrete, evaluated under identical mixture design conditions. Concrete mixtures were prepared with replacement levels of 10%, 20%, and 30% by weight of cement, at a constant water-to-cement ratio of 0.60 and without chemical admixtures. Mechanical performance was assessed through 28-day compressive strength, while environmental impact was evaluated through embodied carbon calculations covering the cradle-to-gate, construction, and end-of-life stages. A novel Carbon Reduction Efficiency (CRE) index was introduced to quantify the trade-off between carbon savings and strength loss, complemented by a Carbon–Performance Quadrant framework. Results show that FA mixtures achieved a more favorable balance between carbon reduction and mechanical performance than GP mixtures: FA-30 reduced embodied carbon by 26.7% while limiting the strength loss to 9.3%, whereas GP-30 achieved a comparable 24.0% carbon reduction at the cost of an 18.9% strength loss. FA-20 emerged as the most balanced replacement level, reducing embodied carbon by 17.8% while maintaining a strength loss of only 5.2%. The findings provide practical guidance for selecting supplementary cementitious materials in low-to-medium strength applications such as pavements, mass concrete, and leveling layers.

Keywords: Fly ash; Recycled glass powder; Carbon reduction efficiency; Compressive strength; Low-carbon concrete.

1 Introduction

Cement manufacturing contributes substantially to the carbon budget, accounting for roughly 7-8% of the man-made CO2 emissions [1]. Due to the immense volumes of concrete produced globally, even slight reductions in cement usage can yield cumulative savings. For this reason, partial replacement of cement with industrial byproducts has become a common approach. Two of the most used alternatives are fly ash (FA) and glass powder (GP).

The primary mechanism of FA is the pozzolanic reaction, in which it interacts with calcium hydroxide produced during cement hydration. This reaction forms additional C-S-H gel, densifying the pore structure and improving long-term durability. However, as a result of this relatively slow mechanism, more FA may reduce early-age strength [3]. The mechanism of glass powder is similar when it is ground fine enough to become reactive. In general, it has a

positive effect on strength and permeability at replacement levels of about 10–20%, but any further increase causes a decrease in these properties [4]. Studies on the environmental effects of concrete mixes containing FA and GP, prepared under the same conditions and applied at the same substitution ratios, are limited in the literature. Few studies have compared FA–GP blends [5, 6]; however, controlled comparative studies in practical engineering metrics like CO_2 per unit of strength remain scarce.

This paper aims to fill that gap. FA and GP were tested at replacement levels of 10%, 20%, and 30% under identical conditions (w/c = 0.60, no admixtures), reflecting the low-to-medium strength concretes used in pavements, mass fills, and leveling layers. Beyond simply reporting carbon and strength values side by side, we propose a Carbon Reduction Efficiency (CRE) metric–defined as the amount of carbon saved per unit of strength sacrificed–and present the results using a Carbon–Performance Quadrant. This visualization is intended to clearly identify which replacement level is practically advantageous.

2 Materials and Methods

A total of seven different mixtures were made: a control mixture of only Portland cement, and three FA and three GP mixtures with cement substitution amounts of 10%, 20%, and 30% by weight. No chemical admixtures were used, while the water-to-cement ratio was kept at 0.60 for all mixes. This way, any discrepancies that may be noted will be due solely to the difference in the replacement material used, not to other changes in the mix design. The maximum size of aggregates did not exceed 20 mm. All mix proportioning details are listed in Table 1.

Table 1. Concrete mixture proportions.

Mix Code	Cement (kg)	Additive	Additive (kg)	Water (L)	Sand (kg)	Aggregate (kg)
Control	350	–	0	210	708	1085
FA-10	315	Fly ash	35	210	708	1085
FA-20	280	Fly ash	70	210	708	1085
FA-30	245	Fly ash	105	210	708	1085
GP-10	315	Glass powder	35	210	708	1085
GP-20	280	Glass powder	70	210	708	1085
GP-30	245	Glass powder	105	210	708	1085

The fly ash used was a low-calcium type per EN 450-1 [7] ($SiO_2 + Al_2O_3 + Fe_2O_3 > 70\%$), and the glass powder was ground soda-lime glass waste, composed primarily of silica ($SiO_2 \approx 69.4\%$) along with Na_2O and CaO. Five cubes were cast per mixture — 35 in total – and tested at 28 days following TS EN 12390-3 [8]. Embodied carbon was calculated by multiplying each material's mass by its emission factor, using the ICE database for cement, fly ash, and aggregate, and a Tier-1 IPCC estimate for the glass powder [9, 10]. Additionally, a flat 28.0 kg CO_2/m^3 was added for transport, construction, and end-of-life, based on assumptions of a 100 km haul, 5 kWh/m^3 of construction energy, and a 70% recycling rate [11] – constant for all mixtures, as these stages are independent of the cement replacement level.

To obtain a relatinship between the environmental and mechanical sides of the picture, we defined a Carbon Reduction Efficiency (CRE) index:

$$CRE = \Delta EC / \Delta fc = (ECcontrol - ECmix) / (fc,control - fc,mix) \quad (1)$$

Here, ΔEC and Δfc represent the reductions in embodied carbon (kg CO_2/m^3) and 28-day compressive strength (MPa), respectively, relative to the control mixture. A higher CRE indicates greater carbon savings per unit of strength loss (per MPa). A Carbon–Performance Quadrant was also constructed, with the control mixture (27.0 MPa, 362.47 kg CO_2/m^3) as the origin, where the x-axis represents strength and the y-axis represents total embodied carbon – providing a visual assessment of which mixtures fall within a favorable zone.

3 Results and Discussion

The 28-day compressive strength of the control mixture was 27.0 MPa. As the replacement levels increased, FA exhibited a gradual reduction in compressive strength. The compressive strength was 26.8, 25.6, and 24.5 MPa at replacement levels 10%, 20%, and 30%, respectively. On the other hand, a more pronounced reduction was observed in compressive strength of GP mixtures. The corresponding compressive strengths were 26.2, 23.4, and 21.9 MPa at replacement levels of 10%, 20%, and 30%, respectively. This indicates that the compressive strength of GP-30 was approximately 19% lower than that of the control mixture. The compressive strength of each mixture remained within the 21.9-27.0 MPa band. This is typical for low-to-medium-strength concrete at the given water-to-cement ratio (Fig. 1). The one-way ANOVA confirmed statistically significant differences among the seven mixtures ($F(6,28)= 43.95$, $p< 0.01$, $\eta^2= 0.904$).Tukey's HSD post-hoc test indicated that FA and GP separated significantly from each other at replacement levels above 10%.

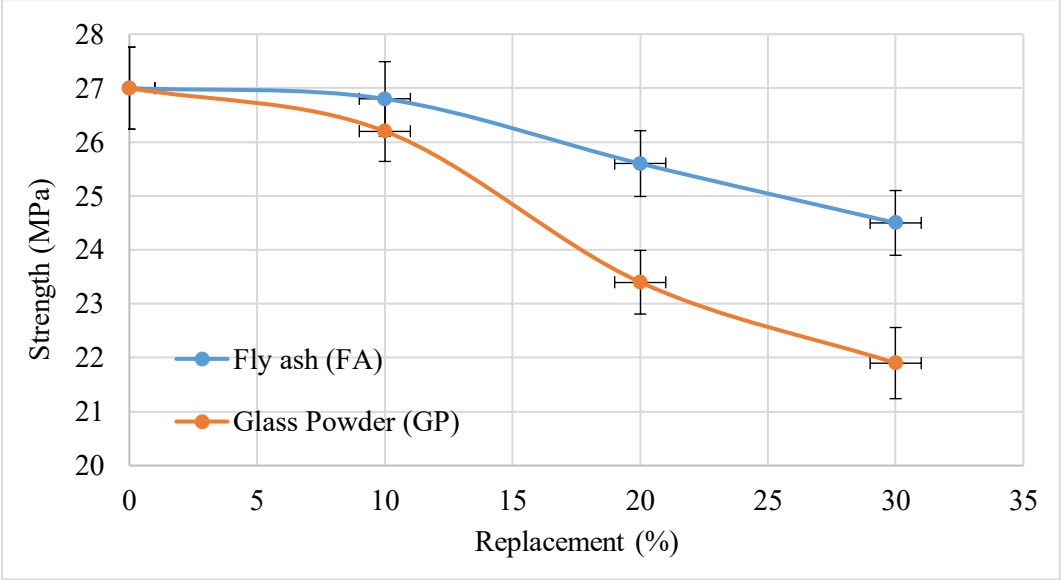

Fig. 1. 28-day compressive strength of FA and GP mixtures (error bars show standard deviation).

To assess embodied carbon and carbon intensity, the analysis incorporated the transportation, construction, and end-of-life stages. The control mixture exhibited the highest overall carbon footprint, amounting to 362.47 kg CO_2/m^3. For both replacement materials, embodied carbon decreased as the replacement level increased. FA-30 achieved a 26.7% reduction (265.66 kg CO_2/m^3), while GP-30 followed closely with a 24.0% reduction (275.32 kg CO_2/m^3). However, embodied carbon values alone are insufficient for the evaluation of the environmental performance of the mixtures. The carbon intensity (CI) was calculated by normalizing the embodied carbon with respect to compressive strength (CI = EC/fc). FA replacement mixtures

showed steady improvement, decreasing from 12.32 kg CO_2/MPa at FA-10 to 10.84 kg CO_2/MPa at FA-30 — a 19.2% improvement over the control's 13.42 kg CO_2/MPa. In contrast, the GP replacement mixtures remained relatively unchanged, ranging from 12.57 to 13.01 kg CO_2/MPa across the series. This indicates that the carbon savings due to reduced cement content are largely offset by the accompanying strength losses (Table 2).

Table 2. Embodied carbon (EC), 28-day compressive strength (fc), and carbon intensity (CI) of all mixtures.

Mix Code	EC (kg CO2/m3)	fc (MPa)	CI (kg CO2/m3/MPa)	CO2 Reduction (%)
Control	362.47	27.0	13.42	–
FA-10	330.20	26.8	12.32	8.9
FA-20	297.93	25.6	11.64	17.8
FA-30	265.66	24.5	10.84	26.7
GP-10	333.42	26.2	12.73	8.0
GP-20	304.37	23.4	13.01	16.0
GP-30	275.32	21.9	12.57	24.0

The Carbon Reduction Efficiency (CRE) index, which represents the relationship between mechanical performance and environmental benefit, was calculated as the ratio of embodied carbon reduction to compressive strength reduction relative to the control mixture (CRE = ΔEC / Δfc). Table 3 and Fig. 2 clearly demonstrate that FA provided greater carbon reduction per unit of strength lost (CRE) than GP at every comparable replacement level. FA-20 achieved a CRE of 46.1 kg CO_2/MPa with a strength loss of only 5.2%, whereas GP-20 achieved a CRE of only 16.1 kg CO_2/MPa with a considerably higher strength loss of 13.3%.The CRE value of FA-10 (161.4 kg CO_2/MPa*)* appears unusually high; however, this is largely an artifact of the minimal 0.2 MPa strength reduction — dividing by a near-zero value inflates the ratio. Therefore, this figure should be interpreted alongside CI rather than on its own.

Table 3. Carbon Reduction Efficiency (CRE) index of FA and GP mixtures.

Mix	ΔEC (kg CO2/m3)	Δfc (MPa)	Strength Loss (%)	CRE (kg CO2/MPa)
FA-10	32.3	0.2	0.7	161.4
FA-20	64.5	1.4	5.2	46.1
FA-30	96.8	2.5	9.3	38.7
GP-10	29.1	0.8	3.0	36.3
GP-20	58.1	3.6	13.3	16.1
GP-30	87.2	5.1	18.9	17.1

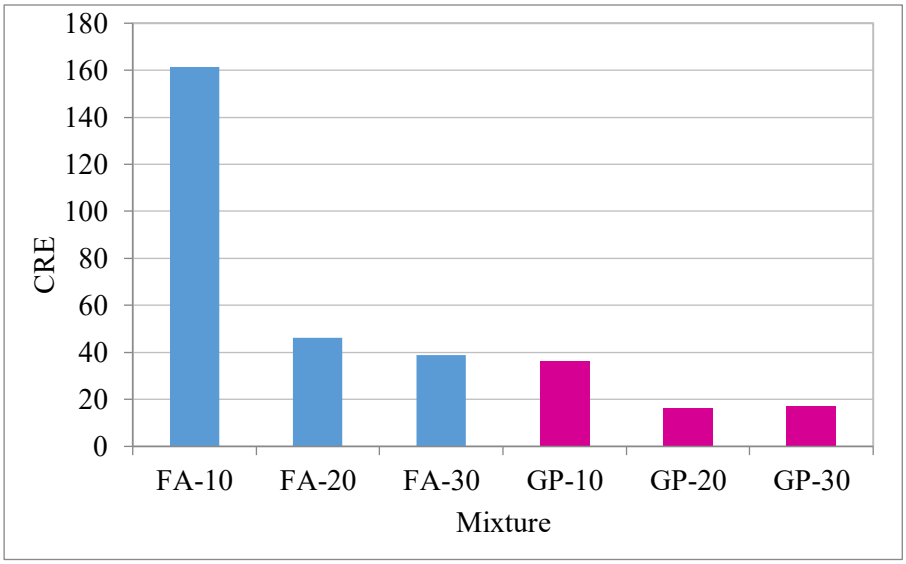

Fig. 2. Carbon Reduction Efficiency (CRE) index for FA (blue) and GP (pink) mixtures.

To evaluate the trade-off between carbon footprint and mechanical performance, a carbon–performance quadrant analysis was carried out. In this framework, the control mixture served as the reference point. The plot was divided into four quadrants, which represent the strength and carbon performance of each mixture relative to the control. Fig. 3 presents the carbon–performance quadrant analysis results. As shown in Fig. 3, none of the mixtures were positioned in Zone I, which is due to the strength reduction inherently associated with cement replacement. Instead, all mixtures were positioned in Zone II (lower carbon, lower strength). Among the mixtures, FA-20 and FA-30 were located closest to the Zone I boundary, offering 17.8% and 26.7% carbon savings alongside modest strength losses of 5.2% and 9.3%, respectively. GP-20 and GP-30 were located further from that boundary – similar carbon savings, but with higher strength losses, indicating a more limited applicable range for glass powder once replacement exceeds 10%.

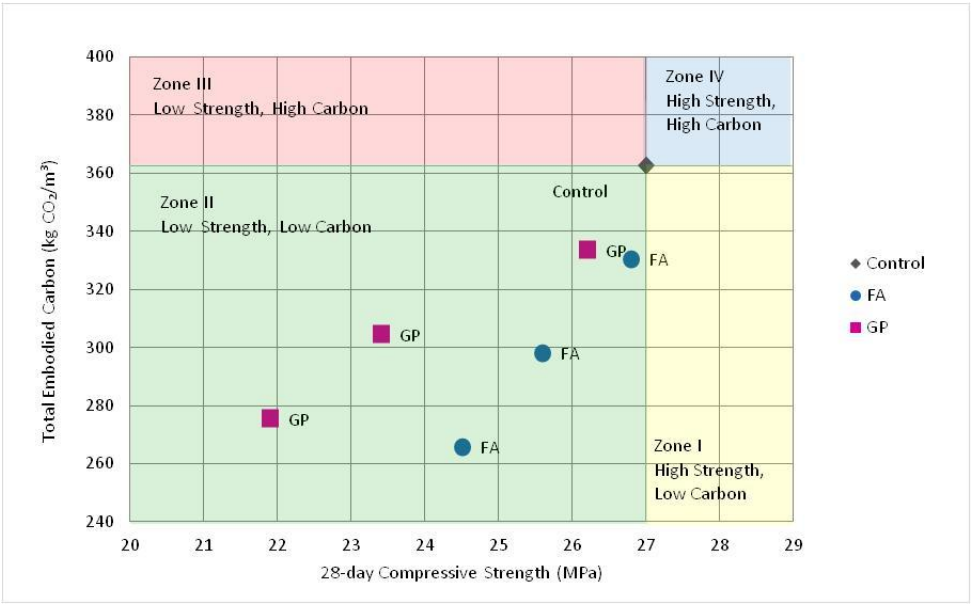

Fig. 3. Carbon–Performance Quadrant Analysis of FA and GP concrete mixtures.

The combined evaluation using the CRE index and the carbon–performance quadrant identified FA-20 as the most balanced mixture, achieving a 17.8% reduction in embodied

carbon with only a 5.2% reduction in compressive strength. If reducing embodied carbon is prioritized over maximizing compressive strength, FA-30 may also be considered, although its slower long-term strength development should be taken into account. By comparison, glass powder appeared to be competitive only up to a replacement level of approximately 10%, beyond which the strength penalty outweighed the environmental benefit.

4 Conclusions

In this study, FA and GP were investigated as partial cement replacements at replacement levels of 10%, 20%, and 30%. The concrete mixtures were produced without chemical admixtures and at a constant water-to-cement ratio of 0.60 to enable a direct comparison of the effects of the two supplementary cementitious materials on mechanical and environmental performance. The mixture containing 30% fly ash demonstrated the highest environmental efficiency, with a carbon intensity of 10.84 kg CO_2/MPa, corresponding to a 19.2% reduction compared with the control. For recycled glass powder, the 20% replacement level offered the most balanced performance, while higher replacement ratios led to more pronounced strength losses. This study provides a direct comparison of FA and GP under identical mixture conditions using performance-normalized environmental indicators. The results indicate that, under the tested conditions, fly ash exhibits a better combination of carbon emission reduction and mechanical strength than recycled glass powder. These conclusions rest on 28-day results from a single mix design; therefore longer-term testing and a broader set of durability measures would be a natural next step.

Abstract. Sustainability goals and stricter environmental protection requirements now guide a wide range of experts, from materials scientists to architects, to find practical ways to incorporate byproducts and waste materials into concrete construction. The urgent focus on climate change has led researchers to investigate materials like polymers and pozzolans as additives, offering ecological solutions to reduce heavy cement use and lower carbon emissions from concrete structures. This study explores the effects of supplementary cementitious materials, specifically fly ash, ground granulated blast-furnace slag, and silica fume, on delaying chloride-induced corrosion initiation and influencing service-life outcomes under Mediterranean marine chloride conditions. Life-365 is employed to conduct a comparative service-life assessment using a realistic dynamic diffusion approach, combined with a multi-category life cycle assessment framework to facilitate interpretation beyond a single climate indicator. The analysis has been adapted to the conditions of the Antalya coastal region, considering seasonal temperature fluctuations to reflect sensitivity to chloride flow. The results, quantified through service life level indicators, indicated that at 50 mm cover, replacing 40% of cement with a pozzolan mix containing 10% silica fume, 15% slag, and 15% fly ash offers the greatest carbon reduction, although multi-category results reveal significant environmental trade-offs regarding toxicity. Additionally, increasing concrete cover from 30 mm to 50 mm consistently prolongs the predicted time to corrosion initiation and extends overall service life across all mixtures, with the degree of improvement heavily depending on binder composition.

Keywords: Life cycle; fly ash; slag; silica fume.

1 Introduction

Concrete remains indispensable to buildings and infrastructure; however, long-term performance is frequently determined by durability rather than strength, particularly in chloride-laden coastal environments. From a sustainability standpoint, durability is not only a technical requirement but also a life-cycle driver because interventions add up over time, cumulatively increasing material use, energy consumption, and associated environmental burdens. Consequently, service-life differences can alter sustainability conclusions even when initial environmental impacts appear similar. Recent literature on cement and concrete decarbonization emphasizes that sustainability outcomes depend on broader system choices and transparent modeling assumptions [1]. Country-specific life cycle assessment (LCA) studies indicate that decarbonization is possible by aligning energy systems and technologies with local conditions and inventory assumptions [2]. Recent sustainability-oriented studies state that environmental conclusions for cement and concrete are highly sensitive to methodological

choices and system framing. Reviews of current practice highlight that differences in functional unit selection, boundary definition, and scenario assumptions can lead to substantially different comparative outcomes, even when the same material system is evaluated [3-4]. Scenario-based LCA of concrete production at the building scale, different datasets indicate that embodied-carbon values can vary significantly across datasets, highlighting the need for consistent boundaries and careful comparability [5].

Carbon assessments can also be affected by the long-term uptake of CO_2 by cement-based materials through carbonation, which complicates net emission assessments and highlights the need for consistent methodological treatment [6]. These findings suggest that sustainability should be evaluated together with durability. If supplementary cementitious materials (SCM) mixtures delay the commencement of corrosion, fewer repairs are needed, which reduces the total environmental burden over the service life. Experimental microstructural evidence supports the plausibility of pore refinement and durability improvements in Portland cement systems partially replaced by fly ash, slag, and silica fume [7]. Systems incorporating both coal fly ash and Ground Granulated Blast Furnace Slag (GGBFS) have been investigated for chloride diffusion behaviour and are relevant to strategies aimed at reducing chloride ingress in reinforced concrete [8]. Multiscale modelling for fly ash concretes suggests that mixture-dependent microstructural features can be combined with effective chloride diffusion predictions [9]. Long-term aged slag and fly ash concretes have been evaluated using data-driven methods linking mixture characteristics to durability indicators, reinforcing that performance evolves with age and mixture properties [10].

Existing research on SCMs generally focuses on their individual effects on concrete durability or isolated embodied carbon metrics. However, this study distinguishes itself by bridging the critical gap between long-term service-life prediction and a comprehensive environmental impact assessment. The primary novelty of this research lies in its multi-dimensional approach. First, it directly couples chloride-induced corrosion initiation modeling, performed via Life-365 (v2.2.3), with a multi-category LCA framework. This expands the environmental evaluation beyond the standard Global Warming Potential (GWP) to include ozone layer depletion, human carcinogenicity, and ecological toxicity. Second, this study explicitly investigates the synergistic interaction between material composition—varying dosages of fly ash, slag, and silica fume—and geometric protection by comparing structural elements (beams and slabs) under different concrete cover depths (30 mm and 50 mm). Finally, to ensure regional accuracy and practical relevance, the service-life modeling incorporates site-specific monthly temperature profiles from Antalya, Türkiye, capturing the dynamic nature of chloride diffusion under realistic coastal Mediterranean conditions. By integrating these elements, this study provides a holistic, durability-informed sustainability perspective, demonstrating how long-term maintenance reductions drive the true environmental performance of reinforced concrete

2 Materials and Methods

Six distinct concrete mix designs with different weight percentages of slag, fly ash, and silica fume, along with a base design without admixtures, were formulated to study these pozzolans as partial cement substitutes. The life-365 model was used to evaluate the service life and life cycle of the concrete produced. These materials, the mix design, and the model's principles are explained in the following sections.

2.1 Pozzolons

SCMs refine concrete microstructure and boost durability by reducing permeability through the pozzolanic reaction, in which reactive silica/alumina from SCMs combines with portlandite to form additional C–S–H, densifying the pore structure and limiting aggressive-agent transport

[11]. Fly ash generates extra cementitious compounds that lower cost and carbon footprint, while ultrafine silica fume from alloy production acts as both a pozzolan and microfiller, physically densifying the matrix, raising strength and bond, and aiding waste management.

In Turkey, blended cements already hold a substantial market share (40.7 % of strength classes 32.5 and above in 2017), and ready-mix practice routinely incorporates SCMs (average fly ash 38.2 kg/m³, blast-furnace slag 2.3 kg/m³), confirming their practicality for chloride-exposed coastal infrastructure. Local Mediterranean supply chains further support this: silica fume is produced in Antalya, ground granulated blast-furnace slag is available from İSDEMİR in İskenderun, and fly ash can be sourced from regional plants such as Yatağan and Tunçbilek, making high-SCM mixes feasible for Antalya's coastal construction.

In the present study, six concrete mixes (scenarios) were prepared and tested to obtain the optimal mix design, as detailed in Table 1.

Table 1. Concrete mix designs (Type I cement) weight values

Scenario	Amount (Kg)	Cement (kg)	Fly Ash (kg)	Slag (kg)	Silica Fume (kg)
1	400	380	10	10	0
2	400	360	20	20	0
3	400	350	20	20	10
4	400	340	20	20	20
5	400	300	40	40	20
6	400	240	60	60	40

The control design (baseline mix) consisted of approximately 400 kg/m³ cement, 900 kg/m³ sand, 1000 kg/m³ coarse aggregate (5-10 mm), and 160 kg/m³ drinking water resulting in a water-cement ratio of 0.42 and a density of 2460 kg/m³. All mixtures were defined in Life-365 with w/cm = 0.42. Mix #1 consisted of 2.5% Class F fly ash, 2.5% slag, and 0% silica fume. Mix #2 increased Class F fly ash and slag to 5.0% each while keeping silica fume at 0%. Mix #3 retained 5.0% Class F fly ash and 5.0% slag and added 2.5% silica fume. Mix #4 kept Class F fly ash and slag at 5.0% and increased silica fume to 5.0%. Mix #5 increased Class F fly ash and slag to 10.0% each and used 5.0% silica fume. Mix #6 used the highest SCMs contents, with 15.0% Class F fly ash, 15.0% slag, and 10.0% silica fume. Ordinary Portland cement constituted the remaining binder fraction in each mixture. This structured progression enables interpretation of durability trends as SCMs dosage increases while preserving comparability by holding other mixture parameters constant. In all scenarios, we kept the total volume of pozzolans lower than the Portland cement content in concrete mixtures to guarantee enough calcium hydroxide (CH) for the pozzolanic reaction, sufficient early strength, good workability, and compliance with performance standards as suggested in the relevant literature [7,12].

2.2 Servis Life Prediction and LCA

In this study, chloride-induced corrosion initiation is estimated by modelling ingress as diffusion-controlled transport via a closed-form solution of Fick's second law, yielding chloride concentration as a function of time and depth. To capture Mediterranean coastal seasonality, a dynamic diffusion process is used in place of annual averages: the diffusion coefficient varies with time and temperature within a two-dimensional equation solved by the Crank–Nicolson method. Surface-chloride boundary conditions are strengthened to reflect Antalya's high-salinity marine environment, recognising that this concentration—driven by coastline proximity and elevated temperatures—is the dominant durability parameter [3]. Deterministic surface-chloride calculations and probabilistic service-life estimates then employ an aging factor, activation energy, and reference values of 28 days and 293°K [14].

Table 2. A comparison of the varying results for the diffusion coefficient with the ageing factor

Mixture	D28 (m^2/sec)	Aging Exponent (m)	Chloride Threshold (Ct, %wt. conc.)	Energy Activation (U)
Mix 1	8.8716E-12	0.23	0.050	35000J/mol
Mix 2	8.8716E-12	0.27	0.050	35000J/mol
Mix 3	5.8729E-12	0.27	0.050	35000J/mol
Mix 4	3.8878E-12	0.27	0.050	35000J/mol
Mix 5	3.8878E-12	0.34	0.050	35000J/mol
Mix 6	1.7038E-12	0.41	0.050	35000J/mol

The model of deterioration shown in Fig. 1 consists of two distinct phases: chloride penetration, followed by a period of corrosion leading to unacceptable damage. Life-365 provides an option to estimate surface chloride and apparent diffusion parameters from chloride profile measurements consistent with ASTM C1556, enabling calibration when laboratory or field data are available. The framework further represents service life as initiation time plus a propagation period (See Figure 1) and can generate repair schedules and life-cycle cost calculations based on intervention timing and user-defined repair strategies. While corrosion propagation in real-world structures is highly dependent on binder composition, concrete resistivity, cracking, and moisture state, Life-365's mathematical framework is primarily designed to calculate the initiation phase via Fickian diffusion. Therefore, a constant propagation period of 6 years was adopted for all scenarios. This standardized assumption intentionally isolates the comparative effects of SCMs on chloride ingress and initiation time, rather than attempting to provide an absolute, definitive prediction of structural failure. Following this, we calculate the Service Life Level (SLL) through the ratio of lifelong of each sample mixture (tri) to the service lifelong of baseline sample (trb) for six designs listed in Table 2.

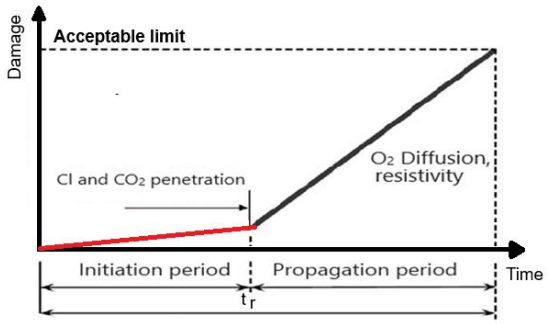

Fig. 1. Components of Concrete Service Life Calculation

2.3 Service-Life Evaluation for Reinforced Concrete

In addition to the general durability interpretation for reinforced concrete elements, a dedicated evaluation was performed for reinforced concrete beams and slabs to explicitly investigate the interaction between mixture composition and cover depth under chloride exposure. Beams and slabs were selected because they represent a common structural element in buildings and are often more sensitive to cover depth variations due to reinforcement placement and bending-induced cracking tendencies. All the scenarios were evaluated under a consistent modelling framework.

As illustrated in Fig. 2, the beam geometry was defined as a prismatic member with a length of 1.0 m and an overall depth of 250 mm; beam width was not treated as a governing parameter for the comparisons reported here because the analysis targets corrosion initiation at

reinforcement depth. The water-to-cementitious materials ratio was held constant at w/cm = 0.42 for all mixtures to isolate the effect of SCMs incorporation. Two concrete cover depths were considered in the beam analysis: 30 mm (3 cm), representing conventional practice, and 50 mm (5 cm), representing an enhanced durability design scenario. All other exposure-related parameters were held constant across scenarios, and a repeating monthly temperature profile representative of a coastal Mediterranean climate was applied over the analysis horizon. To broaden the structural interpretation of the study, the service-life analysis was also extended to reinforced concrete slabs model under the same environmental and mixture assumptions.

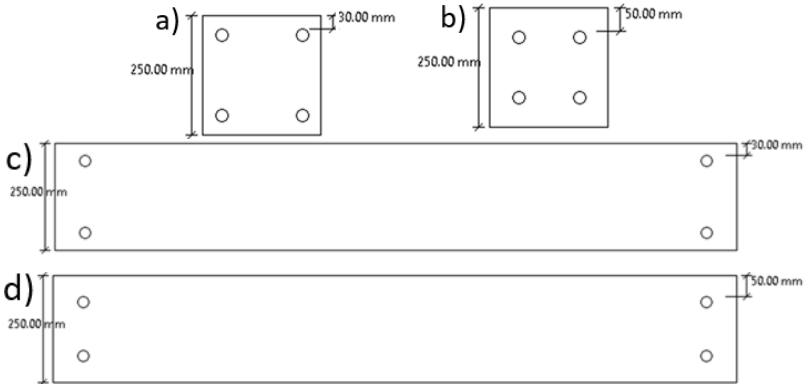

Fig. 2. Dimensions of the experimental reinforced concrete beam (a and b) and slab (c and d)

For the slab analysis, the element type was defined in Life-365 as a slab/wall member. The slab thickness was taken as 250 mm, the reference area was 1 m², and the corresponding concrete volume was 0.20 m³. Similar to beam scenarios, two reinforcement depths, corresponding to concrete covers of 30 mm and 50 mm, were considered. The same six SCM-containing mixtures used in the beam analysis were adopted for the slab scenarios, and the same Antalya monthly temperature profile and w/cm ratio of 0.42 were maintained throughout. In this way, the slab analysis was incorporated to determine whether the durability trends observed in beams would remain valid for another common reinforced concrete member under identical exposure and binder conditions.

3 Results

The results indicate a systematic increase in predicted corrosion initiation time as SCM content increases, with a strongly non-linear response at higher SCM dosages. At 30 mm cover, SCM do not significantly increase service life. However, higher SCM contents, especially in Mix #6 (i.e., 15% fly ash + 15% slag + 10% silica fume), clearly extend the initiation time. At 50 mm cover, the influence of mixture composition became substantially more pronounced, indicating a strong interaction between geometric protection and mixture quality under diffusion-controlled chloride ingress. Similar mixture-dependent effects on chloride diffusion behaviour have been discussed for fly ash and slag blended systems [8] and in long-term evaluations of aged SCM concretes [10]. From a sustainability perspective, these beam results reinforce the importance of durability-oriented design for structural elements subjected to chloride exposure, because delaying corrosion initiation reduces the likelihood and frequency of repair interventions that contribute additional material and energy burdens over the service life.

The results of this study are interpreted from a durability-informed sustainability perspective, where predicted corrosion initiation times and intervention schedules are considered key drivers of long-term environmental burdens, rather than focusing solely on initial embodied impacts. Contemporary cement and concrete literature increasingly emphasize that sustainability outcomes depend on system-level choices, regional context, and methodological boundaries rather than on single material substitutions [1,2,5]. These findings underline the importance of situating mixture-level durability improvements within a broader sustainability framing.

The modelling results indicate that increasing SCM incorporation, particularly in ternary systems combining fly ash, slag, and silica fume, can systematically delay chloride-induced corrosion initiation. The beam results illustrate this clearly through the large initiation-time shift from Mix 1 to Mix 6 at both cover depths and the particularly strong increase observed when higher SCM dosages are paired with increased cover. In the long term, these delays become directly relevant to sustainability because repair and maintenance interventions introduce additional material and energy demands.

Infrastructure-focused sustainability literature emphasizes that maintenance cycles can dominate cumulative environmental burdens when service life is limited, especially for chloride-exposed structures [15,16]. Within this framework, the increase in durability, achieved by SCM-rich mixtures represents a path to sustainability, supported not only by the initial reduction in cement content but also, by a decrease in the frequency of interventions. A critical implication of this interpretation is that sustainability assessment based on a single indicator may be insufficient. Scenario-based LCAs show that strategies reducing climate impacts can change other environmental categories depending on inventory assumptions and boundaries [5].

Fig. 3 presents the environmental input profile used in Life-365, including the historical monthly temperature derived from observational data for Antalya, Türkiye. In addition, the chloride exposure boundary condition was defined using a time-dependent surface chloride build-up assumption where the surface chloride level increases over the initial years and then reaches a plateau at a regional maximum value. This seasonal and time-dependent exposure representation was adopted to reflect the sensitivity of chloride transport and corrosion initiation to temperature and long-term chloride accumulation under coastal Mediterranean conditions.

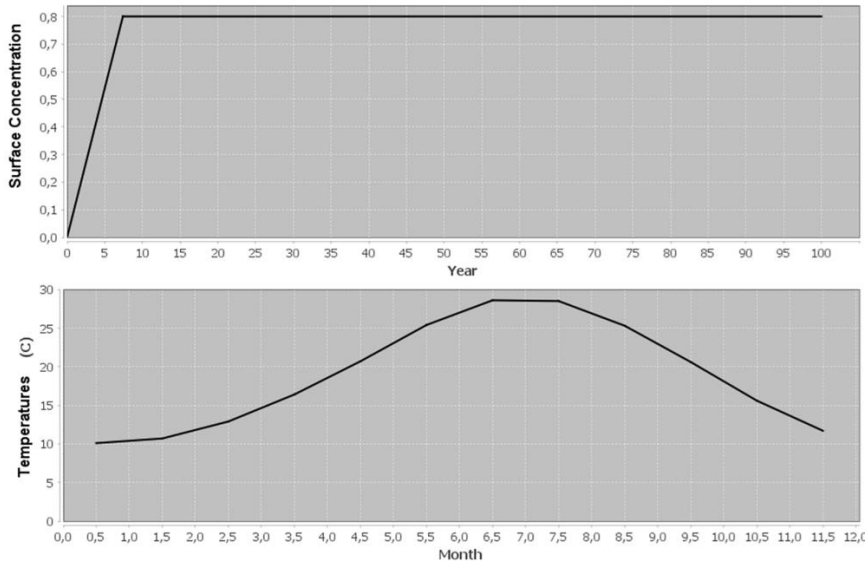

Fig. 3. Graph of changes in ion concentration and average monthly ambient temperature of concrete

To evaluate the combined influence of mixture composition and cover depth under the same exposure framework, seven binder configurations were defined at a constant w/cm ratio of 0.42: a base mix with no SCM replacement (Class F fly ash = 0%, slag = 0%, silica fume = 0%), and six SCM-containing mixtures (Mix #1–Mix #6) as specified in the Life-365 software. Under the Antalya temperature profile, the base mix provides a reference for cover-depth sensitivity: at 30 mm cover, the predicted initiation time was 2.2 years with a total service life of 8.2 years, whereas at 50 mm cover the initiation time increased to 4.5 years and total service life to 10.5 years. The same cover effect was observed across SCM mixtures, but the magnitude depended strongly on SCM dosage. At 30 mm cover, predicted total service life increased from 8.4 years

(Mix 1) to 19.5 years (Mix 6), while at 50 mm cover total service life increased from 10.8 years (Mix 1) to 53.3 years (Mix 6).The other mixtures values at 30 mm cover, total service life values were 8.5 (Mix 2), 9.2 (Mix 3), 10.3 (Mix 4), and 11.1 years (Mix 5), whereas at 50 mm cover these increased to 11.4, 13.4, 16.4, and 19.5 years, respectively. Because the propagation period was kept constant (6.0 years), the observed differences in total service life were driven primarily by changes in predicted corrosion initiation time. Overall, the results demonstrate a clear interaction: increasing cover depth consistently delays initiation for all mixtures, and increasing SCM dosage further amplifies this delay—especially at higher replacement levels—indicating that geometric protection (cover) and mixture quality act synergistically in diffusion-controlled chloride ingress.

A parallel set of service-life predictions was also obtained for reinforced concrete slabs in order to compare member-level durability behavior under the same chloride exposure conditions. Similar to the beam results, the slab predictions showed that both increasing cover depth and increasing SCM content led to longer corrosion initiation times and longer total service life. For the slab scenarios with 30 mm cover, the predicted corrosion initiation times were 3.2, 3.4, 4.4, 5.7, 6.8, and 18.2 years for Mix #1 through Mix #6, respectively. With a constant propagation period of 6.0 years, the corresponding total service life values became 9.2, 9.4, 10.4, 11.7, 12.8, and 24.2 years. When the cover depth was increased to 50 mm, the predicted initiation times increased to 6.4, 6.9, 9.6, 13.4, 17.8, and 63.7 years, while the corresponding total service life values increased to 12.4, 12.9, 15.6, 19.4, 23.8, and 69.7 years, respectively.

These slab results confirm the same overall pattern observed in the beam analysis. Increasing the concrete cover from 30 mm to 50 mm consistently improved both the predicted corrosion initiation time and the total service life for all mixtures. In addition, the improvement became more pronounced as the SCM replacement level increased, with Mix 6 again providing the strongest durability performance among the evaluated alternatives.

When the beam and slab results are considered together, the same durability ranking among mixtures is preserved in both member types, even though the absolute service-life values differ. This indicates that the beneficial influence of SCM incorporation is not limited to a single structural element definition but can also be observed in slab scenarios under the same exposure and temperature assumptions. In both member types, the combined effect of higher SCM replacement and greater concrete cover produced the most favorable durability outcomes, showing that mixture design and geometric protection should be evaluated together rather than separately.

The results of the environmental assessment for the mixtures are summarized in Table 3. For each mix and cover depth, Table 3 reports the selected LCA indicators (GWP, ODP, carcinogenicity, and ecological toxicity) expressed per cubic meter of concrete, together with the corresponding percentage changes relative to the Base mix at the same cover depth. This structure enables direct comparison of mixture effects at fixed cover (e.g., Base vs Mix 6 at 30 mm) and cover effects at fixed mixture, supporting a durability-informed sustainability interpretation in which longer predicted service life is linked to reduced maintenance-driven burdens across multiple impact categories.

When the 3 cm cover depth is considered, the increase in total service life between successive mixture designs is relatively limited for low-SCM mixtures. Compared to the base mixture, Mix #1 shows only a marginal increase of approximately 1.02 times, followed by a further 1.01 times increase from Mix 1 to Mix 2. A noticeable improvement appears when moving from Mix 2 to Mix 3, with an increase of about 1.08 times, and continues from Mix 3 to Mix 4 with 1.12 times increase. The transition from Mix 4 to Mix 5 yields a moderate gain of approximately 1.08 times, whereas a pronounced jump is observed between Mix 5 and Mix 6, where total service life increases by about 1.76 times.

At the 5 cm cover depth, a similar trend is observed but with generally stronger gains between mixture designs. The increase from the base mixture to Mix 1 is approximately 1.03×, followed by a 1.06× increase from Mix 1 to Mix 2. A clearer improvement occurs between Mix 2 and Mix 3, corresponding to a 1.18× increase, and this effect becomes more noticeable from Mix 3 to Mix 4 with an increase of about 1.22×. The transition from Mix 4 to Mix 5 results in a further 1.19× increase, while the largest improvement again occurs between Mix 5 and Mix 6, where total service life increases by approximately 2.73×. These results indicate that incremental increases in SCM content produce limited service-life gains at low replacement levels, whereas significantly larger improvements happen once higher SCM dosages are combined with increased cover depth.

Environmental impacts were quantified using the standardized life-cycle inventory and characterization models embedded within the Alternative Case Scenario (ACS) Calculation tool provided by the American Concrete Institute (ACI). The GWP was quantified in kg CO_2-eq/m³, representing aggregated greenhouse gas emissions relative to carbon dioxide. Human carcinogenicity (CTUh/m³) was generated by the ACS tool's default characterization framework to represent potential human health risks, respectively. Ozone layer depletion was quantified in kg CFC-11-eq/m³, expressing the relative contribution of ozone-depleting substances to stratospheric ozone loss. Ecological toxicity was expressed in comparative toxic units for ecosystems (CTUe/m³), representing potential impacts of emissions on freshwater ecosystems through fate–exposure–effect modelling. By relying on the ACS tool's internal database for material processing and default supply-chain logistics, the environmental contribution of each mixture can be compared under a standardized framework

Transport can be incorporated in the inventory using a mass–distance activity approach (ton-kilometre), computed as the product of delivered mass for each constituent and an assumed hauling distance. Including transport is justified because life-cycle conclusions are sensitive to inventory definition and scenario choices; methodological reviews emphasize that boundary and scenario assumptions can materially affect comparative outcomes [3,4]. Scenario-based regional cement LCAs indicate that non-climate categories can become hotspots depending on background conditions such as grid mix and process characteristics [2]. For long-term analysis, transport linked to intervention activities may accumulate and become non-trivial when maintenance frequency is high, consistent with the observation that maintenance cycles can dominate cumulative burdens when service life is limited [15,16]. Therefore, transport was treated explicitly in the inventory rather than assumed to be negligible.

In practical terms, these metrics allow material-related emissions to be translated into comparable impact values; for example, cement production contributes to GWP primarily through CO_2 emissions from clinker production, while trace emissions associated with fuel combustion and raw material processing contribute to carcinogenicity and ecological toxicity indicators. By assigning characterization factors to inventory flows, the environmental contribution of each mixture can be expressed in terms of kilograms of carbon dioxide equivalent per cubic meter, comparative toxic unit for humans per cubic meter (CTUh/m³), kilograms of trichlorofluoromethane per cubic meter (kgCFC-11-eq/m³), and comparative toxic unit for ecosystems per cubic meter CTUe/m³, Megajoules per cubic meter ,enabling direct comparison of mixtures with different SCM contents under a durability-informed service-life framework. LCA was conducted using the ACS Calculation tool provided by the American Concrete Institute (ACI). This tool standardizes the environmental impacts of concrete mixtures across multiple categories. For each mix and cover depth, Table 3 reports the used LCA indicators expressed per cubic meter of concrete.

Table 3. Environmental impacts attained for the baseline (400kg cement) and mixing scenarios

Impact	Unit	Baseline	Mix #1	Mix #2	Mix #3	Mix #4	Mix #5	Mix #6
Global Warming	$kgCO_2/m^3$	368.309	355.602	342.895	339.172	335.449	310.035	277.174
Carcinogenicity	$CTUh/m^3$	5.22E-06	5.20E-06	5.18E-06	5.52E-06	5.87E-06	5.83E-06	6.48E-06
Ozone Layer Depletion	$KgCFC-11/m^3$	1.59E-05	1.53E-05	1.48E-05	1.48E-05	1.49E-05	1.38E-05	1.28E-05
Ecological Toxicity	$CTUe/m^3$	606.350	601.106	595.862	626.870	657.878	647.390	698.918
Fossil Fuel	MJ/m^3	145.713	110.439	122.632	133.520	134.173	134.825	140.269

The comparative LCA results in Table 3 point out different environmental performances across different impact categories between the mixtures. Increasing SCM content strongly improves climate conditions, but environmental impacts can vary.

In terms of GWP, Mix #6 provides the highest advantage, and achieves a 25% reduction in carbon emissions compared to Baseline. In addition, Mix #5 and #6 show the lowest Ozone Layer Depletion, making high-SCM systems significantly effective for climate conditions.

On the other hand, high-SCM mixtures offer certain drawbacks in terms of toxicity. While Mix #6 minimizes carbon emission, it exhibits the highest human carcinogenicity and ecological toxicity. In contrast, Mix #2 offers the most balanced profile and provides the lowest carcinogenic potential and optimal ecosystem protection. Additionally, about Fossil Fuel consumption, Mix #1 is the most efficient, as higher SCM dosages slightly increase energy demand due to material processing and logistics.

In summary, while Mix #6 is the ideal choice for carbon-reduction targets, the multi-category LCA reveals an inherent environmental trade-off. B As no normalization has been carried out across categories, it is not possible to determine with certainty which is objectively the ‘best’ mixture. However, Mix #2 presents an alternative compromise scenario that limits carcinogenic potential while still providing moderate durability benefits.

3.1 Comparative Discussion of Beam and Slab Behaviors

When the beam and slab results are considered together, the same overall durability ranking among mixtures is preserved in both member types, even though the absolute service-life values differ. In both beams and slabs, increasing SCM content led to longer corrosion initiation times and longer total service life, and this improvement became more pronounced when the concrete cover was increased from 30 mm to 50 mm. This indicates that the beneficial influence of SCM incorporation is not limited to a single structural element definition but remains consistent across both member types under the same exposure and temperature assumptions.

A comparison relative to the Base mix further clarifies this trend. For beams at 30 mm cover, the corrosion initiation time increased from 2.2 years for the Base mix to 13.5 years for Mix 6, corresponding to an increase of approximately 6.1 times, while the total service life increased from 8.2 to 19.5 years, representing an increase of about 138%. At 50 mm cover, the same comparison shows an even stronger improvement: the initiation time increased from 4.5 years to 47.3 years, or approximately 10.5 times, while the total service life increased from 10.5 to 53.3 years, corresponding to an increase of about 408%. These results indicate that, for beams, the improvement associated with higher SCM replacement becomes substantially more significant at higher cover depth.

A similar pattern was observed for slabs, but with even larger absolute gains. At 30 mm cover, the slab initiation time increased from 2.9 years for the Base mix to 18.2 years for Mix

#6, corresponding to an increase of approximately 6.3 times, while the total service life increased from 8.9 to 24.2 years, representing an increase of about 172%. At 50 mm cover, the initiation time increased from 5.8 years to 63.7 years, which corresponds to approximately 11.0 times the Base value, while the total service life increased from 11.8 to 69.7 years, representing an increase of about 491%. Like the beam results, these slab results show that the influence of SCM incorporation becomes much more pronounced at higher replacement levels and at greater cover depth.

Another important observation is that the relative gains at low SCM dosages remained limited in both member types, whereas much larger improvements were obtained at the higher replacement levels, particularly in Mix #5 and Mix #6. This suggests that minor SCM additions provide only modest durability benefits relative to the Base mix, while higher combined dosages of fly ash, slag, and silica fume produce a much stronger resistance to chloride ingress. Therefore, the results do not simply indicate that SCM use is beneficial in general; rather, they show that the magnitude of the benefit depends strongly on replacement level and becomes especially significant when combined with increased concrete cover.

Within the present model setup, the slab cases yielded longer initiation times and longer total service lives than the corresponding beam cases at the same depth and mixture level. However, this difference should be interpreted as a model-based comparison within the adopted member definitions rather than as a universal practical ranking for all structural conditions. The more important finding is that the same material trend is preserved in both element types: higher SCM replacement and greater cover depth consistently produced the most favorable durability outcomes. This supports the interpretation that mixture design and geometric protection should be evaluated together rather than separately in durability-oriented reinforced concrete design.

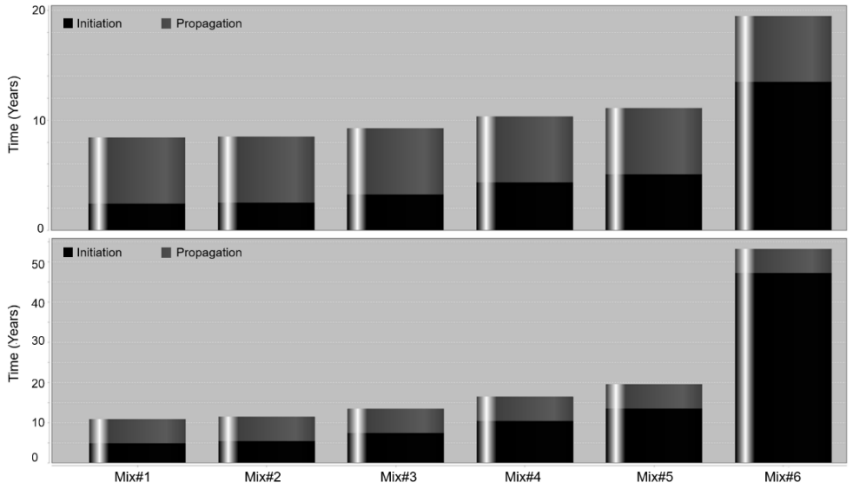

Fig. 4. Service life of the concrete produced with different designs compared to the service life of the base concrete when cover is 3 cm (top panel) and 5 cm (bottom panel)

To explicitly quantify these durability improvements, the SLL indicators were evaluated for each scenario. For the 30 mm cover depth, the results are as follows: SLL values of 1.02, 1.04, 1.12, 1.26, 1.35, and 2.38 for Mix #1 through Mix #6, respectively. For the 50 mm cover depth, the SLL values demonstrate more increase, recorded as 1.03, 1.09, 1.28, 1.56, 1.86, and a notable peak of 5.08 for Mix #6. These SLL indicators clearly illustrate that while lower SCM replacement levels provide low benefits, the relationship between high pozzolanic content and increased concrete cover depth results in a considerable enhancement in structural durability.

4 Conclusion

This study shows that SCMs critically enhance the durability of chloride-exposed reinforced concrete and thereby improve long-term sustainability by reducing maintenance demand. Beam

and slab modelling demonstrated that raising cover depth from 30 mm to 50 mm increased both corrosion-initiation time and total service life for every mixture, with the magnitude of the gain strongly dependent on binder composition; higher SCM dosages further prolonged initiation, so that the fixed 6-year propagation period left differences in overall service life driven almost entirely by initiation-time changes. Comparative results confirmed that elevated combined fly-ash, slag and silica-fume contents consistently delayed chloride-induced corrosion onset, establishing mixture design and adequate cover as complementary controls on diffusion-driven deterioration. Under the dynamic Mediterranean diffusion model these gains were quantified by SLL indicators that peaked at 5.08 for the highest-SCM mixture. When coupled with multi-category LCA, the extended service life reduces repair interventions and the associated material and energy burdens across global-warming potential, ozone depletion and ecological toxicity; yet trade-offs remain, with the highest-SCM design maximizing carbon reduction while moderate substitution yields a more balanced human-health toxicity profile. Collectively the findings support a durability-oriented sustainability strategy in which service-life extension is recognized as a primary mechanism for lowering cumulative environmental impacts.

Abstract.

The traditional sieve analysis method has long been used to determine aggregate particle size distribution, which plays a crucial role in the mechanical and durability properties of concrete. However, the inability to apply the traditional sieve analysis method to hardened concrete, particularly in post-earthquake debris assessments, has prompted researchers to explore alternative approaches. In this context, image processing-based analysis methods have gained considerable attention in recent years.

This study proposes an image-based particle analysis method for the characterization of aggregate particles by systematically comparing different preprocessing workflows in ImageJ. The effects of different thresholding, binarization (black-white), particle separation, analysis settings on particle size distribution results were evaluated. The results demonstrated that preprocessing settings have a significant influence on the determination of particle size distribution. Therefore, accurate analysis settings are crucial for obtaining reliable, repeatable, and traceable results. Finally, the aggregate granulometry curve obtained with different preprocessing settings was compared with experimental results obtained from the conventional sieve analysis method. It is believed that this study will contribute to the creation of a standard application procedure for image-based aggregate particle size analysis in the future, and has the potential to provide rapid and reliable results, especially in the evaluation of post-earthquake debris.

Keywords: *Image processing, particle size distribution, ImageJ, thresholding, binarization*

1. Introduction

Aggregate particle size distribution has a significant effect on the strength and durability properties of concrete [1] [2] [3] [4]. In addition, particle size is quite important in geotechnical studies related to the soil [5] [6]. Traditionally, sieve analysis methods are used to determine the particle size distribution of aggregate and soil samples. However, the time-consuming nature and practical limitations associated with applying this method in large-scale infrastructure projects, areas without laboratory facilities, and construction site environments requiring rapid decision-making, as well as its inability to be used in examinations of hardened concrete, etc., have led researchers to seek alternative methods. In this field, image processing techniques have emerged as a significant alternative [7]. These techniques enable the determination of the particle size distribution in hardened concrete, as well as to visualize and quantify the macro and micro voids in the concrete [8]. Some disadvantages of the methods used to determine cavity structure are leading researchers to this field. The inadequacy of traditional porosity assay results in determining closed voids and capillary voids, the inability

to determine the macro void structure due to the small sample size in devices such as SEM, and the disruption of capillary and micro void structures by the pressure applied in pressure porosimetry experiments are among the disadvantages. For this reason, imaging techniques that provide both practical and realistic results have begun to be proposed. In this field, void structure can be revealed from images obtained with artificial intelligence-based imaging models [9] and devices such as versatile modular polarized microscopes [10].

Image processing techniques for particle size analysis generally rely on determining particle areas from the image captured and calculating the ratio of these area values [11]. These analyses can be performed on samples taken from a mixed aggregate or soil sample pile. In these studies, results obtained through imaging are usually compared with sieve analysis test results to verify the method [12] [13].

The nature of the applied image analyses varies depending on the imaging purpose. In addition to determining the size distribution of macroparticles [14], it is also possible to perform microanalyses that allow for the separation of fine aggregates, cement and mineral additives from each other with image analyses [8]. While macro analyses can be performed with high-resolution camera images, micro analyses generally require microscopic imaging techniques such as SEM, TOM, and BSE [15] [16]. However, given the difficulty in accessing these advanced imaging methods, the extra time required to obtain and evaluate results, and the high costs when mass use is necessary, research continues into developing different techniques for microimaging [17].

This study focuses on estimating aggregate particle size distribution through imaging of cross-sections taken from hardened concrete samples. Although studies on the use of imaging techniques for this purpose have been frequently conducted in recent years, information regarding the necessary settings in analysis programs is quite limited. However, establishing standardized procedures is crucial for situations where it is not possible to verify imaging results by comparing them with experimental results. For this purpose, this study evaluates the preprocessing steps for ImageJ software and offers suggestions for accurately determining particle size distribution. This study systematically compares different preprocessing workflows for determining aggregate granulometry from hardened concrete sections using ImageJ, verifies these workflows through experimental sieve analysis, and discusses the suitability of different workflows for different particle size ranges. Due to its open access feature, this program was chosen for evaluation in post-earthquake debris assessments, particularly in environments lacking laboratory facilities such as construction sites, as it provides quick and easy access for users. In the analysis program, the effects of different thresholding, binary (black-white) conversion, particle separation, etc., analysis settings on particle size distribution results were comparatively examined. The data obtained showed that the analysis settings have a significant effect on the results. Therefore, it is considered important to standardize the analysis settings in order to obtain reliable, repeatable, and traceable results.

2. Materials and Methods

For the study, cylindrical specimens with a diameter of 100 mm and a length of 200 mm were prepared in accordance with the TS EN 12350-1 [18] standard. The particle size distribution of the aggregates used in the manufacture of the specimens is presented in Figure 1. The top and bottom surfaces of the samples, which were cured for 7 days, were smoothed by grinding with a grinding machine, and then each sample was cut into three pieces using a cutting device (Figure 2). The sample surfaces were wetted before imaging to increase the visibility of the aggregate particles. Then, the sample surfaces were imaged using the experimental setup shown

in Figure 3. Particle analysis was performed using image of the central surfaces, as this would more accurately represent the aggregate distribution.

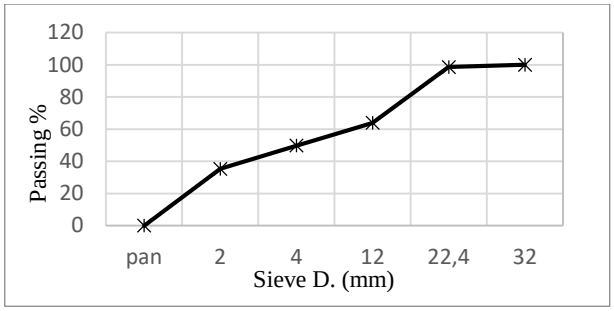

Figure 1. Aggregate sieve analysis results used in sample production.

Figure 2. Preparation of hardened concrete samples.

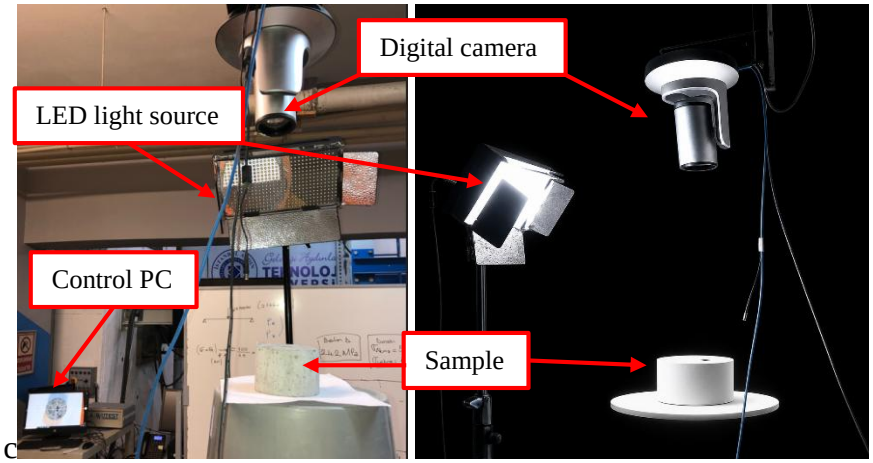

Figure 3. Viewing setup.

After the imaging process was completed, the analysis procedures were carried out. First, the images were converted to 8-bit and scaled using the built-in scale bar to achieve a sample diameter of 100 mm (Figure 4). To investigate the effect of preprocessing operations on the characterization of aggregate particles, ten different image processing workflows presented in Table 1 were evaluated. As can be seen in Table 1, binary (black-and-white) image generation, filling voids on the particles (Fill Holes), separating combined particles (Watershed), and edge erosion (Erode) options were applied in different combinations as preprocessing. The analysis ranges were determined by considering the sieve diameters used in the concrete. Since the analysis was performed considering the areas of the particles, the areas corresponding to two consecutive sieve diameters was entered into the analysis menu, and the total area of the particles remaining between these areas, the number of particles, and the average particle area were calculated. Since the calculated area values are the areas of the particles remaining on the

sieve, the cumulative areas passing through each sieve were also calculated as a percentage, and granulometry curves were obtained for each analysis.

Table 1. Ten different preprocessing steps applied.

Method No	Image Processing Workflow	Description
M-1	Binary	Binary image generation only
M-3	Binary → Fill Holes	Filling internal holes within particles
M-7	Binary → Fill Holes → Watershed	Hole filling followed by particle separation
M-8	Binary → Erode → Watershed	Edge erosion followed by particle separation
M-9	Binary → Erode → Fill Holes → Watershed	Erosion, hole filling, and particle separation
M-10	Binary → Erode → Fill Holes	Erosion followed by hole filling
M-11	Binary → Fill Holes → Erode	Hole filling followed by erosion
M-12	Binary → Fill Holes → Erode → Watershed	Hole filling, erosion, and particle separation
M-13	Binary → Erode	Binary image with erosion
M-14	Binary → Watershed	Binary image with particle separation

3. Findings and Discussion

This study aimed to establish a standardized preprocessing method for determining aggregate granulometry using imaging techniques on hardened concrete surfaces in Image-J program. Nine images from three samples divided into three parts were used. Each image was analyzed using ten different methods presented in Table 1. The percentage values passing through each sieve were determined from the area values obtained from the images, and the average and standard deviation values for each sieve size were calculated and presented in Table 2. Mean

Absolute Error (MAE) and Root Mean Square Error (RMSE) values were also added to the table to determine which pretreatment step yielded the closest result to the experimental granulometry. Since 100% of the particles passed through the 32 mm sieve in all analyses, they were not included in the MAE and RMSE calculations. The results are also presented graphically in Figure 5. According to these results, considering all sieve diameters, it can be said that the analysis performed according to the M-7 method, which has the lowest MAE and RMSE values, gave the closest result to the experimental sieve analysis. This is followed by M-8, M-9, and M-12, respectively. It is noteworthy that particle separation preprocessing was applied in all of these methods. In addition, the lower MAE values calculated in the M-7 and M-8 methods show that in cases where fine and coarse aggregates need to be evaluated together, results closer to experimental data are obtained in methods where both void filling and edge erosion preprocessing are not used.

Table 2. Comparison of image processing workflows based on average passing percentage (± standard deviation), MAE and RMSE.

Passing Percentage (%) (Average / Standard deviation)

[1] Experimental sieve analysis results, [2] MAE: Mean Absolute Error, [3] RMSE: Root Mean Square Error

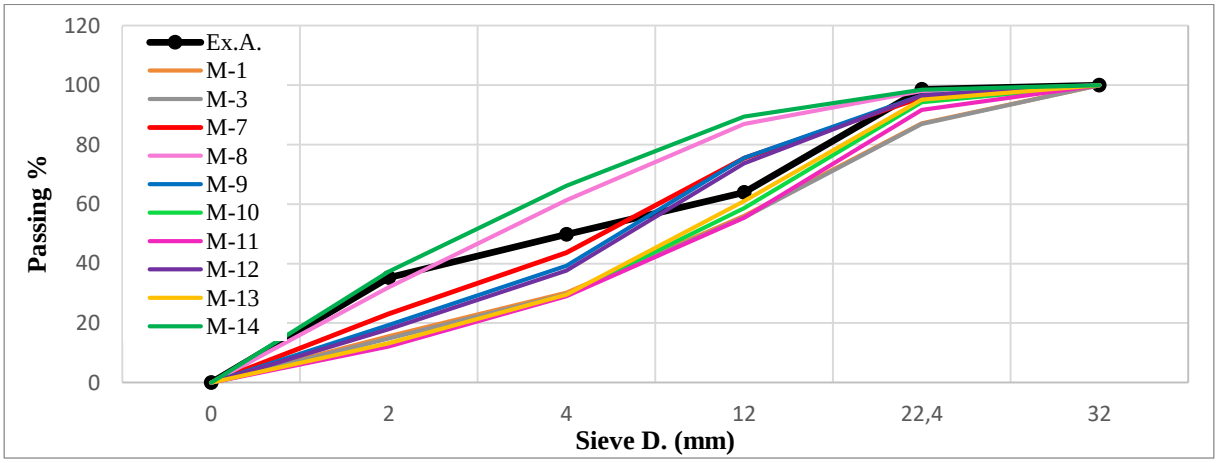

Figure 5. Comparison of image-based particle analysis and experimental sieve analysis

Particle images obtained from analyses performed on the same image for each method presented in Table 1 are shown in Figure 6 for a sample. Here, particle images obtained from analyses performed on the same sample image for the range of 113.1-394.08 mm^2 (12-22.4 mm) are shown. The images were found to be important in revealing the effect of pre-analysis settings on particle number and size. For example, when only binary (black-and-white) image generation (Figure 6.a), binary and Fill Holes (Figure 6.b) are applied to this image, an increase

in the number of particles and therefore an increase in the scanned area is observed. Similarly, there are significant differences between the results obtained when Fill Holes is applied first and then Watershed is applied (Figure 6.c) and the images obtained when Erode is applied first and then Watershed is applied (Figure 6.d). Similar differences are observed for all methods. It is particularly noteworthy that in the image where only particle Watershed preprocessing is applied after binary generation, there are no particle images at all for this mesh size (Figure 6.j). These differences, presented as an example in Figure 6, are observed for all imaging processes.

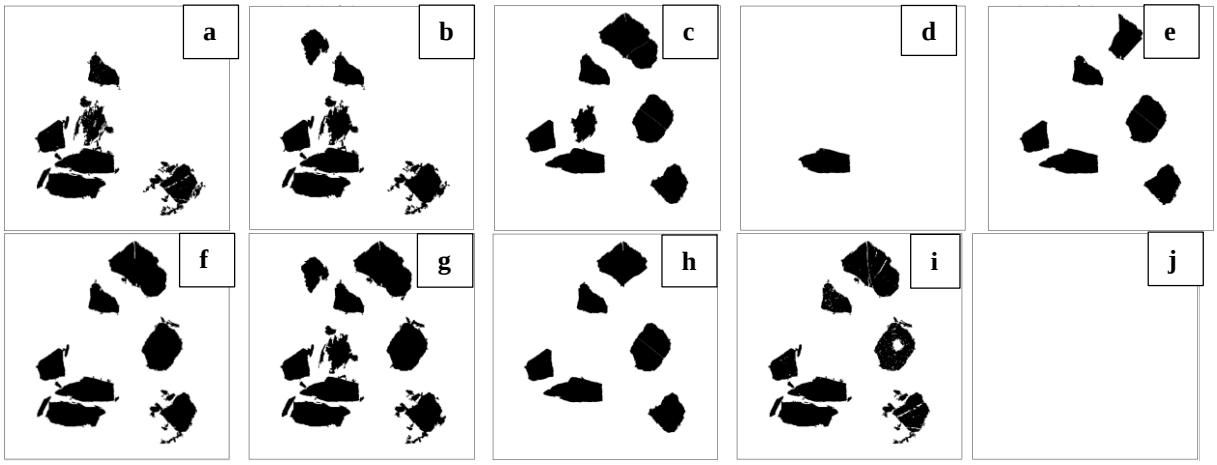

Figure 6. Particle images obtained from analyses performed on a sample for the range of 113.1-394.08 mm^2 as an example: a) M-1, b) M-3, c) M-7, d) M-8, e) M-9, f) M-10, g) M-11, h) M-12, i) M-13, j) M-14

Considering the differences presented in Figure 6 and examining Figure 5, it is seen that different pretreatment steps are effective in predicting the fine and coarse aggregate particle size distribution. To numerically evaluate this situation, the analyses performed for sieve openings between 0-4 mm and 4-32 mm were considered separately, and MAE and RMSE were calculated. The evaluation results are presented in Table 3 and Figure 7. As can be seen, Method-8 provides the closest results to the experimental result for fine aggregates. This is followed by Method-7 and Method-14 with the same MAE values. It is observed that "Watershed" was applied in the pretreatment steps in these three methods, which have the lowest MAE values. This finding emphasizes the importance of particle separation in the visualization of fine aggregates. Separating particles that are in contact with each other has resulted in more successful fine aggregate visualization. In Method 8, the voids on the aggregate particles were first closed using "Fill Holes," then the particle edges were abraded with "Erode," and finally, the particles were completely separated using "Watershed," resulting in a successful outcome for fine aggregates. For coarse aggregates, the closest result to the experimental grain distribution was obtained from Method-13, followed by Methods-10 and 12. Looking at the preprocessing settings, it is seen that "Erode" was applied to the images in all three methods. In Method-13, which yielded the best result for coarse aggregates, only "Erode" was applied after converting the image to binary (black-and-white). This preprocessing setting abraded the particle edges by approximately 1 pixel, resulting in the separation of aggregate grains. Applying "Fill Holes" after "Erode" to the image caused the spaces between closely spaced particles to refill, thus slightly increasing the MAE. The subsequent "Watershed" preprocessing setting is thought to have a negative effect because it caused some aggregate grains, which are actually single pieces, to be separated and displayed as different grains due to color differences in their natural structure.

These results are also significant in that they highlight the importance of the preprocessing sequence. For example, Methods 10 and 11 demonstrate a significant effect of the "Erode-Fill Holes" application sequence on the results. In Method 10, "Erode" was applied first, followed by the "Fill Holes" setting. In Method 11, "Fill Holes" was applied first, followed by "Erode". This resulted in a significant difference when considering sieve openings in the 4-32 mm range. In Method 11, applying Fill Holes first caused two separate aggregate particles located close together to be perceived as a single aggregate particle, and the subsequent Erode application eroded the edges of this combined aggregate.

Table 3. Comparison of image processing workflows based on MAE and RMSE for fine and coarse aggregate fractions.

Fine aggregate (0–4 mm)			Coarse aggregate (4–32 mm)		
Method No	MAE[1]	RMSE[2]	Method No	MAE[1]	RMSE[2]
M-1	19,6	19,6	M-1	9,7	9,9
M-3	20,3	20,3	M-3	10,0	10,2
M-7	9,2	9,6	M-7	7,1	8,3
M-8	7,4	8,5	M-8	11,8	16,3

4. Results

This study focuses on predicting aggregate particle size distribution through imaging of cross-sections taken from hardened concrete samples. For this purpose, preprocessing steps in ImageJ software were evaluated, and suggestions for accurately predicting particle size distribution were made. A systematic comparison of different preprocessing workflows, their validation through experimental sieve analysis, and the suitability of different workflows for different particle size ranges were discussed. The results obtained are presented below.

- When comparing the analysis results after 10 different preprocessing steps, it was determined that the image processing order has a significant effect on aggregate particle

size distribution, and that an appropriate preprocessing workflow should be selected to obtain reliable image analysis results.

- The method (Method-7) that applied the Binary → Fill Holes → Watershed preprocessing steps in sequence, using all sieve diameters used in concrete samples for general particle size distribution, provided the lowest MAE and RMSE values and the best agreement with the experimental sieve analysis results.
- Analysis results have shown that applying separate preprocessing steps for coarse and fine aggregates in particle size evaluations allows for obtaining results closer to experimental results. For the fine aggregate fraction (0–4 mm), the M-8 method, which uses Binary → Erode → Watershed, showed the best performance with 7.4% MAE and 8.5% RMSE. In contrast, for the coarse aggregate fraction (4–32 mm), the M-13 method, which uses Binary → Erode, produced the lowest MAE and RMSE values with 3.2% MAE and 3.2% RMSE.
- When comparing experimental results with methods that yielded lower MAE and RMSE values, the "Watershed" preprocessing step stood out in fine aggregate preprocessing, while the "Erode" preprocessing step stood out in coarse aggregate preprocessing.

The proposed methodology offers a practical and low-cost alternative for estimating aggregate size distribution in hardened concrete. The proposed method has the potential to support future image analysis applications, while highlighting the importance of pre-processing steps in analyses.

Acknowledgments

The author would like to express her sincere gratitude to İstanbul Aydın University and Prof. Dr. Cem Aydemir for his continuous support throughout this study. The author also gratefully acknowledges Boğaziçi Beton Zeytinburnu Akin Production Plant and Mr. Erol Kaya for providing the concrete specimens used in this research. Special thanks are extended to the laboratory technical staff of İstanbul Aydın University, Ms. Nurgün Temizer and Mr. Necmi Ömerustaoğlu, for their valuable assistance with the cutting and grinding of the concrete specimens.

Finally, the author would like to express her deepest gratitude to Prof. Dr. Savaş Erdem for introducing the image analysis approach that formed the foundation of this study.

Abstract. The use of crumb rubber (CR) as a partial replacement for fine aggregate offers a sustainable alternative for recycling end-of-life tires while reducing the consumption of natural resources. However, its influence on concrete properties requires further investigation. This study experimentally evaluates the mechanical, elastic, and durability properties of concrete in which 10%, 20%, 30%, and 40% of the fine aggregate was replaced by CR by volume. Compressive strength (CS), splitting tensile strength (STS), stress–strain behavior, modulus of elasticity (MOE), Poisson's ratio, impact load response, sorptivity, and freeze-thaw resistance were investigated. The results showed that CS and STS decreased progressively with increasing CR replacement ratio. Likewise, the MOE decreased, whereas Poisson's ratio remained essentially unchanged. Despite the reduction in strength, concrete containing 10% CR exhibited a STS comparable to that of the reference (REF) concrete while demonstrating a significantly higher energy absorption capacity under impact loading. Sorptivity tended to decrease at 10% and 20% replacement levels but significantly increased when the replacement ratio reached 30% and 40%. After 50 freeze-thaw cycles, the CS of the REF mixtures decreased by approximately 25%, whereas mixtures containing CR exhibited strength increases ranging from 8% to 14%. Nevertheless, surface scaling was observed in the CR concretes while no noticeable surface deterioration occurred in the REF concrete. These findings indicate that low replacement levels of CR, particularly 10%, can significantly improve impact resistance and enhance freeze-thaw performance while maintaining acceptable mechanical properties.

Keywords: Crumb rubber concrete, Mechanical properties, Elastic properties, Impact resistance, Freeze-thaw resistance.

Introduction

The modern construction industry is under severe environmental pressure due to intensive natural resource consumption and high greenhouse gas emissions. While Portland cement

production is responsible for approximately 5-8% of global CO_2 emissions, mining activities carried out for aggregate procurement also lead to ecosystem destruction [1]. In parallel with this situation, approximately 1 billion waste tires are generated globally each year, and this stock is projected to reach 5 billion units annually by 2030 [2]. The vulcanized, cross-linked polymeric structure of tires makes their biological decomposition in nature difficult [3]. While the uncontrolled storage of waste poses public health and fire risks, its incineration leads to the emission of toxic smoke [1]. To minimize these risks, one of the most robust circular economy approaches is the partial utilization of waste tires in the form of crumb rubber (CR) as a replacement for natural aggregate [1–3].

Rubberized concretes are produced by granulating waste tires and replacing a certain portion of the natural fine aggregate [1,4]. Life cycle assessments reveal that rubber-modified concretes reduce the carbon footprint and dependency on natural aggregate resources [3]. However, the technical challenge created by the use of rubber in concrete is that it leads to mechanical strength losses due to the weak Interfacial Transition Zone (ITZ) formed with the cement matrix, which stems from the low stiffness and hydrophobic nature of rubber [1]. Microstructural analyses conducted by Garcia-Troncoso et al. [5] also confirm this distinct ITZ gap between the rubber particle and the cement matrix. In the literature, surface modification techniques, such as chemical pretreatments with sodium hydroxide (NaOH) [6] or aqua-thermal treatments (ATT) proposed by Sanjaya et al. [7], are applied to mitigate these disadvantages. Furthermore, despite the losses in mechanical strength, as demonstrated in dynamic tests by Xiong et al. [3] and Eltayeb et al. [8], the flexible structure of the rubber additive alleviates stress concentrations at crack tips, thereby imparting a ductile fracture characteristic to the material. At high strain rates, the energy absorption capacity of rubberized aggregate concrete is far superior to that of normal concrete. In seismic performance tests conducted by Chao et al. [9], it was also proven that the energy damping capacity of components containing rubber increases. In terms of durability, analyses carried out by Zhai et al. [6] show that, due to the water-repellent nature of rubber, capillary water absorption pathways are interrupted within the 10-20% band; however, when this critical threshold is exceeded, ITZ vulnerabilities exert negative effects on freeze-thaw resistance. In infrastructure engineering, as emphasized in the study conducted by Zakerzadeh et al., the use of CR in mixtures such as Stone Mastic Asphalt (SMA) offers advantages such as extended service life and crack limitation [2]. Shafabakhsh et al. [10] and Assaggaf et al. [11] also support, through dry methods, that waste tire-derived rubber increases flexibility in asphalt mixtures.

In light of these scientific findings, the primary objective of the present study is to determine the optimum utilization rate by investigating the effects of using CR at various ratios on the mechanical and durability properties of concrete, and to contribute to both existing literature and future research.

2 Materials and Method

A reference (REF) mixture was designed with a 360 kg/m³ cement and a water-to-cement (W/C) ratio of 0.50. The mixtures incorporated CEM II/A-L 42.5 R cement, natural sand, crushed sand, and crushed stone (with a maximum aggregate size of 16 mm), with specific gravities of 3.03, 2.56, 2.74, and 2.70 g/cm³, respectively. The aggregate proportions were adjusted to closely follow the B16 reference grading curve specified in the TS 802 [12]. Subsequently, four different concrete mixtures were designed by replacing the total fine aggregate in the REF mixture with CR, which has a specific gravity of 1.00 g/cm^3, at volumetric replacement ratios of 10%, 20%, 30%, and 40%. The designed concrete mixtures were named as CR10, CR20, CR30, and CR40 based on their fine aggregate replacement percentages. Two different types of CR, namely fine (0.125–1 mm) and coarse (0.5–4 mm), were utilized in the designs. To ensure compatibility with the particle size distribution of the fine aggregates used, the fine and

coarse CRs were blended at a ratio of 40% and 60%, respectively. The mix proportions per cubic meter of the concrete mixtures are presented in Table 1.

The slump test was performed on the fresh concrete in accordance with EN 12350-2 [13]. To achieve the target S2 workability class, a polycarboxylate-based superplasticizer (SP) was utilized. Its dosage relative to the binder content is presented in Table 1. For each mixture, eight 100×100×100 mm cubic specimens, six Φ100×200 mm cylindrical specimens, one 70×70×280 mm prismatic specimen, and three 150×600×35 mm prismatic specimens were cast. The specimens were cured in lime-saturated water at 20±2 °C until reaching a curing age of 28 days.

Table 1. Mix proportions (kg/m^3).

	REF	**CR10**	**CR20**	**CR30**	**CR40**
Cement	360	360	360	360	360
Water	180	180	180	180	180
Natural Sand	307	276	246	215	184
Crushed Sand	657	591	526	460	394
Crushed Stone	865	865	865	865	865
Fine CR	0	14.4	28.8	43.2	57.6
Coarse CR	0	21.6	43.2	64.8	86.3
SP (%)	0.9	0.6	0.5	0.5	0.4

Out of the produced cubic specimens, four were subjected to the compressive strength (CS) test in accordance with the EN 12390-3 [14], while the remaining four specimens were subjected to the freeze-thaw test. For this purpose, specimens were subjected to 50 freeze–thaw cycles after 28 days of standard water curing. Each cycle consisted of 8 hours of freezing at −40°C and 16 hours of immersion in water at +20°C.

A deformation-controlled compression test was performed on four of the cylindrical specimens using lateral and vertical LVDTs to obtain the stress-strain curves. From these curves, the Poisson's ratio and modulus of elasticity were determined. The remaining two cylindrical specimens were cut in half perpendicular to long axis, yielding four Φ100×100 mm specimens for each mixture. The splitting tensile strength (STS) test was conducted on these obtained specimens in accordance with the EN 12390-6 [15]. Meanwhile, the single 70×70×280 mm prismatic specimen was divided into three equal pieces with a cross-sectional area of 70×70 mm², and the sorptivity coefficients of the samples were measured based on the amount of capillary water absorption over a 4-hour period. The weight of the specimens was measured in the dry state (0 min), as well as at 5, 10, 20, 30, 60, 90, 120, 180, and 240 min. The formula used for the sorptivity coefficient (k) is

$$q^2 = k \times t \tag{1}$$

where q=water absorption per unit area; and t=time. The sorptivity coefficient, k, was determined as the slope of the linear relation drawn between q and $\sqrt{t}$.

On the 150×600×35 mm prismatic specimens, impact tests were performed using a spring-actuated universal impact testing device [16], as illustrated in Figure 1. The specimens were supported at two points, and an impact load was applied to their midpoint. In the experiments, the impact load–time relationship, the velocity of the impact trolley at the moment of impact with the specimen, and the post-impact motion–time data were obtained using the DEWE-43A data acquisition device, which has a high data acquisition rate. Using the data recorded during the experiments, the “impact force–time” and “post-impact motion–time” relationships were evaluated.

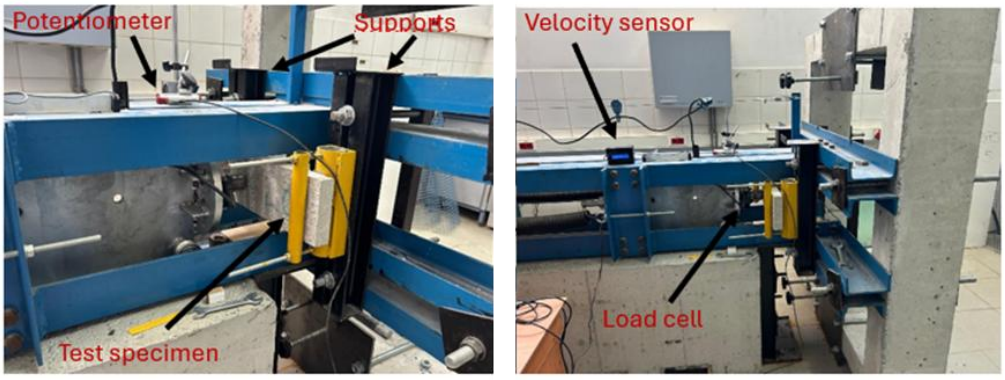

Fig. 1. Impact test device.

3 Results and Discussions

3.1 Strength and Stress-Strain Relations

The CS and STS values were determined as the mean of the results along with their standard deviations. The results are presented as bar charts in Figure 2.

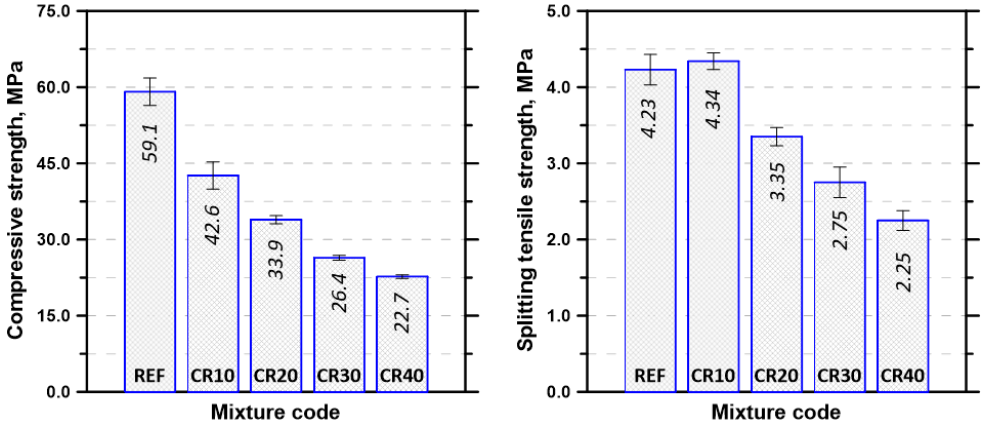

Fig. 2. Bar graph of CS results (*left*), and STS results (*right*). (*Error bars: ±1St.Dev.*)

The CS systematically decreased with the increase in CR replacement. This reduction is attributed to the lower stiffness of CR particles compared to natural aggregates, which creates an elastic incompatibility between the CR and cement matrix [1]. Another reason is that while the cement paste is hydrophilic, CR is hydrophobic. Due to this incongruity, the cement gel cannot bond strongly to the CR surface, resulting in a weak ITZ between them [1,5]. Regarding the STS results, a slight increase was observed at 10% CR replacement compared to the REF mixture, followed by a systematic decrease beyond this replacement level. However, analyzing the STS/CS ratios reveals a value of 0.07 for REF, whereas this ratio revolves around 0.10 for CR-containing mixtures (approximately 50% higher than REF). Due to its rigid structure, concrete exhibits brittle behavior and is highly sensitive to voids or defects, which leads to sudden failure under tensile loads and reduces tensile strength. Conversely, the flexible nature and deformability of CR prevent sudden crack initiation. Furthermore, when a crack reaches a CR particle, the particle acts as a fiber, slowing down crack propagation and dissipating energy by changing the crack path, thereby enhancing the ductility of the concrete.

The stress-strain relationships were obtained using four specimens for each mixture, and a representative behavior from each is shown in Figure 3.

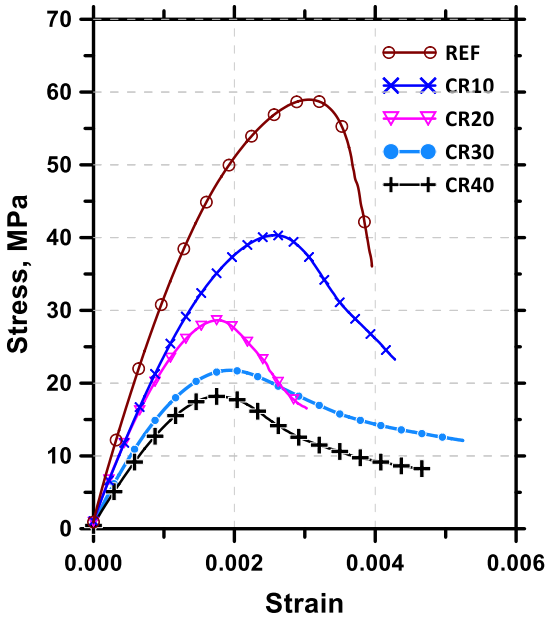

Fig. 3. Representative graphs for stress-strain relations.

As shown in Figure 3, the slope of the descending branch decreased with increasing CR replacement, which is a significant indicator of an enhanced energy absorption capacity. Furthermore, the strain values corresponding to the peak stress significantly decreased with increasing CR replacement. The modulus of elasticity (MOE) and Poisson's ratio, calculated from the stress-strain curves, are presented as bar charts in Figure 4. Similar to the CS results, the MOE decreased as the CR replacement increased, which is attributed to the same factors underlying the reduction in CS. Regarding the Poisson's ratio, on the other hand, the CR replacement caused no significant change, with the ratio calculated at approximately 0.18 for all mixtures.

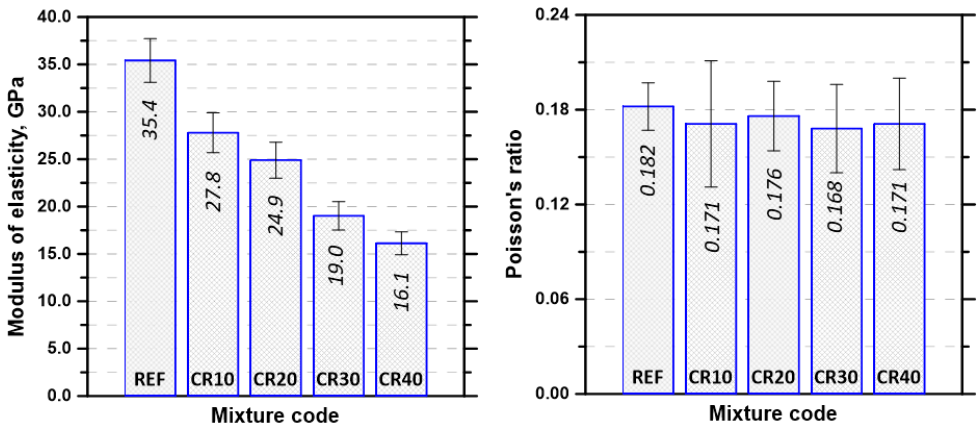

Fig. 4. MOE (*left*) and Poisson's ratio (*right*) results. (*Error bars: ±1St.Dev.*)

3.2 Sorptivity and Freeze-thaw test results

The bar charts of the calculated sorptivity values are presented in Figure 5. Similar to the trends reported by Zhai et al. [6], the sorptivity coefficients exhibited a distinct biphasic behavior with increasing CR content. Within the 10–20% replacement band (CR10 and CR20), the sorptivity values slightly decreased compared to the REF mixture. This reduction is attributed to the hydrophobic nature of the rubber particles, which effectively blocks and interrupts the interconnected capillary pathways. However, once this critical threshold was exceeded, a

significant increment was observed for the CR30 and CR40 mixtures. This sharp upward trend indicates that at higher replacement levels, the defects associated with the weak ITZ and increased micro-porosity dominate the matrix, thereby facilitating water penetration despite the hydrophobic character of the rubber.

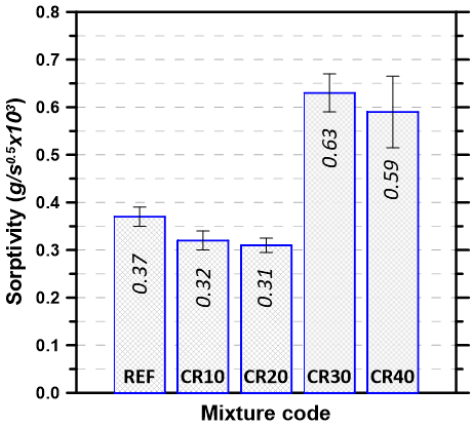

Fig. 5. Sorptivity results. *(Error bars: ±1St.Dev.)*

The freeze–thaw performance of the specimens was evaluated using two approaches: (i) the surface material loss (scaling) from the specimen faces after cycling (*cm³/100 cm²*), and (ii) the CS of the specimens after cycling, which was compared with the 28-day standard cured reference strengths. A photograph showing the surface condition of the specimens after 50 cycles is given in Figure 6. The amount of surface material loss is presented in Figure 7 (*left*), while the variation in CS relative to the 28-day standard cured specimens, as a function of CR replacement ratio, is shown in Figure 7 (*right*).

Fig. 6. Surface views of the specimens after 50 freeze–thaw cycles.

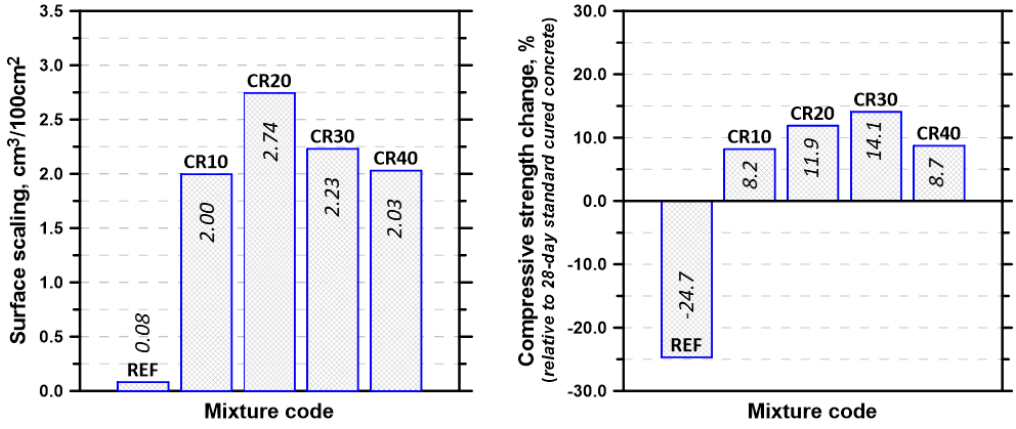

Fig. 7. Surface scaling as a function of CR replacement ratio (*left*), CS variation relative to 28-day standard cured specimens as a function of CR replacement ratio (*right*).

When Figure 6 is examined, no scaling, spalling, or significant surface deterioration was observed on the REF specimens after the freeze–thaw cycles. This visual assessment is also supported by the results presented in Figure 7 (left). Compared to the rubber-containing groups, the REF specimens exhibited negligible surface scaling. In contrast, as shown in Figure 6, noticeable surface scaling was observed in the CR-containing specimens. The most severe volume loss was recorded in the CR20 concrete, reaching 2.74 $cm^3/100\ cm^2$.

As seen in Figure 7 (*right*), an opposite trend to the surface scaling results is observed. After freeze–thaw cycles, the REF specimens exhibited approximately 25% reduction in CS compared to their 28-day standard cured counterparts, whereas all CR-containing mixtures showed strength increases ranging between 8% and 14%. This behavior is attributed to the ability of CR-modified concretes to more effectively dissipate internal stresses developed during freeze–thaw action. Volumetric expansion of pore water during freezing, together with thermal strains induced by an approximately 60°C temperature difference throughout the cycles, generates additional stresses within the cementitious matrix. The elastic nature of CR particles helps absorb part of these stresses, reducing stress concentrations and limiting microstructural damage. In addition, due to their low stiffness and deformable nature, CR particles may act similarly to entrained air voids by providing local relief zones for the expansion of freezing water. This mechanism can reduce hydraulic and crystallization pressures, thereby contributing to improved freeze–thaw resistance. As a result, internal damage induced by freeze–thaw cycles is likely mitigated, and continued hydration may also contribute to the observed strength gain in CR-containing specimens. However, this beneficial effect is not sufficient to prevent surface deterioration.

3.3 Energy Absorption under Impact Force

The force–time graphs obtained under impact are presented in Figure 8 (*left*). These graphs illustrate the maximum force values generated at the moment of impact, the time-dependent variation of the force, and the system's dynamic response. It was assumed that the impact trolley damaged the specimen and that its subsequent partial free motion occurred over a time interval of approximately 0.016 seconds. Data regarding the impact trolley's motion after striking the specimen are presented graphically in Figure 8 (*right*).

The resulting velocity-time graphs provide important information for evaluating the system's kinematic behavior after a collision, its tendency to rebound or continue in the direction of motion, and the mechanism of energy transfer. In this context, the velocity-time curves were analyzed over a time interval of up to 0.016 seconds in order to determine the impact energy absorbed by the specimens until damage occurred. In addition, the change in momentum (I_p) at the moment of impact was obtained by calculating the area under the impact force-time graph up to 0.016 seconds. The velocity (V_r) of the impact vehicle after striking the specimen was calculated using Equation 2, based on the impulse value. Once V_r is determined, the residual kinetic energy of the impact trolley can be calculated. The energy absorbed by the concrete plate specimen (E_{abr}) was calculated by subtracting the impact energy from the rebound energy using Equation 3 [17]. The results presented in Table 2 allow for an evaluation of the specimens' energy absorption capacities (E_{abr}) based on their average values.

$$V_r = V_{impact} - \frac{I_p}{m} \tag{2}$$

$$E_{abr} = E_{impact} - 0{,}5\ x\ m\ x\ V_r^2 \tag{3}$$

Where *m* presents the mass of the impact vehicle. When REF specimens are compared with specimens containing different proportions of rubber, it is evident that the rubber content has an effect on energy dissipation behavior. The energy absorption values of the concrete specimens, calculated based on varying rubber contents, are shown in Figure 9.

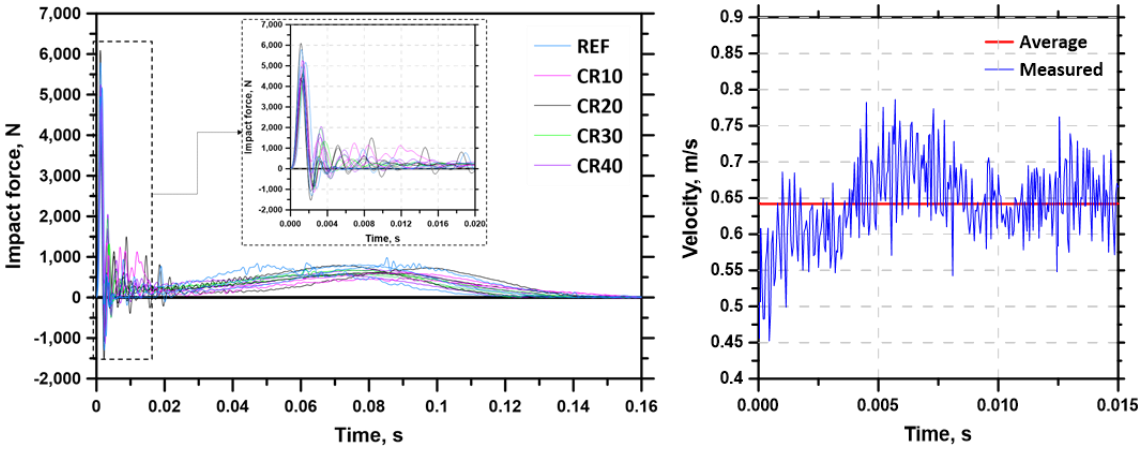

Fig. 8. Impact force-time graphs obtained from the experiments (*left*), and data on the post-impact motion of the impact trolley (*REF specimen*) (*right*).

Table 2. Absorbed energy ($E_{abr\text{-}mean}$, *Joule*)

Sample #	**REF**	**CR10**	**CR20**	**CR30**	**CR40**
1	6.59	4.55	3.73	3.99	4.36
2	3.55	8.07	4.66	5.48	4.74
3	2.97	7.65	6.11	4.66	4.81
Average:	4.37	6.76	4.83	4.71	4.64

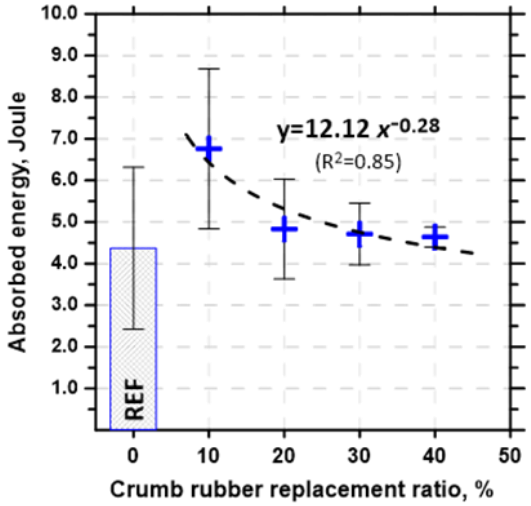

Fig. 9. CR replacement ratio *vs.* absorbed energy. (*Error bars: ±1St.Dev.*)

In Figure 9, it can be observed that the incorporation of CR into concrete increases the amount of absorbed energy under impact loading compared to the REF mixture. The most pronounced improvement was obtained at a 10% CR content. However, when the rubber-containing concretes are evaluated within themselves, the absorbed energy values decrease with increasing rubber content. This behavior can be explained by the significant reductions in compressive and STSs associated with higher rubber replacement ratios. These results indicate that the energy absorption capacity depends not only on the amount of CR but also strongly on the mechanical strength properties of the concrete. Indeed, when the REF concrete and the concrete containing 10% CR, which exhibit similar STSs, are compared, it is clearly seen that even a 10% rubber replacement leads to a significant increase (55%) in absorbed energy relative to the REF mixture.

4 Conclusions

This study experimentally evaluated the feasibility of incorporating CR as a partial volume replacement (10% to 40%) for fine aggregate in concrete, focusing on its mechanical, elastic, and durability properties.

The experimental results demonstrate a progressive reduction in CS, STS, and MOE with increasing CR content, while Poisson's ratio remains virtually unaffected. However, a detailed analysis of the STS/CS ratios reveals that CR-containing mixtures exhibit a ratio of approximately 0.10, nearly 50% higher than the 0.07 recorded for the REF concrete, indicating a significant improvement in relative tensile performance and a transition toward a less brittle failure mode. This enhanced ductility is further substantiated by the stress–strain behavior and the outstanding energy absorption capacity under impact loading, particularly at the 10% CR replacement level, which maintains an STS comparable to the REF concrete.

In terms of durability, the inclusion of CR drastically improves freeze-thaw performance; after 50 cycles, the REF mixture suffered a 25% strength loss while CR concretes exhibited a strength increase of 8% to 14%. However, regarding surface durability, noticeable surface scaling occurred in the CR concretes, whereas the REF concrete showed no significant surface deterioration. Furthermore, sorptivity characteristics are optimized at lower replacement levels (10% and 20%) but degrade significantly at higher contents (30% and 40%).

Overall, the findings conclusively indicate that a low replacement level, specifically 10% CR, represents an optimal threshold.

Abstract. Tetraethyl orthosilicate (TEOS) is the latest reactive silica source added to the geopolymer matrix, which effectively promotes gel formation, increases the rate of geopolymerization, and improves the pore structure. This research specifically used TEOS as an active component of an innovative alkaline activator to enhance the short- and long-term properties of geopolymer mortars reinforced with fibers. The binder used was either 100% granulated blast furnace slag (GBFS) or a combination of 75% GBFS and 25% Class F fly ash (FA). The activating solution included sodium silicate (57.8%), 8 M sodium hydroxide (28.9%), and TEOS (13.3%). The activator-to-binder (A/B) ratio was 0.7. CF and SF fibers were used at volume fractions of 0.25% and 0.75%, respectively, to assess their impact on geopolymer matrix crack resistance and mechanical performance. Curing was conducted in ambient atmosphere: by conventional thermal treatment at 70°C for 48 h, and by an innovative electrical curing method using electrodes that generate resistive heating within the mortar samples. Compressive, flexural, and splitting tensile strength as well as ultrasonic pulse velocity (UPV) of geopolymer composite specimens were measured at ages of 7 and 28 days. It was established that TEOS significantly enhanced matrix densification and reduced porosity, whereas electrical curing accelerated geopolymerization, resulting in improved early-age strength compared to other curing methods. Moreover, the effect of fibers on tensile strength and crack resistance was positive, especially for higher fiber volume fractions.

Keywords: Geopolymer; Tetraethyl orthosilicate; Electrical curing; Mechanical properties.

1 Introduction

Tetraethyl orthosilicate (TEOS), also called ethyl silicate or tetraethoxysilane, is a silicon-based alkoxide that has attracted significant interest due to its ability to form silica-enriched networks via hydrolytic condensation reactions. In contrast to the mineral additions, which usually serve as inert filler materials, TEOS participates in the formation of siloxane structures, modifies the pore structure, decreases permeability, and increases structural integrity. Hydrolysis of TEOS leads to the transformation of TEOS molecules into silanol groups and to their further condensation into interlinked silica networks, thereby refining the microstructure and stabilizing the material. Due to such features, TEOS is widely used as a consolidant for porous materials and as a precursor in sol–gel technologies. Moreover, hybrid and modified systems

based on TEOS are used to improve the mechanical performance of composite materials, provide corrosion resistance, and address brittleness-related issues such as crack formation. Performance improvements using TEOS have been confirmed in a variety of engineering research studies [1-3]. Johnson and Worrall [4] studied the application of TEOS to seal the pore structures of zeolitic materials and to analyze changes in ion-exchange performance compared with unmodified samples. The authors found that TEOS treatment decreased pore connectivity and increased physical stability. Similar results were obtained by Altube et al. [5] when studying the properties and corrosion resistance of sol-gel coatings prepared by TEOS and deposited on aluminum alloys. Attention was paid to the influence of pH on the hydrolysis process, and it was shown that an electrochemical coating based on TEOS provides better corrosion protection than traditionally dip-coated coatings. Another investigation conducted by Kucuk and Demirkal [6] showed that incorporating TEOS into zirconium phosphate/polyethylene oxide composites prepared using the sol-gel method renders the material thermally stable up to 300°C without losing water retention capability. Bian et al. [7] studied the effect of TEOS on the performance of rubber-modified asphalt and found that it positively influences physical and rheological properties and high-temperature stability. However, a TEOS content that was too high decreased fatigue resistance. Thus, all of the abovementioned studies demonstrated the potential to improve the material's performance using TEOS. Despite the intensive use of TEOS in advanced materials, its application in construction materials remains rather limited. Research on TEOS applications is mainly devoted to performance improvement, surface modification, and pore refinement, rather than to its incorporation into cementitious binders. Barberena-Fernández et al. [8] studied the applicability of TEOS as a component of nano-lime and nano-silica treatments used for Portland cement mortars and found that TEOS contributes to porosity reduction, improves compressive and flexural performance, maintains the surface appearance, and increases water repellence of the materials. In comparison with the large number of research studies on TEOS applications in coating, composite materials, asphalt technology, recycled aggregate, and conventional cement-based materials, only a very few papers on TEOS applications in geopolymer systems exist. A comprehensive literature review showed a lack of research on the interaction between TEOS and a geopolymer binder. Among the existing papers, the contribution of dos Reis et al. [9], who used methylpolysiloxane, methylphenylpolysiloxane, and TEOS in the synthesis of hybrid geopolymer materials prepared from natural kaolin, should be mentioned. While it was shown that the incorporation of silica-based organosilicon compounds is possible, no geopolymer mortars or concretes were produced in the course of this research, so it can be regarded as unrelated to the structural application of geopolymer binders. Also, the role of TEOS as an ingredient in the alkaline activator was not systematically investigated. Therefore, the question of the influence of TEOS on the kinetics of geopolymerization, gel formation, pore refinement, and the mechanical performance of geopolymer mortars remains unclear. In addition to the activator chemistry, curing conditions are another factor influencing the properties of geopolymer materials. Thermal curing is widely used to accelerate dissolution and polycondensation processes. However, the search for alternative curing techniques to make the reaction more efficient and consume less energy continues.

Electrical curing has become a promising technique because it induces internal heating through conductive paths and does not require additional thermal input. However, the interaction between electrically initiated curing and TEOS-modified geopolymer binders remains unknown. There is also a lack of information on the influence of the combination of TEOS-assisted activation and fiber reinforcement on the performance of geopolymer binders. The addition of carbon fibers (CFs) and steel fibers (SFs) may affect crack propagation, stress transfer, conductivity, and curing efficiency; however, no studies have addressed this topic [10, 11].Considering the aforementioned gaps in previous research, the aim of the present study is

to develop TEOS-modified geopolymer mortars activated by a hybrid NaOH+Na_2SiO_3+TEOS system. Special attention will be paid to the assessment of TEOS not as an external surface treatment or additive, but as a part of the alkaline activator. Moreover, carbon and steel fibers will be incorporated to investigate their influence on mechanical behavior under different curing environments. Comparison of ambient, thermal, and electric curing will allow assessing the efficiency of such curing conditions in terms of strength development and matrix densification. Compressive strength, flexural strength, splitting tensile strength, and ultrasonic pulse velocity (UPV) tests will be carried out. Thus, the present research will make a contribution to a limited body of literature on TEOS-assisted geopolymerization and will reveal the influence of activator chemistry, reinforcement, and curing conditions on the performance of high-performance geopolymer mortars. The scope of the study was limited to a geopolymer mortar with a binder composed of 75 wt.% GBFS and 25 wt.% FA activated by an 8 M NaOH+Na_2SiO_3+TEOS system. Mechanical performance was investigated up to 28 days using compressive, flexural, splitting tensile, and UPV tests. Investigations into long-term durability, shrinkage, permeability, and microstructure were outside the scope of this research and may be the subject of future studies.

2 Materials and Methods

2.1 Materials

The geopolymer mortars that have been mixed in the current study have been synthesized by combining aluminosilicate precursors, which have included ground granulated blast furnace slag (GBFS), acquired from Oyak Cement (İstanbul, Türkiye), and class F fly ash (FA), obtained from the Catalagzı Thermal Power Plant (Zonguldak, Türkiye). The mixing ratio included 75 wt.% GBFS and 25 wt.% FA, with natural river sand as the fine aggregate *(Table 1).* Chemical activation was performed by means of the alkaline liquid activator, including an 8 M solution of analytical grade sodium hydroxide pellets (99 % purity, AS Kimya, İstanbul, Türkiye) and commercially available sodium silicate solution (AS Kimya, İstanbul, Türkiye) with approximate silica and soda content of 27.2% and 8.2%, respectively. To facilitate additional silica supply, tetraethyl orthosilicate (TEOS) has been added to the activator mixture. Therefore, the composition of the activator mixture was constituted with approximately 58.7% of sodium silicate solution, 27.0% of sodium hydroxide solution, and 14.3% of TEOS in terms of the total activator weight. TEOS used for experimental work has been the commercial oligomerization-grade tetraethyl orthosilicate (Dynasylan 40®, Degussa-Evonik), with a degree of polymerization of about 4. In order to increase the reactivity of silica and ensure the formation of a more continuous geopolymeric structure, hydrophobic amorphous silica nanoparticles with functionality of 1,1,1-trimethyl-N-(trimethylsilyl)silanamine (Aeroxide LE1®, Degussa-Evonik), with the average particle size of about 14 nm, have been added to the TEOS-containing activator mixture. Nanoparticles have been used to refine the microstructure, improve gel structure, and reduce porosity by increasing matrix density. The mechanical reinforcement of composite materials was achieved by applying different types of fibers, characterized by distinctive geometry and physical properties. Hooked end steel fibers (SF) with a length of 35 mm were used to increase crack-arresting and load-carrying capability after crack formation *(Table 2).* Chopped carbon fibers (CF) (SIGRAFIL®, SGL Carbon, Wiesbaden, Germany) with the same length of 35 mm and density of 1.80 g/cm³ were applied to increase tensile strength and provide stress transfer through the matrix *(Table 3).*

2.2 Optimization of the Alkaline Activation System

Prior to the experimental program, a detailed optimization analysis was conducted to determine the optimal parameter combination required to activate the GBFS-FA geopolymer mortar system. A number of trial mixtures, referred to as B2-B10, were prepared to examine the impact of the activator composition, precursor proportions, mixing procedure, TEOS addition, and curing regime on both fresh-state properties and mechanical performance of mixtures. Initial mixtures were designed using a balanced binder composition, whereas the activator contained a rather low content of NaOH and Na_2SiO_3. TEOS was added to the mixture within the predefined concentration range to assess its effect on reaction rate, gel formation, and microstructure improvement. Initial formulations, designed with an activator/binder mass ratio of 0.45, showed poor workability, and hence the mixture preparation was complicated. To improve the rheological properties, an additional amount of water was added, resulting in an activator/binder ratio of 0.70. Even though this change led to successful specimen preparation, the mechanical properties of the mixtures were still unacceptable. The reason was that the level of activation did not provide a sufficient rate of geopolymerization reaction. Therefore, the chemical composition of the activator was successively varied, especially in B3 and B4 mixtures, due to the increase in the content of NaOH and Na_2SiO_3. As a result, precursor dissolution improved, and the reaction rate increased significantly. During the optimization process, TEOS was not used as an individual additive; instead, its effect was investigated alongside the impact of activator chemistry on the reaction. Further modifications were performed in the series of B5-B8 mixtures due to the variation of activator composition and precursor proportions in order to investigate TEOS behavior in different chemical environments. More significant changes were introduced starting with the B9 series mixtures; however, their mechanical performance proved rather poor, and they were therefore rejected for further investigation. In addition to variations in chemical composition, the effects of different curing regimes were also studied. Elevated-temperature curing was shown to significantly increase the reaction rate and improve strength development at early ages. Hence, some mixtures were cured at approximately 70°C for 48 hours and then stored at room temperature (25 °C). Evaluation of workability, strength development, processability, and curing effect revealed that the system's performance cannot be attributed solely to the use of TEOS. Instead, the most appropriate results were obtained from the combination of optimal values for activator chemistry, precursor composition, mixing procedure, and curing regime. The most balanced mixture, which showed the best results, was the B4 mixture, and it was chosen as the reference system for further investigations *(Table 4).*

Table 4. Preliminary optimization mixtures, processing modifications and compressive strengths.

Mix ID	GBFS (g)	FA (g)	NaOH (g, 8 M)	Na_2CO_3 (g)	Na_2SiO_3 (g)	TEOS (g)	Sand (g)	Key Modification / Observation	Compressive Strength (MPa) (7d)	Compressive Strength (MPa) (28d)
B2	225.0	–	27.0	–	49.5	22.5	562.5	Initial activator-to-binder ratio was 0.45; due to insufficient workability, 50 g of distilled water was added, increasing the ratio to approximately 0.70. No additional water was used in subsequent mixtures because of the low strength obtained.	–	–
B3	225.0	–	35.0	–	65.0	57.5	562.5	Increased activator content compared with B2.	4.88, 6.85 (equipment malfunction); later average: 11.90	13.45
B4	225.0	–	42.5	–	92.5	22.5	562.5	Cured at 70°C for 48 h and subsequently stored under moist conditions at 25°C until testing; TEOS was not added dropwise.	15.00, 17.50	18.43
B5	225.0	–	38.25	4.25	92.5	22.5	562.5	Na_2CO_3 was dissolved in a small amount of water and incorporated into the activator under magnetic stirring.	39.96, 44.12	53.05
B6	225.0	–	41.25	–	82.5	22.5	562.5	Trial mixture prepared with an activator-to-binder ratio of 0.65.	37.91, 45.13	40.24
B7	225.0	–	45.0	–	90.0	22.5	562.5	Mixing continued for 60–90 min until a noticeable viscosity change occurred; sand was added afterward.	26.00, 25.73	21.35
B8	225.0	–	45.0	–	90.0	22.5	562.5	4.5 g nano-SiO_2 was incorporated instead of Na_2CO_3.	24.51, 26.83	19.90
B9	157.5	67.5	45.0	–	90.0	22.5	562.5	GBFS, FA, and sand were first homogenized; TEOS was introduced dropwise while NaOH and Na_2SiO_3 were continuously stirred.	33.20, 35.23	20.43
B10	157.5	67.5	38.25	4.25	92.5	22.5	562.5	TEOS incorporated through controlled dropwise addition.	18.22, 22.88	26.21
B4-2	–	–	–	–	–	–	–	**Repeated B4 formulation for verification purposes.**	**35.45, 36.00**	–

***Note:** The preliminary optimization program was designed to evaluate the influence of activator composition, TEOS incorporation strategy, precursor type, supplementary additives, and curing methodology on strength development. Among the investigated formulations, B5 exhibited the highest 28-day compressive strength (53.05 MPa) within the primary optimization series. The results further demonstrated that controlled TEOS addition, precursor selection, and activator chemistry substantially affected geopolymerization efficiency and mechanical performance.

2.3 Mix Design

All geopolymer mortars tested in this work were prepared according to the optimized mix design developed in the preliminary investigation stage. The geopolymer binder was composed of 75 wt.% GBFS and 25 wt.% FA, while NS was used as the fine aggregate material with the S/B ratio of 2.5. The activator-to-binder (A/B) ratio was set at 0.75. As an alkaline activator, the NaOH+Na_2SiO_3+TEOS solution was utilized with an approximate molar ratio of 2.17:1:0.53, respectively. NaOH concentration was always equal to 8 M in all mixtures. Since the activity of TEOS depends heavily on its hydrolysis and dispersion in the activating solution, special attention was paid to the procedure for its preparation. In contrast to approaches involving pre-hydrolysis, ultrasonic treatment, vacuum-assisted dispersion, or the TEOS nanosilica-assisted hybrid technique, a practical, scalable procedure was employed. The adopted procedure is the same as CU3-TEOS in *Table 5,* except that TEOS is added dropwise to the alkaline solution. To perform the selected method, TEOS was first poured into a plastic cylinder with a diameter of approximately 5 cm and a height of 100 cm, fitted with an outlet valve. Another cylindrical container with a diameter of approximately 15 cm and a height of

100 cm was placed below the upper container and filled with the previously prepared NaOH+Na_2SiO_3 solution. NaOH solutions were prepared 4–5 days in advance and stored under laboratory conditions until use. Then, the NaOH and Na_2SiO_3 solutions were mixed to obtain the alkaline solution. Further, TEOS was dripped from the upper cylinder into the alkaline solution under magnetic stirring for 6–7 h. To avoid any undesirable influence of moisture and CO_2 from the atmosphere, both cylinders were sealed with nylon stretch film during the dripping and stirring procedures. Once the activator solution was prepared, the solid materials were mechanically mixed for approximately 2–3 min. The prepared activator solution was added, and mixing was continued for 4–5 min to achieve better wetting and particle interaction. After that, the mixture was rested for approximately 60–90 min to allow the initiation of reaction processes and the development of the initial geopolymer gel. Fine aggregate was added to the mixture after the maturation period, and final mixing was performed for approximately 2–3 min. The described optimal procedure has been applied to all subsequent mixes to achieve an optimal balance between processability and mechanical characteristics. *Table 6* shows the quantities of ingredients and obtained results of geopolymer mortars containing 0.50 vol.% CF prepared at various reactant-to-binder ratios for the casting volume of 250 cm^3 (two 50 mm cube specimens).

Table 5. TEOS-based geopolymer mortars containing 50 wt.% GBFS and 50 wt.% FA.

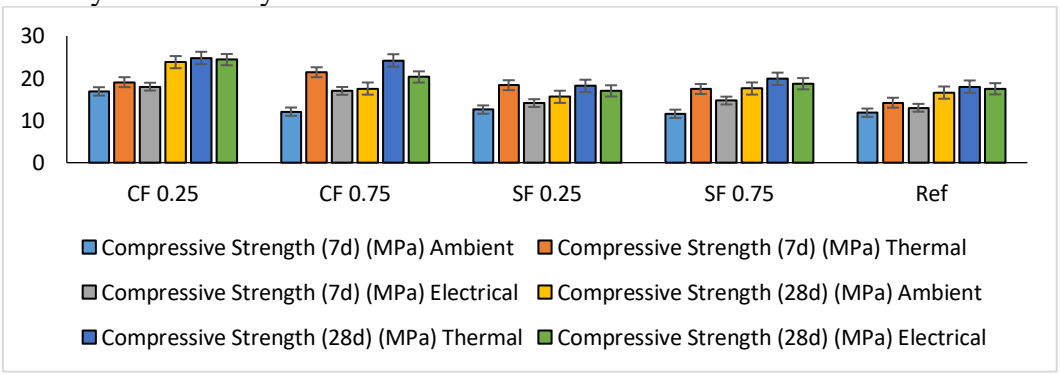
Series Code	Distinguishing Feature	Sol–Gel Preparation	Activator System	EtOH/H_2O Ratio	Mixing Method	Additives	Curing Regime	Expected Effect
CU1-TEOS-Ref	Reference TEOS formulation	TEOS + EtOH (60°C, 30 min) + HNO_3 + H_2O	Direct 10 M NaOH activation	1/1	Magnetic stirring	None	80°C for 24 h	Limited reaction development; benchmark mixture
CU3-TEOS-Drip	Controlled dropwise NaOH addition	Same procedure as CU1	8 M NaOH introduced gradually	1/3	Vacuum-assisted and magnetic mixing	None	60°C for 48 h followed by ambient curing	Balanced gel formation and controlled reaction progression
CU5-TEOS-HighSi	High-silica-content formulation	Sol–gel synthesis with 5% Na_2SiO_3 incorporation	10 M NaOH	1/1	Homogenization	Na_2SiO_3	80°C for 24 h	Improved Si/Al balance and network development

Table 6. Mixture proportions and compressive strengths of geopolymer mortars incorporating 0.50 vol.% CF at different A/B ratios (250 cm^3 batch volume).

Component	A/B Ratio = 1.10	A/B Ratio = 0.90	A/B Ratio = 0.75
Binder (g)	130.21	130.21	130.21
GBFS (75 wt.%) (g)	97.66	97.66	97.66
FA (25 wt.%) (g)	32.55	32.55	32.55
Activator (g)	143.23	117.19	97.66
8 M NaOH (27 wt.%) (g)	38.67	31.64	26.37
Na_2SiO_3 (58.7 wt.%) (g)	84.08	68.79	57.32
TEOS (14.3 wt.%) (g)	20.48	16.76	13.96
NS (B/S= 1:2.5) (g)	325.52	325.52	325.52
CF (1.80 g/cm^3, 0.50 vol.%) (g)	2.25	2.25	2.25
Compressive Strength after 48 h of Curing at 70°C (MPa)	14.78	16.12	21.73

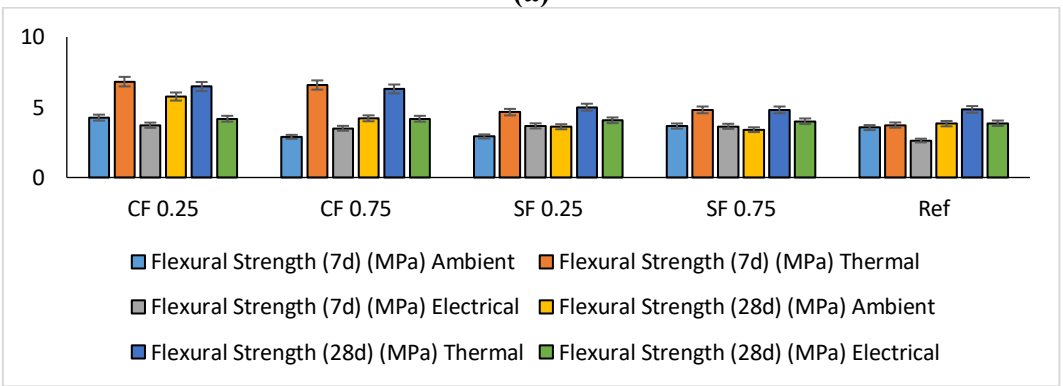
***Note:** Among the investigated formulations, the highest compressive strength was achieved at an activator-to-binder ratio of 0.75, reaching 21.73 MPa after 48 h of curing at 70°C. Accordingly, this ratio was selected for all subsequent phases of the experimental program due to its superior mechanical performance.

2.4. Methods



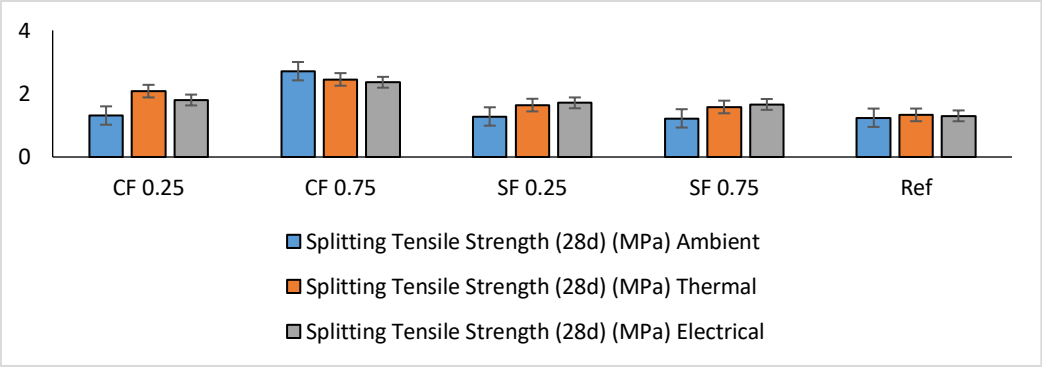
Fresh geopolymer mortars were cast into 40 × 40 × 160 mm steel prism molds and compacted on a vibrating table. After demolding, the specimens were subjected to ambient curing, thermal

curing at 70 °C for 48 h, or electrical curing, and then stored under laboratory conditions until testing at 7 and 28 days. Flexural and compressive strength tests were conducted in accordance with EN 196-1. Flexural strength was first determined by a three-point bending test on 40 × 40 × 160 mm prism specimens, after which the two fractured halves of each prism were immediately used for compressive strength measurements. The reported values represent the average of three specimens for each mixture.



3 Results and Discussions

As shown in *Fig. 1,* the usage of TEOS significantly altered the performance characteristics of GBFS–FA-based geopolymer mortars under all curing conditions. Apart from being a source of silicon, TEOS acted as a structural modifier, leading to densification of the geopolymer gel, pore refinement, and a denser matrix due to enhanced interfacial interactions between the binder and the reinforcing additives. Therefore, mortar mixtures with CFs and SFs outperformed the reference samples in terms of compressive, flexural, and splitting tensile strengths, as well as UPV. Under the influence of alkalinity, the formation of Si–O–Si and Si–O–Al bonds led to a denser microstructure and lower internal discontinuities, resulting in more efficient stress transfer within the geopolymer composite. Thus, the reference sample had compressive strengths of 11.83 MPa, 14.20 MPa, and 13.00 MPa under ambient, thermal, and electrical curing, respectively; however, significantly higher strengths were observed in some TEOS-assisted mixtures. Among them, CF 0.25 could be referred to as one of the most effective samples, since its compressive strengths were 16.88 MPa under ambient curing, 19.07 MPa under thermal curing, and 18.00 MPa under electrical curing, resulting in 42.7%, 34.3%, and 38.5% improvements, respectively, in comparison to the reference specimens. It can be seen that TEOS successfully enhances the reaction leading to the formation of geopolymer products responsible for strength development. This trend is even more visible on day 28, when compressive strengths were 23.81 MPa, 24.80 MPa, and 24.40 MPa for ambient, thermal, and electrical curing, respectively, which was more than 43.5%, 37.8%, and 39.4% greater than the reference value of 16.59 MPa. As can be concluded from the results, the improvement remains significant at later ages, and it is caused by the participation of silica species derived from TEOS in further matrix densification, via filling residual microvoids and the development of the geopolymer network. The same effect was observed in tensile parameters. The splitting tensile strengths of 1.31 MPa, 2.08 MPa, and 1.80 MPa were achieved with CF 0.25 under ambient, thermal, and electrical curing, resulting in improvements of 5.6%, 56.4%, and 38.5%, respectively, compared with the reference value of 1.24 MPa. The fiber–matrix interface strength is increased, enabling better crack bridging and stress redistribution by CFs. Also, UPVs showed that a more homogeneous internal structure developed, as CF 0.25 had UPVs of 2731 m/s under ambient curing, 2830 m/s under thermal curing, and 2582 m/s under electrical curing, all greater than the reference value of 2473 m/s. Moreover, the improvement of the flexural properties was also observed, since CF 0.25 had flexural strengths of 5.76 MPa, 6.47 MPa, and 4.18 MPa, which resulted in the improvements of 50.4%, 33.6%, and 8.3%, respectively, in comparison to the control sample. The further increase in the CF content to 0.75% led to a quite different response, especially regarding the tensile properties. Under ambient curing, a splitting tensile strength of 2.71 MPa, 118% greater than that of the control sample and one of the highest values obtained during the experiment, was achieved. Under thermal and electrical curing, values of 2.45 MPa and 2.36 MPa, representing improvements of 84% and 81.5%, respectively, were observed. However, the improvement in compressive strength in this case was comparatively low, with values of 17.55 MPa, 24.22 MPa, and 20.30 MPa under ambient, thermal, and electrical curing, respectively. This can be explained by the fact that, along with increased crack-arresting efficiency, fiber clustering reduces the mixture's ability to carry compressive loads. The flexural strengths were 4.21 MPa, 6.30 MPa, and 4.18



MPa under ambient, thermal, and electrical curing, respectively, while the UPV of 2808 m/s under thermal curing confirmed the efficiency of TEOS-assisted CF reinforcement in improving the internal structure and crack arrest. In turn, SF-containing formulations showed a more balanced relationship between increased stiffness and crack arrest efficiency. So, although the SF 0.25 sample did not exceed the reference sample in compressive resistance under ambient curing and had a value of 15.60 MPa, which was about 6% less than the reference value, its performance under thermal and electrical curing was quite good, since its strengths were 18.18 MPa and 17.00 MPa, respectively. Much more important is the influence of SFs on the tensile parameters, as the splitting tensile strengths of 1.28 MPa, 1.64 MPa, and 1.71 MPa under ambient, thermal, and electrical curing, respectively, were 3%, 23%, and 31.5% higher than the reference value. This trend shows that SFs successfully prevent microcrack coalescence and delay their propagation, thereby improving crack resistance without a dramatic increase in compressive properties. This conclusion is supported by the fact that the UPV of 2658 m/s under thermal curing was more than 1.3% greater than the reference value, showing that the internal structure was relatively dense and continuous. Also, the flexural performance of 5.00 MPa under thermal curing was 3% greater than that of the control sample. The SF 0.75 mixture demonstrated optimal performance under thermal curing, with a compressive strength of 19.86 MPa, an improvement of 10.3% over the control sample. A favorable response was also observed under electrical curing, as it produced a compressive strength of 18.70 MPa and an improvement of 6.8%. Furthermore, the splitting tensile strength of 1.66 MPa under electrical curing was 27.7% greater than the reference value, while the flexural strength of 4.81 MPa under thermal curing was very close to the reference level. Overall, SFs primarily improve crack stability and ductility.

Fig. 1. Comparison of the mechanical and physical properties of TEOS-modified fiber-reinforced geopolymer mortars under different curing regimes: (a) compressive strength, (b) flexural strength, (c) splitting tensile strength, and (d) UPV at 7 and 28 days.

4 Conclusions

- The optimum A/B ratio was determined as 0.75, yielding a compressive strength of 21.73 MPa after 48 h of curing at 70°C.
- Among the initial optimization mixes, the B5 mix had the highest compressive strength of 28 days, which was 53.05 MPa.
- The highest splitting tensile strength in the experiment was 2.71 MPa in the CF 0.75 mix under ambient conditions, which was an enhancement of about 118% compared to the control sample.
- The maximum flexural strength of 6.47 MPa was exhibited by the CF 0.25 mix under oven curing condition, whereas its enhancement relative to the control sample was about 33.6%.
- The compressive strengths of the SF reinforced geopolymer mortar were found to be 19.86 MPa, and splitting tensile strengths were 1.71 MPa.
- SF-reinforced geopolymer mortars reached compressive strengths up to 19.86 MPa and splitting tensile strengths up to 1.71 MPa, depending on curing condition and fiber dosage.

Abstract. Tetraethyl orthosilicate (TEOS) plays a crucial role in geopolymer systems by acting as a highly reactive silica source. It enhances gel connectivity, reduces pore size, and improves microstructural stability. In this study, TEOS-modified fiber-reinforced geopolymer mortars (GMs) were produced using 100% GBFS and a 75:25 GBFS–Class F fly ash (FA) mixture activated with a hybrid alkaline solution composed of sodium silicate (57.8%), sodium hydroxide (28.9%). and TEOS (13.3%), with an activator-to-binder (A/B) ratio of 0.7. Carbon (CF) and steel (SF) were incorporated at volumetric ratios of 0.25% and 0.75%. Based on mechanical performance results obtained at 7 and 28 days, selected mixtures were subjected to durability evaluations, including high-temperature exposure tests (200, 400, 600, and 800 °C). The degradation mechanisms were assessed through changes in residual strengths and ultrasonic pulse velocity (UPV). The findings revealed that TEOS significantly improved thermal stability by enhancing matrix integrity and limiting microcrack formation. Fiber reinforcement played a critical role in bridging cracks and maintaining load-bearing capacity under elevated temperatures, while also substantially reducing surface wear under abrasive conditions. Particularly at higher fiber contents, specimens exhibited lower strength loss and improved resistance to thermal and mechanical degradation. Overall, the combined effect of TEOS modification and fiber reinforcement resulted in geopolymer mortars with superior durability performance. highlighting their strong potential for use in aggressive service environments, this approach presents a highly promising avenue for the development of advanced geopolymer composites.

Keywords: Geopolymer; Tetraethyl orthosilicate; Electrical curing; Durability properties.

1 Introduction

Recently, Tetraethyl orthosilicate (TEOS), also known as tetraethoxysilane/ethyl silicate, has received considerable attention for its high efficiency in improving the microstructural stability and durability of inorganic building materials. The silicon alkoxide having the formula $Si(OC_2H_5)_4$, TEOS, undergoes hydrolysis in contact with moisture, producing silanol (Si–OH) groups that subsequently condense, giving rise to the complex siloxane (Si–O–Si) network. Unlike typical mineral admixtures containing silica, which mostly act as fillers, TEOS participates in chemical reactions, helping to form additional silica structures and refine the pore structure. Thanks to its low viscosity and chemical and thermal stability, TEOS can be easily incorporated into porous matrices and used in aggressive environments that require

durable materials. Therefore, TEOS became one of the key sol–gel precursors and efficient modifiers for advanced cementitious and geopolymeric materials. The efficiency of TEOS has been demonstrated in many engineering applications, including cultural heritage preservation and advanced composite materials. Thus, in stone conservation, TEOS is widely used as a consolidant due to its high penetration and ability to increase cohesion in deteriorated porous materials. Johnson and Worrall [1] have demonstrated that TEOS efficiently seals the zeolite pore structure, reducing pore connectivity and improving resistance to physical deterioration. Likewise, Altube et al. [2] studied TEOS-based sol-gel coatings applied to aluminum alloys and demonstrated that proper control of TEOS hydrolysis results in significantly greater corrosion resistance than traditional coating methods. Furthermore, in another study, Kucuk and Demirkal [3] have produced zirconium phosphate/polyethylene oxide composites from TEOS as a starting material using the sol–gel method, thus obtaining materials with excellent thermal stability up to 300 °C and good water retention properties. Similarly, Bian et al. [4] demonstrated that TEOS improves the rheological and physical properties, as well as the high-temperature stability, of crumb rubber-modified asphalt; however, excessive TEOS reduces fatigue resistance. All these studies demonstrate that TEOS is much more than a silica source – it is a powerful microstructural engineer, improving not only mechanical properties but also durability. In cement-based materials, TEOS has mostly been studied as a surface treatment or consolidant rather than a binder component. For example, Barberena-Fernández et al. [5] demonstrated that combining TEOS with nano-lime or nano-silica significantly decreases porosity while increasing compressive and flexural strengths, water repellency, and surface integrity in Portland cement (PC) mortars.

Geopolymers are among the most promising alternatives to ordinary Portland cement (OPC) due to their much lower carbon emissions, higher chemical resistance, and improved mechanical properties. Geopolymerization does not involve hydration; rather, it involves the dissolution of aluminosilicates in a very alkaline environment, followed by polycondensation, producing three-dimensional aluminosilicate gel networks. GBFS and Class F fly ash (FA) are the most commonly used geopolymer precursors due to complementary chemical composition. GBFS acts as a source of reactive calcium, forming C-(A)-S-H gels that promote rapid strength development, while FA provides aluminosilicates that contribute to N-A-S-H gel formation, thereby providing durability and chemical resistance. Hence, GBFS-FA geopolymer systems provide an optimal balance between early-age strength and durability, enabling the simultaneous use of waste materials. Despite significant progress in geopolymer science and technology over the past two decades, most research has focused on optimizing precursor composition, activator concentration, and curing conditions to improve composite material performance. Relatively few studies have considered the modification of activator chemistry using reactive organosilicon compounds such as TEOS. The number of existing studies on the usage of TEOS in geopolymer compositions has been quite limited so far, and all have been focused on the synthesis of hybrid organic-inorganic materials without considering their application in structural geopolymer mortars. For example, dos Reis et al. [6] synthesized hybrid geopolymeric materials based on kaolinite using TEOS; however, this research did not include structural mortar applications or durability assessment. Thus, the effects of TEOS on the kinetics of geopolymerization, gel network formation, pore refinement, thermal stability and engineering performance should be investigated in more detail. The curing method is another influential parameter that affects the performance of geopolymer-based materials. Ambient, thermal, and water curing have been used to date to facilitate geopolymerization. High-temperature curing can accelerate dissolution and condensation processes, thus facilitating fast strength development and denser microstructure formation. Nonetheless, the traditional oven-curing method involves heat transfer from the surface to the interior of the sample, resulting in a thermal gradient and microcracking due to differential shrinkage.

Recently, electrical curing has been proposed as an alternative to facilitate geopolymerization by generating heat within the sample via Joule heating. This method allows achieving a more uniform temperature distribution, a shorter curing time, lower energy consumption, and improved efficiency of the geopolymerization process. Recent studies by Cai et al. [7], Aygun et al. [8], and Ekmekci [9] have shown that the use of conductive fillers can significantly increase the effectiveness of electrical curing by improving the electrical conductivity of the geopolymer matrix. To achieve both conductivity and increased crack resistance, some conductive reinforcements have recently been introduced into geopolymer-based compositions. Carbon fibers (CFs) possess high tensile strength and excellent electrical conductivity; steel fibers (SFs) can provide crack bridging ability and increased post-cracking toughness. It has been demonstrated that these conductive materials can significantly enhance the efficiency of early-age geopolymerization, mechanical properties, and electrical conductivity. However, there is almost no information on the interactions between these conductive materials and TEOS-modified alkaline activator systems, especially their durability under harsh environmental conditions.

Durability has become one of the key requirements for geopolymer construction materials, as structural elements are exposed to various deteriorating factors, such as high temperatures, wear, freezing-thawing and chemical corrosion, during their lifetime. Among these deteriorating agents, high-temperature exposure plays an important role, as the dehydration of geopolymer gels, thermal incompatibility of matrix components, pore pressure, and microcracking can lead to the loss of structural integrity. Thus, testing the residual properties of geopolymer mortars after high-temperature exposure allows evaluating their applicability for fire-resistant and high-temperature structural applications. A detailed review of the literature demonstrates the important research gap. Despite the great potential of TEOS for microstructure refinement in various materials, the introduction of TEOS into hybrid activator systems for GBFS-FA geopolymer mortars has not yet been studied. In addition, the effects of TEOS modification, conductive reinforcements, and curing methods on the durability parameters, especially thermal stability, have not yet been investigated. Therefore, investigating these effects is needed to develop durable geopolymer-based composites. Thus, this study evaluates the durability performance of TEOS-modified fiber-reinforced geopolymer mortars using the hybrid activator system NaOH + Na_2SiO_3 + TEOS. CFs and SFs have been used as reinforcing materials, and the mixtures optimized for mechanical performance have been tested using the UPV and elevated-temperature exposure at 200, 400, 600, and 800 °C.

2 Materials and Methods

2.1 Materials

Geopolymer mortars in the current research were produced through the synthesis of a blended aluminosilicate precursor system based on granulated blast-furnace slag (GBFS) obtained from Oyak Cement (İstanbul, Turkey) and class F fly ash (FA) from Catalagzı Thermal Power Plant (Zonguldak, Turkey). A precursor mixture in the form of a dry powder was prepared in a composition containing 75 wt.% GBFS and 25 wt.% FA ratios. Natural river sand was used as the fine aggregate material *(Table 1).* Geopolymer synthesis was achieved by chemical activation of aluminosilicate precursors with an aqueous solution of sodium hydroxide pellets (99%, AS Kimya, Istanbul, Turkey) dissolved in distilled water, yielding an 8 M NaOH solution. and a commercial sodium silicate solution (AS Kimya, Istanbul, Turkey) having 27.2% SiO_2 and 8.2% Na_2O. Additionally. tetraethyl orthosilicate (TEOS) was added to the activator mixture to serve as a silica source and to ensure proper reaction conditions for geopolymer synthesis. An activator solution with 58.7% sodium silicate. 27.0% sodium hydroxide and 14.3% TEOS by weight was received. All TEOS applied in the current research was a commercial oligomeric tetraethyl orthosilicate (Dynasylan 40®. Degussa-Evonik) with

an average degree of polymerization of about 4. To enhance the reactivity of silica and to receive a more homogeneous structure. hydrophobic silica nanoparticles modified with 1.1.1-trimethyl-N-(trimethylsilyl)silanamine (Aeroxide LE1®. Degussa-Evonik) were introduced to the TEOS-containing activator mixture. The average particle size of silica nanoparticles was about 14 nm. Several types of fibers were used to provide mechanical reinforcement of geopolymer composite materials. Hooked-end SFs of 35 mm in length were used to enhance the crack arrest capability and load-bearing capacity of composite materials after cracking *(Table 2).* Chopped CFS (SIGRAFIL®. SGL Carbon. Wiesbaden. Germany) of 35 mm in length and density of 1.80 g/cm³ were applied to increase the tensile strength of composite materials and improve stress transfer *(Table 3).*

2.2 Optimization of the Alkaline Activation System

Before performing the experiments, various tests were conducted to optimize the activation scheme for the GBFS-FA geopolymer mortar system. A number of experimental mixes (B2-B14) were produced in order to evaluate the joint influence of the activator chemistry, ratios of precursors, mixing scheme, TEOS addition, and curing on fresh-state properties and mechanical characteristics of mortars. Initially, the mixes were prepared using well-balanced combinations of GBFS and FA. Small amounts of NaOH and Na_2SiO_3 were used as the activation agent in the mixture. TEOS was added in a specified amount to investigate its effects on reaction rate, gel formation, and microstructure. First, the mixes with an activator/binder ratio of approximately 0.45 had poor workability, which prevented specimen preparation and compaction. Additional water was added to achieve an activator/binder ratio of 0.70. This improved the rheological properties but yielded poor engineering properties, suggesting that the activation is insufficient to intensify the geopolymerization process. Next, the activator chemistry was changed gradually by increasing the amounts of NaOH and Na_2SiO_3 in mixes B3 and B4. This improved precursor dissolution and increased reaction rate. At all the optimization steps, TEOS was never investigated independently. Instead, the effect of this additive was evaluated as part of the activator composition, considering its impact on silica supply and its contribution to condensation reactions and network formation. Mixes B5-B8 were developed with the gradual change in the ratios of the activators and precursors to evaluate the effect of TEOS under various conditions of the mixture. More significant changes in the mix composition were introduced in the B9 series; however, they had poor engineering properties and were therefore not considered further. Along with the mix investigation, the effect of curing was investigated. High-temperature curing showed good potential to accelerate

reaction rates and develop strength at early ages. That is why certain mixes were cured at 70°C for 48 hours, then stored at 25°C under laboratory conditions. It was shown that investigating workability, strength development, processability, and curing conditions cannot reveal the effect of TEOS on geopolymer mortars. In turn, optimal results were obtained by optimizing the activator ratio, precursor ratios, mixing, and curing. As a result of the analysis, precursor ratios were identified as optimal and chosen as the reference material for further experiments *(Table 4).*

Table 4. Preliminary optimization mixtures, processing modifications and compressive strengths.

Mix ID	GBFS (g)	FA (g)	NaOH (g, 8 M)	Na_2CO_3 (g)	Na_2SiO_3 (g)	TEOS (g)	Sand (g)	Key Modification / Observation	Compressive Strength (MPa) (7d)	Compressive Strength (MPa) (28d)
B2	225.0	–	27.0	–	49.5	22.5	562.5	Initial activator-to-binder ratio was 0.45; due to insufficient workability, 50 g of distilled water was added, increasing the ratio to approximately 0.70. No additional water was used in subsequent mixtures because of the low strength obtained.	–	–
B3	225.0	–	35.0	–	65.0	57.5	562.5	Increased activator content compared with B2.	4.88, 6.85 (equipment malfunction); later average: 11.90	13.45
B4	225.0	–	42.5	–	92.5	22.5	562.5	Cured at 70°C for 48 h and subsequently stored under moist conditions at 25°C until testing; TEOS was not added dropwise.	15.00, 17.50	18.43
B5	225.0	–	38.25	4.25	92.5	22.5	562.5	Na_2CO_3 was dissolved in a small amount of water and incorporated into the activator under magnetic stirring.	39.96, 44.12	53.05
B6	225.0	–	41.25	–	82.5	22.5	562.5	Trial mixture prepared with an activator-to-binder ratio of 0.65.	37.91, 45.13	40.24
B7	225.0	–	45.0	–	90.0	22.5	562.5	Mixing continued for 60–90 min until a noticeable viscosity change occurred; sand was added afterward.	26.00, 25.73	21.35
B8	225.0	–	45.0	–	90.0	22.5	562.5	4.5 g nano-SiO_2 was incorporated instead of Na_2CO_3.	24.51, 26.83	19.90
B9	157.5	67.5	45.0	–	90.0	22.5	562.5	GBFS, FA, and sand were first homogenized; TEOS was introduced dropwise while NaOH and Na_2SiO_3 were continuously stirred.	33.20, 35.23	20.43
B10	157.5	67.5	38.25	4.25	92.5	22.5	562.5	TEOS incorporated through controlled dropwise addition.	18.22, 22.88	26.21
B4-2	–	–	–	–	–	–	–	**Repeated B4 formulation for verification purposes.**	**35.45, 36.00**	–

***Note:** The preliminary optimization program was designed to evaluate the influence of activator composition, TEOS incorporation strategy, precursor type, supplementary additives, and curing methodology on strength development. Among the investigated formulations, B5 exhibited the highest 28-day compressive strength (53.05 MPa) within the primary optimization series. The results further demonstrated that controlled TEOS addition, precursor selection, and activator chemistry substantially affected geopolymerization efficiency and mechanical performance.

2.3 Mix Design

All geopolymer mortars examined in the current research were fabricated using a recipe optimized during the preliminary tests. In particular, the geopolymer binder consisted of 75 wt.% GBFS and 25 wt.% FA. The fine aggregate (natural sand – NS) was added with S/B = 2.5. Throughout the experimental campaign, the A/B value remained 0.75. As for the alkaline

activator, it consisted of NaOH, Na_2SiO_3, and TEOS in the mass proportions of 2.17:1:0.53, respectively. All examined mortars were fabricated by applying a constant 8 M NaOH solution. As mentioned earlier, the activity of TEOS largely depends on the hydrolysis and dispersion properties of the substance; thus, it was necessary to pay special attention to the preparation procedure of the activator. Some researchers use pre-hydrolyzed TEOS, the ultrasonic method, vacuum dispersion, or TEOS nanosilica hybridization. However, it is worth noting that TEOS was added directly to the solution in the CU3-TEOS method described in *Table 5.* First of all, TEOS was loaded into a vertical cylindrical plastic container with a diameter of 5 cm and a height of 100 cm, equipped with a controlled outlet valve; another vertical cylinder, with a diameter of 15 cm and a height of 100 cm, was placed under the first one and filled with the previously prepared NaOH + Na_2SiO_3 solution. Solutions of NaOH were prepared approximately four to five days before mixing and stored in laboratory conditions. Then the NaOH and Na_2SiO_3 solutions were mixed to prepare an alkaline solution. Afterward, TEOS was transferred from the first cylinder to the second cylinder, with simultaneous magnetic stirring to ensure controlled hydrolysis and proper dispersion of TEOS in the liquid phase. The whole process took 6-7 hours. To avoid possible influence of water vapor and carbon dioxide, both cylinders were wrapped in the nylon stretch film. After preparing the activator, the dry mixing of the solid precursors lasted 2-3 minutes. The modified activator solution was then added, and the mixing was continued for 4-5 minutes. This allowed achieving wetting and the chemical reaction between the particles. Next, the mixture was left for 60-90 minutes to start reactions and form the initial geopolymeric gels. Only after that period was the fine aggregate added, and mixing continued for 2-3 minutes. The procedure described above was used for all subsequent mixes, as it enabled achieving optimal processability and mechanical characteristics. *Table 6* presents the quantities of components and the results of geopolymer mortars with 0.50 vol.% CF fabricated at different R/B ratios, with a casting volume of 250 cm^3. This quantity of material allows the production of two specimens in the shape of 50 mm cubes.

Table 5. TEOS-based geopolymer mortars containing 50 wt.% GBFS and 50 wt.% FA.

Series Code	Distinguishing Feature	Sol–Gel Preparation	Activator System	EtOH/H_2O Ratio	Mixing Method	Additives	Curing Regime	Expected Effect
CU1-TEOS-Ref	Reference TEOS formulation	TEOS + EtOH (60°C, 30 min) + HNO_3 + H_2O	Direct 10 M NaOH activation	1/1	Magnetic stirring	None	80°C for 24 h	Limited reaction development; benchmark mixture
CU3-TEOS-Drip	Controlled dropwise NaOH addition	Same procedure as CU1	8 M NaOH introduced gradually	1/3	Vacuum-assisted and magnetic mixing	None	60°C for 48 h followed by ambient curing	Balanced gel formation and controlled reaction progression
CU5-TEOS-HighSi	High-silica-content formulation	Sol–gel synthesis with 5% Na_2SiO_3 incorporation	10 M NaOH	1/1	Homogenization	Na_2SiO_3	80°C for 24 h	Improved Si/Al balance and network development

Table 6. Mixture proportions and compressive strengths of geopolymer mortars incorporating 0.50 vol.% CF at different A/B ratios (250 cm^3 batch volume).

Component	A/B Ratio = 1.10	A/B Ratio = 0.90	A/B Ratio = 0.75
Binder (g)	130.21	130.21	130.21
GBFS (75 wt.%) (g)	97.66	97.66	97.66
FA (25 wt.%) (g)	32.55	32.55	32.55
Activator (g)	143.23	117.19	97.66
8 M NaOH (27 wt.%) (g)	38.67	31.64	26.37
Na_2SiO_3 (58.7 wt.%) (g)	84.08	68.79	57.32
TEOS (14.3 wt.%) (g)	20.48	16.76	13.96

Component	A/B Ratio = 1.10	A/B Ratio = 0.90	A/B Ratio = 0.75
NS (B/S= 1:2.5) (g)	325.52	325.52	325.52
CF (1.80 g/cm³, 0.50 vol.%) (g)	2.25	2.25	2.25
Compressive Strength after 48 h of Curing at 70°C (MPa)	14.78	16.12	21.73

***Note:** Among the investigated formulations, the highest compressive strength was achieved at an activator-to-binder ratio of 0.75, reaching 21.73 MPa after 48 h of curing at 70°C. Accordingly, this ratio was selected for all subsequent phases of the experimental program due to its superior mechanical performance.

2.4 Methods

Based on the mechanical properties achieved at 7 and 28 days selected geopolymer mortar mixtures have been examined for durability namely resistance to high temperatures. The samples have been heated at 200, 400, 600, and 800 °C using an electrically controllable laboratory furnace. The heating process was performed at a heating rate of 5 °C/min until the required temperature was reached, then the sample was held at that temperature for 2 hours. After this period, the samples have been naturally cooled to room temperature within the same furnace. UPVs have been measured before and after thermal exposure in accordance with ASTM C597 to assess the internal integrity and damage evolution of the geopolymer mortars.

3 Results and Discussions

Figs. 1 and *2* illustrate the compressive strength, flexural strength, and UPV results for Ref, CF 0.25, CF 0.75, SF 0.25, and SF 0.75 mortars after heat treatment. Thermal degradation depended on microstructural degradation, ITZ damage, and the loss of load-transfer capability. Compressive strength was affected by the load-bearing capacity of the structure, while flexural strength was determined by the crack propagation process. UPV showed the structural homogeneity of the material. Heating the specimens to 200 °C did not cause any significant degradation, as prism weight losses did not exceed 1%, indicating that moisture evaporated. CF0.75 retained about 92% of its initial UPV, compared with only 79% for the reference mortar. In addition, CF0.75 retained more than 90% of its initial flexural strength, whereas the reference mortar retained only about 73% of its strength. SF0.75 also maintained more than 80% of its flexural capacity. Regarding compression, SF0.25 exhibited the highest residual strength (>94%), while the reference mortar retained about 89% of its initial strength. These results show that moderate heat treatment promoted further geopolymerization and matrix densification, while fibers were effective in limiting thermally induced microcracking. At 400 °C, dehydration and microcracking prevailed; therefore, UPV and mechanical properties decreased. However, CF0.25 showed the highest UPV, while CF0.75 obtained the highest residual flexural strength. With regard to compression, SF0.25 and SF0.75 preserved about 72-73% of the initial compressive strength, which is better than CF-reinforced mortars and the reference mortar. Carbon fibers positively affected crack bridging and bending resistance in mortars, while steel fibers were better at stress redistribution and preserving load transfer. At 600 °C, irreversible microstructural degradation prevailed due to progressive dehydration, pore-size growth, and loss of matrix cohesion. Consequently, compressive strength, flexural strength, and UPV decreased substantially. However, both types of fibers performed better than the reference mortar, though their effectiveness as reinforcements declined due to a weakened fiber-matrix interface. Nonetheless, SF mixtures showed slightly higher UPV and superior compressive strength compared with CF mixtures. After heat treatment at 800 °C, progressive degradation of the geopolymer matrix was observed in all samples. Extensive dehydration, interfacial debonding, and crack interconnection led to the lowest UPV and mechanical properties. Although fiber reinforcement could not prevent extensive degradation in mortars, SF0.75 exhibited the highest residual flexural and compressive strengths, confirming the superior thermal resistance of steel fiber reinforcements at high temperatures. In general, thermal

degradation began with the beneficial densification of the matrix at 200 °C, progressed to progressive dehydration and cracking at 400-600 °C, and culminated in extensive degradation of the matrix at 800 °C. Carbon fibers were more effective at maintaining flexural strength through crack bridging, while steel fibers provided the best compressive strength retention.

4 Conclusions

- TEOS-modified geopolymer mortars reinforced with fibers demonstrated satisfactory thermal resistance up to 400 °C. However, all samples showed a significant drop in UPV and mechanical properties due to matrix degradation at 600- 800 °C.
- At 200 °C, the highest level of thermal resistance was shown by CF 0.75, maintaining about 92% of the initial UPV value and over 90% of the initial flexural strength, whereas the maximum value of compressive strength after heating was recorded for SF 0.25 (about 94%).
- At 400 °C, the maximum residual flexural strength was recorded in the sample CF 0.75, while SF 0.25 and SF 0.75 managed to preserve about 72-73% of their initial compressive strength, which indicates good compressive resistance of those samples when subjected to moderate heating.
- All samples showed severe damage after being heated up to 800 °C; however, the most stable thermo-mechanical characteristics were demonstrated by SF 0.75, while the reference mixture had the lowest values of internal integrity and mechanical properties.

Abstract. The collapse of structures during seismic events results in concrete debris that may become contaminated with chemical substances during cleanup and disinfection. This study investigated the variations in compressive strength and ultrasonic pulse velocity (UPV) of two concrete strength classes (C16 and C25) exposed to a 2% (v/v) iodine-based disinfectant (pH 4.5) and a 20% (v/v) oxidative chlorine-based disinfectant. Specimens were examined for cumulative periods of up to 118 days, comprising 28 days of initial water curing followed by 28, 56, and 90 days of chemical immersion. Experimental results indicated that neither disinfectant produced a statistically meaningful reduction in compressive strength relative to the reference water-cured specimens within the examined timescale. However, C25 specimens showed a modest downward offset at 118 days, suggesting a potential sensitivity of denser matrices to prolonged chemical interaction. Notably, UPV measurements did not consistently track compressive strength trends. In C16 specimens, chemically exposed groups exhibited markedly higher UPV values than the reference group at 118 days, shifting their quality classification from "Good" to "Excellent" without a corresponding gain in strength. This divergence is attributed to elevated pore saturation and moisture retention rather than matrix densification. The findings indicate that these disinfectants are unlikely to cause acute structural degradation of concrete debris at the tested concentrations. However, the study underscores that UPV alone can yield misleadingly favorable readings, highlighting the need for caution when relying solely on non-destructive testing for post-disaster debris management.

Keywords: concrete deterioration, disinfectant, oxidizing agent, compressive strength, ultrasonic pulse velocity, post-earthquake debris

1 Introduction

Earthquakes cause widespread structural damage in a short period of time, generating large amounts of debris; the composition and volume of this debris vary significantly depending on the nature of the affected building stock. The safe removal, transport, temporary storage, and final disposal of this debris during the post-disaster process is one of the fundamental components of disaster management [1, 2]. However, concrete debris should not be considered merely as physical waste; concrete is a material that can undergo significant changes during its interaction with the service or exposure environment, which can adversely affect its engineering

properties [3, 4]. These changes in the physical and mechanical properties of concrete can be further exacerbated depending on the type of chemical to which it is exposed, the concentration of the solution, and the presence of concurrent environmental effects [5]. Therefore, the behavior of concrete waste in debris management processes must be evaluated not only in terms of heavy equipment and logistics but also in terms of workplace safety and environmental sustainability; because earthquake debris management can pose additional risks to the environment and public health [2, 6]. In this context, the chemicals used for cleaning, hygiene, and disinfection during the collection, temporary storage, transportation, recovery, and final disposal of debris create an exposure environment that could lead to additional changes in the physical and mechanical properties of concrete [5, 7]. This situation highlights the importance of considering concrete debris not merely as solid waste, but also as an engineering material susceptible to chemical effects and potentially exposed to liquid chemical agents [3, 8]. The degradation of concrete due to external environmental conditions, particularly under chemical attack, has long been a well-known problem [9-14]. Studies examining the effects of chemical exposure on concrete properties have shown that the reduction in compressive strength depends on the type of solution to which the concrete is exposed and its composition [15, 16]. Findings indicate that acidic environments are particularly harmful to cement-based materials; in such environments, calcium-containing hydration products dissolve, calcium hydroxide and calcium silicate hydrate phases separate, and this leads to a weakening of the binding matrix [17, 18]. Furthermore, it has been shown that expansion products accumulating over time damage the walls of capillary voids, reduce the calcium hydroxide concentration, and accelerate strength loss due to the degradation of the C-S-H gel [15, 16]. Studies on wastewater and aggressive chemical environments have also revealed that changes in compressive strength are sensitive to the type of solution and pH, with the most pronounced decrease observed under acidic conditions [15, 19]. In this context, it has been observed that studies on the behavior of concrete in aggressive chemical environments have primarily focused on long-term durability issues such as sulfate attack, acid attack, seawater, chloride penetration, and industrial chemicals. However, various disinfectants are widely used after disasters to reduce the risk of infectious diseases and ensure hygienic conditions, suggesting that disinfectants and oxidizing chemicals used in the aftermath of disasters may also trigger similar degradation mechanisms in concrete debris. In particular, iodine-based and chlorine-based disinfectant solutions are frequently used in search-and-rescue operations, the disinfection of debris sites, temporary shelters, and environmental hygiene applications [20]. During this process, concrete debris may be exposed to these chemical solutions through spraying, washing, or prolonged contact. At the same time, these chemicals can penetrate the soil environment and, in post-disaster reconstruction scenarios, may come into direct contact with concrete [21, 22]. The interaction of chemical substances with the cement matrix of concrete can negatively affect the physical and mechanical properties of concrete by causing degradation of hydration products, changes in pore structure, and the formation of microcracks [23]. However, there are few studies in the literature that directly examine the effects of iodine-based or oxidative chlorine-based disinfectant solutions on concrete following an earthquake [24]. Therefore, the experimental evaluation of the effects of these chemicals on the strength and internal structural integrity of different concrete classes aims to address a significant research gap. Non-destructive methods are generally preferred for the rapid and field-applicable assessment of chemically affected concrete. Ultrasonic pulse velocity (UPV) is one of the most common and widely accepted ultrasonic non-destructive testing methods for assessing the internal continuity and quality level of concrete [25-27]. It has been noted that UPV depends on the material properties of the concrete and the presence of discontinuities such as cracks; it yields higher velocity values in high-quality, intact concrete and lower values in concrete containing internal defects. Furthermore, it has been shown that porosity, microcracks, the state of saturation, and other

physical factors significantly influence UPV results [28, 29]. Previous studies indicate that, in most cases, similar trends exist between UPV and compressive strength [30, 31]. In this context, investigating changes in compressive strength and UPV in concrete with different strength classes following exposure to iodine-based and oxidative chlorine-based disinfectant solutions is important for understanding the mechanism of material degradation, ensuring the safe management of concrete debris after a disaster, and facilitating post-disaster reconstruction processes. The fact that water-cured concrete exhibits higher initial values for UPV and compressive strength also allows for a more controlled interpretation of the changes that occur following chemical exposure [32]. Consequently, such an approach can provide a scientific basis for the technical assessment, classification, and management of chemically contaminated concrete debris. Building on this foundation, the present study reports preliminary findings from a laboratory investigation examining how C16 and C25 concrete specimens responded to two disinfectants over cumulative exposure periods of up to 118 days. Two properties were monitored throughout: compressive strength and UPV. The primary objective was to determine whether clinically relevant concentrations of these agents produced measurable changes in either parameter within a post-disaster timescale. A secondary but equally important question was whether compressive strength and UPV tracked each other consistently under these conditions or diverged, a distinction with direct implications for field debris assessment, where UPV is routinely employed to estimate structural integrity without resorting to destructive testing.

2. MATERIALS AND METHODS

2.1 Concrete Mix Design and Specimen Preparation

Two concrete strength classes were produced: C16 and C25, selected to represent the range of structural concrete quality found in the existing building stock of Istanbul's central districts. CEM II A-V 52.5N cement was used for both classes, and all aggregate was sourced from a single batch to eliminate inter-batch variability. Mix proportions are provided in Table 1. Cylindrical specimens measuring 100 mm in diameter and 200 mm in height were cast in moulds, and demoulded at 24 hours. All specimens were then water-cured at 20 ± 2°C for 28 days before any chemical exposure began.

Table 1. Concrete mix proportions for C16 and C25.

Component	Unit	C16	C25
Cement	kg/m³	200	250
Slag	kg/m³	30	40
Water	kg/m³	196	164
Superplasticizer	kg/m³	1.84	3.63
Fine Aggregate (0–4 mm)	kg/m³	834	647
Coarse Aggregate #1 (4–11,2 mm)	kg/m³	489	405
Coarse Aggregate #2 (11,2–22,4 mm)	kg/m³	357	560
Natural Sand	kg/m³	179	294

2.2 Chemical Exposure Conditions

Following the 28-day water curing period, specimens were assigned to one of three exposure groups: reference (continued water immersion), iodine-based disinfectant solution (2% v/v iodine solution, pH 4.5), and oxidative chlorine-based disinfectant solution (20% v/v chlorine solution). All containers were sealed and maintained at 20 ± 2°C. Specimens were retrieved for testing at cumulative ages of 56 days (28 days water cure + 28 days chemical exposure), 84 days (28 + 56 days), and 118 days (28 + 90 days).

2.3 Test Methods

Compressive strength was measured in accordance with TS EN 12390-3 using a servo-controlled testing machine at a loading rate of 0.5 MPa/s. Three specimens per group and age were tested; results are reported as group means. UPV measurements were carried out immediately before destructive testing, following TS EN 12504-4, using a portable device with 54 kHz exponential transducers in direct transmission mode. Transducers were placed at the mid-height of each cylinder on diametrically opposite faces, with coupling gel applied at each contact point. Transit time was recorded in microseconds and converted to pulse velocity using $v = L/t$, where $L = 200$ mm is the specimen diameter.

3. RESULTS AND DISCUSSION

Table 2 summarizes mean compressive strength and UPV results for all groups and testing ages, together with the quality classification at 118 days.

Table 2. Summary of mean compressive strength and UPV results.

Class	Medium	Compressive Strength (MPa)				UPV (m/s)			UPV quality classification *
		28d	56d	84d	118d	56d	84d	118d	(118d)
C16	Reference (Water)	19.1	21.0	22.0	22.6	4246	4175	4219	Good
C16	iodine-based disinfectant	–	21.1	22.4	22.3	4248	4177	4619	Excellent
C16	oxidative chlorine-based disinfectant	–	21.4	23.1	22.3	4264	4204	4574	Excellent
C25	Reference (Water)	32.1	37.3	38.9	41.5	4640	4773	4773	Excellent
C25	iodine-based disinfectant	–	38.2	38.1	40.3	4571	4532	4858	Excellent
C25	oxidative chlorine-based disinfectant	–	37.8	39.2	38.9	4601	4518	4863	Excellent

** UPV quality scale: > 4500 m/s — Excellent; 3500–4500 m/s — Good; 3000–3500 m/s — Medium; < 3000 m/s — Poor [33]*

3.1 Compressive Strength

For C16 specimens, the reference group exhibited a gradual and consistent strength increase over the entire monitoring period, rising from 21.0 MPa at 56 days to 22.6 MPa at 118 days. This trajectory is consistent with the well-documented behaviour of cement-based materials, in which hydration continues beyond the conventional 28-day reference point and may contribute to incremental strength gains over several months, particularly under continuously moist conditions [34]. The iodine-exposed and chlorine-exposed C16 groups followed a broadly similar pattern. These values are comparable to, and in certain cases marginally exceed, those of the reference group, suggesting that neither chemical environment suppressed continued hydration during the observation period. For C25 specimens, reference compressive strength increased from 37.3 MPa at 56 days to 41.5 MPa at 118 days, confirming the ongoing maturation of this higher-strength class. The iodine-exposed group attained 40.3 MPa and the chlorine-exposed group 38.9 MPa at 118 days, both of which are slightly below the reference value. While these differences are modest, the downward offset observed in C25 may reflect the greater sensitivity of denser, lower-porosity matrices to chemical interaction at the pore surface level, a relationship previously noted in studies examining cement paste behaviour under variable pH environments [35,36]. The mildly acidic character of the iodine-based solution (pH 4.5) is broadly consistent with conditions under which calcium hydroxide dissolution and C-S-H destabilisation are initiated in Portland cement pastes, though such mechanisms typically produce measurable strength losses only at lower pH values or over extended periods [17]. The absence of pronounced strength reduction in the present data may therefore reflect the relatively dilute concentration of the iodine solution, the buffering capacity of the concrete matrix, or the comparatively short duration of exposure within 118-day. The strongly alkaline nature of the oxidative chlorine-based solution, by contrast, would not be expected to dissolve calcium hydroxide and may in some cases promote densification of the interfacial transition zone, which could account for the partial maintenance of strength observed in C16 [37]. Taken together, these results indicate that within the post-disaster timescale examined here, neither disinfectant at the concentrations tested produced a statistically discernible deterioration in compressive strength relative to reference specimens. This does not preclude the possibility of latent or progressive degradation at longer exposure durations, a question that the ongoing microstructural characterization is expected to address.

3.2 Ultrasonic Pulse Velocity

UPV measurements at 56, 84, and 118 days are summarized in Table 2 alongside the UPV quality classification assigned at the final testing age. The results exhibit several features that complement and partially diverge from the compressive strength findings. For C16 reference specimens, UPV values ranged between 4175 and 4246 m/s across the monitoring period, placing this group consistently within the "Good" quality band (3500–4500 m/s). In contrast, both chemically exposed C16 groups recorded markedly higher UPV values at 118 days, 4619 m/s for the iodine group and 4574 m/s for the chlorine group, elevating them into the "Excellent" category (>4500 m/s). UPV is sensitive not only to bulk matrix properties but also to the degree of pore saturation and internal moisture content, factors that are known to exert a significant influence on pulse transmission velocity [38]. Specimens maintained in chemical solutions throughout the exposure period may retain a higher degree of internal saturation relative to reference specimens, even where the chemical properties of the solution differ. This moisture effect may account, at least in part, for the elevated UPV values observed in the chemically exposed groups at 118 days, independent of any genuine change in matrix stiffness or density. A similar saturation-driven inflation of UPV has been reported in comparative

studies examining wet versus dry concrete specimens, where differences of several hundred metres per second have been attributed solely to pore moisture content rather than structural changes [39]. For C25 specimens, the reference group maintained UPV values above 4600 m/s throughout, remaining firmly within the "Excellent" band. The iodine and chlorine-exposed groups exhibited modestly lower UPV values at 84 days, 4532 and 4518 m/s respectively, before recovering to 4858 and 4863 m/s at 118 days, exceeding the reference value of 4773 m/s. This non-monotonic pattern is difficult to attribute to a single mechanism and may reflect competing influences: localised pore modification, moisture redistribution, or minor changes in gel density within the C-S-H framework [40, 41]. Overall, UPV measurements in this study demonstrate a trend broadly consistent with, but not precisely tracking, compressive strength. Specifically, the divergence observed in C16, where UPV places exposed specimens in a higher quality class than the reference, while compressive strength values remain comparable, illustrates that the two parameters do not respond identically to chemical exposure.

3.3 Implications for Post-Earthquake Debris Management

The findings outlined in Sections 3.1 and 3.2 entail significant implications for the systematic assessment and management of concrete debris in post-earthquake contexts. First, the data indicate that exposure to iodine-based and oxidative chlorine-based disinfectant solutions at the concentrations examined here did not produce significant reductions in compressive strength or UPV during the 118-day exposure period. From a debris management perspective, this suggests that, under the conditions simulated in this study, the structural load-bearing capacity of concrete fragments would not be substantially compromised by contact with these agents during typical post-disaster operations. This is a practically relevant finding given that disinfectant application is routine in the weeks and months following a major seismic event [42]. Second, and importantly, the results reveal a measurable divergence between compressive strength and UPV responses. In C16 specimens, UPV values in chemically exposed groups exceeded those of the reference group at 118 days, sufficient to shift the UPV quality classification from "Good" to "Excellent", while compressive strength showed no equivalent improvement. This discrepancy underscores a recognised limitation of UPV as a standalone diagnostic tool: the method is sensitive to pore moisture content, saturation state, and other physical factors that do not necessarily correspond to changes in structural capacity [39]. In the context of field debris assessment, where UPV is frequently employed as a rapid proxy for concrete quality, this finding suggests that prolonged contact with aqueous chemical solutions may produce misleadingly elevated velocity readings that overestimate the actual mechanical performance of a specimen. Field practitioners relying exclusively on UPV to classify chemically contaminated debris should therefore exercise caution, and where possible, corroborate non-destructive readings with complementary methods or targeted destructive sampling [43]. Third, the difference in behavior between C16 and C25 under chemical exposure, with C25 showing a modest but consistent compressive strength offset relative to the reference at 118 days, suggests that concrete quality class may modulate susceptibility to chemical interaction. Higher-strength concretes, characterized by lower water-to-cement ratios and finer pore structures, may present a different exposure dynamic than lower-grade materials. Given that the existing building stock in earthquake-prone urban centers such as Istanbul includes a wide range of concrete quality, from pre-standard construction of potentially sub-C16 grade to modern C30 and above, any future classification framework for chemically contaminated debris would need to account for this variability.

4. CONCLUSIONS

This paper reports preliminary findings from a laboratory study examining the effect of 2% iodine-based disinfectant solution and 20% oxidative chlorine-based disinfectant solution exposure on the compressive strength and ultrasonic pulse velocity of C16 and C25 concrete specimens over cumulative periods of up to 118 days. The main observations are as follows:

1. Neither the iodine-based (2% v/v, pH 4.5) nor the oxidative chlorine-based (20% v/v) disinfectant solution produced a statistically meaningful reduction in compressive strength in C16 or C25 specimens over the 118-day exposure period. Reference and exposed groups remained broadly comparable.
2. UPV values in chemically exposed specimens were, in several cases, equal to or higher than those of reference specimens at equivalent testing ages. For C16 groups, this elevated UPV at 118 days was sufficient to shift the quality classification from "Good" to "Excellent," despite the absence of a corresponding improvement in compressive strength.
3. The divergence between UPV and compressive strength responses, most evident in C16, points to the influence of specimen saturation and pore moisture on pulse velocity measurements. UPV alone should not be treated as a reliable indicator of mechanical performance in concrete that has been in prolonged contact with aqueous chemical solutions.
4. C25 specimens exhibited a modest downward offset in compressive strength relative to the reference under both chemical environments at 118 days, suggesting that the influence of chemical exposure may differ between concrete quality classes, with denser matrices potentially more susceptible to surface-level interaction over time.
5. Within the post-disaster timescale examined here, the disinfectant concentrations commonly applied in field operations appear unlikely to produce acute structural degradation of concrete debris. However, the saturation-related distortion of UPV readings has direct implications for debris classification protocols that rely on non-destructive testing alone.

Abstract. The fact that the effects of global warming have become increasingly tangible and that the production of Portland cement contributes significantly to greenhouse gas emissions has led researchers to develop greener alternatives. One approach is using industrial byproducts to replace cement clinker. In this study, effects of kufeki stone powder on mechanical and durability properties and environmental performance of ordinary Portland cement mortars at different replacement ratios (5%, 10% and 15%) were studied. In addition, kufeki stone powder is also used to produce a well-known alternative limestone-calcined clay cement by replacing the limestone with kufeki powder to investigate kufeki powder's applicability to produce even greener cement. Results were compared to ordinary Portland cement and plain limestone-calcined clay cement reference mixtures. Flexural and compressive strength values were determined at the end of 7 and 28 days of standard curing, in addition to investigations of capillary water absorption and elevated temperature resistance when the samples were subjected to 400 ℃ and 800 ℃. In addition, carbon emissions stemming from each mixture design were calculated through carbon emission factors obtained from databases. Results revealed that low replacement levels of kufeki stone powder could maintain or slightly improve the compressive strength of OPC mortars, although capillary water absorption increased with increasing replacement ratio. In LC3 mortars, replacing the limestone fraction with kufeki maintained compressive strength while markedly reducing capillary absorption, and kufeki-containing mixtures also showed promising residual strength performance after exposure to elevated temperatures.

Keywords: Kufeki powder, sustainability, limestone calcined clay cement, LCA

1 Introduction

Production of Portland cement causes a significant portion of anthropogenic carbon emissions, resulting in approximately 8% of total emissions [1, 2]. This is mostly caused by the energy consumed to calcine and grind the clinker. Thus, although Portland cement has great technical properties, producing one ton of Portland cement releases approximately 0.9 ton CO_2 to the atmosphere [3, 4]. This clearly demonstrates the necessity of taking protective measures in cement production industry and developing greener alternatives [2]. A common approach adopted to ensure sustainability in cement production is using supplementary cementitious materials to replace cement clinker at certain ratios, thus reducing the amount of clinker to be used and to prevent emissions arising from clinker usage to some extent. Some common pozzolans include silica fume, fly ash and ground granulated blast furnace slag. However, in recent years, the availability of these has become limited when compared to cement production demand [5, 6]. This has led researchers to seek other alternatives.

Ternary blended systems have been developed where the synergistic effects of more than one pozzolanic material are utilized to decrease emissions further, whilst sourcing pozzolans from different, more abundant resources. One such alternative is limestone calcined clay cement (LC^3), first proposed by Antoni et al. [7]. LC^3 utilizes the synergistic effects between kaolinitic clay and limestone, as aluminates from kaolinitic clay react with carbonates from limestone to form mono and hemicarboaluminate phases, promoting acceptable strength development while allowing for a greater amount of clinker to be replaced. However, even for LC^3, preserving natural resources is of utmost importance, especially for limestone and clay.

At this point, kufeki stone powder stands out. Kufeki is a fossiliterous hollow cryptocrystalline limestone of Upper Miocene age that was extracted from quarries in the present-day Istanbul provinces of Bakırköy, Sefaköy, Halkalı, and Hadımköy-Sazlıbosna. On the other hand, it is reported that the majority of the quarries are not in operation actively [8, 9]. The matrix of Kufeki limestone largely comprises $CaCO_3$ (93–100%) surrounding the mactra, melanopsis, helix and crinoid pieces. There are no rifts, and it can be found in nature in massive amounts and in intact form [9–11]. The possibility of kufeki stone powder being an amorphous material makes it a good candidate when it comes to replacing cement clinker. Moreover, since it resembles limestone in terms of chemical composition, the idea of using kufeki powder to replace limestone powder in LC^3 is worthy of testing since it has potential to further decrease the already lesser carbon emissions caused by LC^3 production, and to contribute to the preservation of limestone resources.

Literature review reveals that, to the authors' knowledge, kufeki stone powder have not been utilized as a cementitious material to produce any kind of cement, including ordinary Portland Cement (OPC) mortars and LC^3. Arıoğlu and Arıoğlu [8] focused on works of Master Architect Sinan and assessed mechanical properties of kufeki limestone as a building block to understand the reasons lying behind Master Architect Sinan's choice of using kufeki limestone, revealing that carbonation effect helped improving mechanical properties such as compressive, tensile and shear strength. Demir and İlki [9] evaluated mechanical performance of multi-leaf masonry walls belonging to the Ottoman era, one of the constituent materials being local kufeki limestone. Umaroğulları and Kartal [12] assessed physical and mechanical properties of kufeki stones sourced from different quarries, and considering cylindrical and spherical pores within the samples, proposed a mathematical model that defines a relationship between porosity and strength. Eyecioğlu et al. [13] prepared polypyrrole and kufeki stone containing composites by mixing at appropriate ratios and then pressed them to form pellets having a diameter of 10 mm and thickness values of 1-2 mm. Dielectric properties were assessed and different machine learning algorithms were adopted to estimate these properties. Similarly, Eyecioğlu [14] prepared similar samples and trained machine learning models to estimate AC conductivity of the samples produced. Angı et al. [15] assessed Bakırköy kufeki stone as a Global Heritage Stone Resource (GHSR) nominee in terms of its historical use, quarry distribution and mineralogical–petrographic, geochemical, and physico-mechanical characteristics.

As is seen, there has not been an attempt to produce a construction material using ground kufeki stone in powder form. To fill this gap in the literature, it was aimed to investigate the applicability of kufeki stone powder to produce cement mortars. Three different replacement ratios were adopted (5, 10 and 15%) to produce OPC mortars. In addition, due to its resemblance to limestone powder, it was also desired to investigate the possibility of using kufeki stone powder instead of limestone to produce LC^3 mortars. Thus, kufeki stone powder was used to fully replace the limestone in a typical LC^3-50 mixture design, being used to replace 15% of the total binder by mass. Flexural and compressive strength values, capillary water absorption and elevated temperature resistance of mortar samples were assessed. In addition, a life cycle assessment (LCA) analysis was performed in order to determine the amount of $CO_{(e)}$

emission per unit compressive strength to make an evaluation about the environmental performances of the resulting mixture designs.

2 Materials and Methodology

2.1 Materials

Commercial CEM-I 42.5 R Portland cement, kufeki stone powder (KP) and metakaolin (MK) were used. Limestone (LS) was obtained from Anadolu Mikronize, and gypsum (G) was obtained from Trabzon Aşkale Cement Factory. Table 1 shows chemical composition of the kufeki stone powder used in this study. According to Mastersizer results, kufeki stone powder used had a d_{50} value of 25.3 μm. Commercial standardized sand was used as fine aggregate.

Table 1. Semi-quantitative elemental analysis of kufeki stone powder

Oxide	Content (%)
Na_2O	0.034
MgO	0.380
Al_2O_3	0.283
SiO_2	0.695
P_2O_5	0.031
SO_3	0.042
Cl	0.012
K_2O	0.041
CaO	59.113
TiO_2	0.040
MnO	0.013
Fe_2O_3	0.288
SrO	0.028
LOI	38.87

2.2 Methodology

As shown in Table 2, kufeki stone powder was utilized to produce OPC mortars at three different replacement ratios (5%, 10%, and 15% by weight). Additionally, one LC3 mortar, coded as KC3 (kufeki-calcined clay cement), was produced by fully replacing the limestone fraction (representing a 15% replacement ratio of the total binder). As a benchmark, a plain OPC mortar and a typical LC^3 mortar were also produced to compare mechanical and durability properties and environmental performance. Binder-to-aggregate ratio was kept as 1:3, while water-to-binder ratio was 0.50 for all mixture designs. To prepare a mortar batch of approximately 0.768 L, a total of 450 g of binder, 1350 g of standardized sand, and 225 g of water were utilized. Consistency values obtained from flow table test and the amount of superplasticizer used are also given in Table 2.

Table 2. Mixture designs

ID	OPC (%)	KP (%)	MK (%)	LS (%)	G (%)	Consistency (cm)	SP (%)
OPC	100	-	-	-	-	17	0.17
LC3	50	-	30	15	5	17	0.40
K5	95	5	-	-	-	16	0.08
K10	90	10	-	-	-	16	0.04
K15	85	15	-	-	-	16	0.02
KC3	50	15	30	-	5	17	0.35

Samples were cured for 7 and 28 days under standard curing conditions. For the determination of flexural strength, in accordance with ASTM C293-16 [16], six 4x4x16 cm prism samples were produced for each mixture design for 7- and 28-days strength determination. Flexural strength was taken as the average of three values. Compressive strength was determined using the broken pieces of the prisms as the average of six values. For capillary water absorption, in accordance with ASTM C1585 [17], three 5 cm cubic samples were produced for each mixture design. For the determination of elevated temperature resistance, six 5 cm cubic samples were produced; half of them were subjected to 400℃ exposure while the rest was subjected to 800℃. Assessment was made based on residual strength.

For the assessment of environmental performance, a life cycle assessment (LCA) analysis was performed. Emissions associated with cement and concrete production stem from raw materials, transportation and production processes [18]. However, in literature, it is stated that emissions arising from the materials itself are the major contributors and emissions due to transportation and production processes are negligible when compared to these. Thus, this study focused on emissions due to raw materials; emissions factors will be multiplied with the amount of materials used [18, 19]:

$$mCO_2 = \sum_{i+1}^{n}(CO_{2i} x M_i) \quad (1)$$

where CO_{2i} is the emission factor ($kgCO_{2(e)}/kg$) and M_i is the mass of the material used per unit volume (kg/m^3). For this, cradle-to-gate carbon emission factors for raw materials were taken from ICE Database v4.1 [20], factors were multiplied with the amounts of the materials used. In order to make a realistic assessment, total carbon emissions caused by each mixture design was divided by that design's 28-days compressive strength value to reveal carbon emissions per unit strength ($kgCO_{2(eq)}/m^3(MPa)$ [19]:

$$mCO_{2-\sigma} = mCO_2/\sigma \quad (2)$$

where σ is the 28-day compressive strength.

3 Results and Discussion

3.1 Flexural and Compressive Strength

Figures 1-2 show 7 and 28 days flexural and compressive strength values under standard curing conditions.

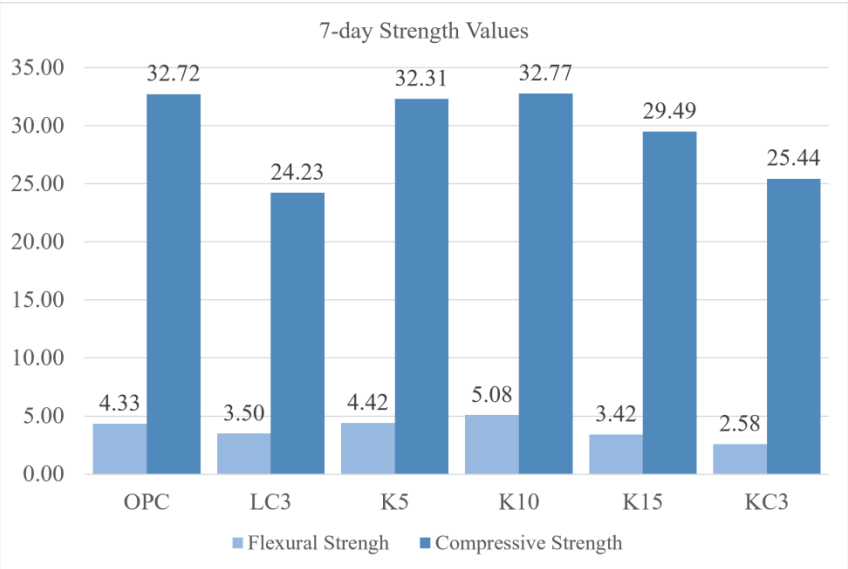

Fig. 1. 7-day strength values

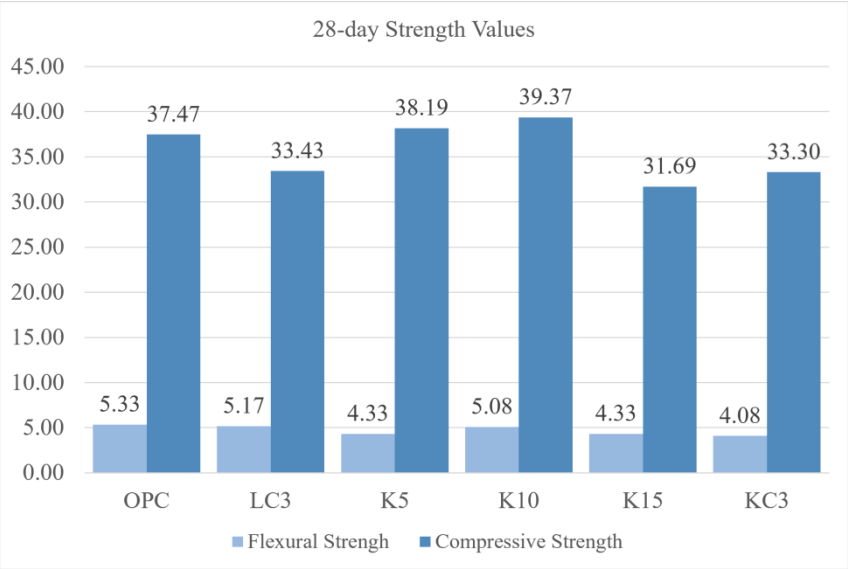

Fig. 2. 28-day strength values

When used to replace CEM-I, kufeki yielded the best results at 10% replacement ratio in terms of compressive strength. While K5 and K10 exhibited 7-day compressive strengths comparable to that of OPC, their 28-day compressive strengths were 1.9% and 5.1% higher, respectively. However, at 15% replacement ratio, 28-day compressive strength was reduced by 15.4%. This might imply the fact that at lower replacement ratios, kufeki stone powder was able to compensate for the dilution effect through filler effect and nucleation; however, at higher replacement ratios dilution effect might become dominant.

When used as a complete replacement for the limestone fraction in LC3, kufeki stone powder increased the 7-day compressive strength by 5.0%, while the 28-day strength remained essentially unchanged, with a reduction of only 0.4% compared with LC3. These results suggest that kufeki stone powder may serve as an alternative carbonate component in LC^3 systems, slightly improving strength development at 7 days without compromising later-age compressive strength.

3.2 Capillary Water Absorption

Figure 3 shows capillary water absorption test results as capillarity coefficients. It is seen that, in OPC-based mixture designs, capillarity coefficients increased by 4.3%, 11.0% and 32.5% for K5, K10 and K15, respectively. Although an increase in capillarity might be viewed as a contradiction despite the preservation or limited increase in compressive strength, such a relationship does not necessarily exist between them. While compressive strength is related to the load-bearing solid matrix, capillary water absorption is controlled primarily by the connectivity of water-permeable pores, the critical pore diameter, and pore tortuosity. Therefore, a low-ratio replacement of the matrix with clay may have led to an increase in interconnected capillary pores or water-permeable internal surfaces without adversely affecting the solid matrix.

When used as a complete replacement for the limestone fraction in LC3, kufeki stone powder decreased capillarity coefficient by 40.3% although 28-day compressive strength remained almost the same. This finding suggests that kufeki stone powder could be an effective carbonate source alternative to limestone for LC^3 matrices while providing advantages in terms of capillary water transportation. On the other hand, since this paper lacks microstructural analyses, this cannot be directly attributed to pozzolanic activity or promotion of

carboaluminate formation. Observed improvement could stem from particle size distribution, morphology, packing density or changes in pore connection structures.

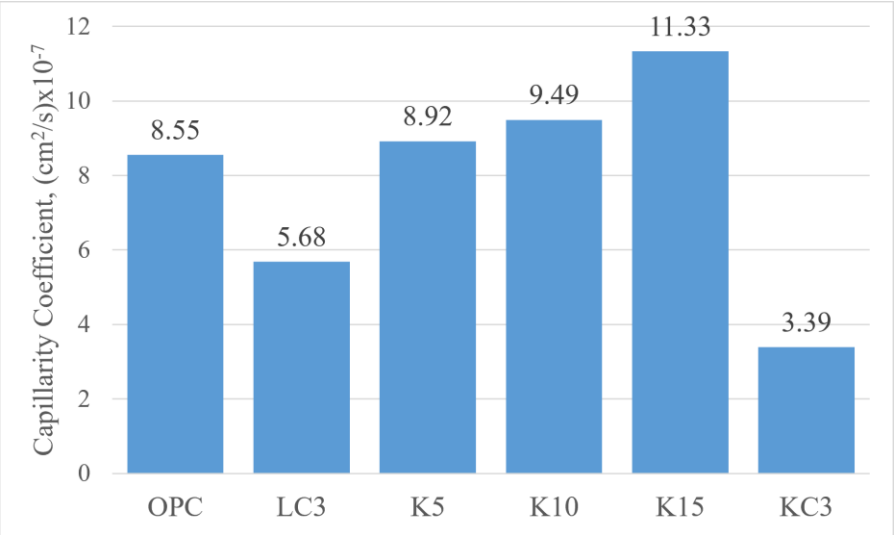

Fig. 3. Capillarity coefficients

3.3 High Temperature Resistance

The residual strengths in percentage are presented in Table 3 for all mix designs and 400℃ and 800℃ heat exposures.

Table 3. Residual strength values (%) after high temperature exposure

ID	400℃	800℃
OPC	67.86	37.90
LC3	100.00	30.63
K5	116.83	28.95
K10	111.07	26.58
K15	129.26	28.57
KC3	109.66	42.92

Exposure to elevated temperatures resulted in markedly different residual compressive strength responses depending on the binder system. At 400 °C, OPC retained only 67.9% of its original compressive strength, whereas K5, K10 and K15 exhibited residual strengths of 116.8%, 111.1% and 129.3%, respectively. Thus, partial replacement of CEM-I with kufeki stone powder appeared to improve strength retention at 400 °C, although no systematic relationship between replacement level and residual strength was observed. The increase above the initial strength may be associated with temperature-induced effects such as further hydration of previously unhydrated particles, moisture removal and temporary changes in the cementitious matrix; however, the underlying mechanism cannot be conclusively identified without further microstructural investigation. At 800 °C, extensive strength loss occurred in all mixtures, and the residual strengths of K5–K15 ranged only between 26.6% and 28.9%, indicating that increasing kufeki content provided no additional benefit at this temperature.

A different trend was observed for the LC3-based mortars. KC3 retained 109.7% and 42.9% of its initial compressive strength after exposure to 400 and 800 °C, respectively, compared with 100.0% and 30.6% for the LC3 reference. These findings suggest that replacing the limestone fraction of LC3 with kufeki stone powder may improve its resistance to elevated

temperatures. Nevertheless, additional mineralogical and microstructural analyses are required to identify the mechanisms responsible for this improvement.

3.4 Life Cycle Assessment (LCA) Analysis

Figure 4 shows LCA analysis results. It is seen that, kufeki stone powder's capability of retaining strength of LC^3 matrix whilst reducing emissions significantly made it possible to obtain the lowest carbon emission per unit strength for KC3 mixture design.

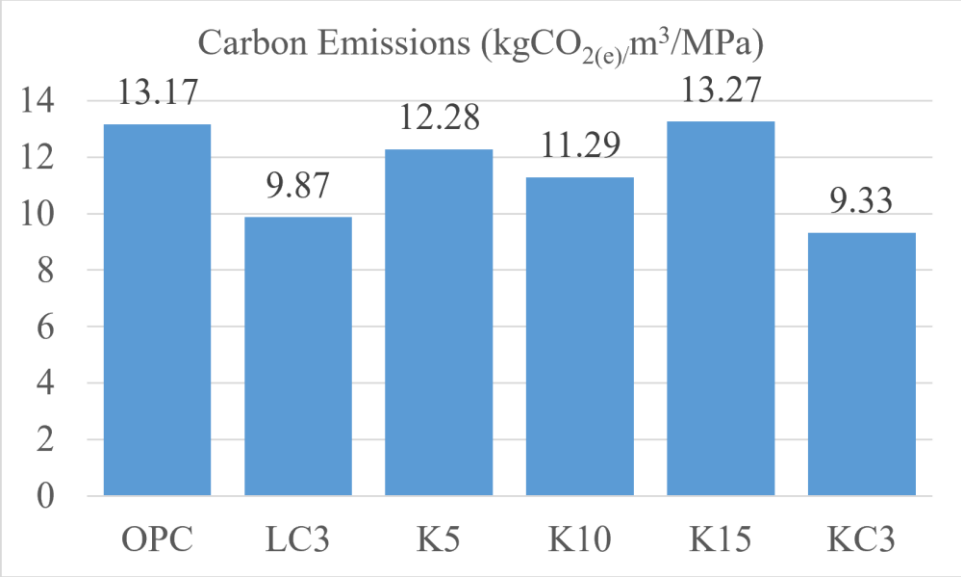

Fig.4. Carbon emissions

4 Conclusion

The main conclusions of this study can be summarized as follows:

- Partial replacement of CEM-I with kufeki stone powder was feasible at low replacement levels. K5 and K10 maintained the 7-day compressive strength of OPC, while their 28-day strengths were 1.9% and 5.1% higher, respectively. However, increasing the replacement ratio to 15% resulted in a 15.4% reduction in 28-day compressive strength.
- Capillary water absorption increased progressively with increasing kufeki content in OPC-based mortars, indicating a possible trade-off between strength preservation and resistance to capillary water transport. In contrast, replacing the limestone fraction of LC3 with kufeki reduced the capillary absorption coefficient by approximately 40% while maintaining comparable 28-day compressive strength.
- Kufeki-containing OPC mortars exhibited residual compressive strengths above 100% after exposure to 400 °C, whereas OPC retained only 67.9% of its initial strength. However, no systematic relationship between kufeki replacement level and residual strength was observed. At 800 °C, substantial strength losses occurred in all mixtures.
- KC3 showed promising thermal performance, retaining 109.7% and 42.9% of its initial compressive strength at 400 and 800 °C, respectively. Overall, the influence of kufeki stone powder appears to depend strongly on the binder system and exposure condition, and further microstructural investigations are required to clarify the underlying mechanisms.
- For K5, K10 and LC3 systems, the use of kufeki stone powder made it possible to decrease equivalent carbon dioxide emissions per unit compressive strength, improving environmental performance.

Future work on the use of kufeki stone powder as a possible supplementary cementitious material for OPC and LC^3 mortars should focus on a broader range of durability properties, and microstructural analyses must be performed in order to fully understand the mechanisms lying behind the obtained improvements or deteriorations in mechanical and durability properties.

Abstract. This study investigates the combined effects of waste tire rubber (WTR) and polypropylene (PP) fiber dosage on the mechanical performance of engineered cementitious composites (ECC), with the aim of promoting waste utilization while maintaining satisfactory engineering properties. WTR replaced natural fine aggregate at levels of 0–40%, while PP fibers were incorporated at volume fractions of 1.0% and 1.5%. Compressive, splitting tensile, and flexural strengths were evaluated at 7 and 28 days. The results showed that increasing WTR content progressively reduced compressive strength, whereas splitting tensile and flexural strengths exhibited non-linear responses, with a noticeable recovery at 20% WTR. Increasing the PP fiber dosage had only a marginal effect on compressive strength but considerably improved tensile and flexural performance. Among the rubber-containing mixtures, the combination of 20% WTR and 1.5% PP fibers provided the most favorable mechanical balance, achieving 28-day compressive, splitting tensile, and flexural strengths of approximately 48.9, 4.59, and 7.50 MPa, respectively. The findings demonstrate that an appropriate combination of WTR and PP fibers can partially offset the mechanical drawbacks associated with rubber incorporation, providing a promising approach for developing resource-efficient ECC while reducing the consumption of natural fine aggregate.

Keywords: Engineered cementitious composites; waste tire rubber; compressive strength; splitting tensile strength; flexural strength

1 Introduction

Engineered Cementitious Composites (ECC) have attracted considerable attention as one of the most advanced cement-based construction materials. First developed by Li et al., ECC is characterized by high tensile ductility, strain-hardening behavior, and multiple microcracking, with tensile strain capacities exceeding 3-5%, providing significantly greater ductility and toughness than conventional concrete [1-4]. Owing to these characteristics, ECC has been widely recognized as a promising material for durable and resilient infrastructure applications.

To improve the sustainability and cost-effectiveness of ECC, increasing attention has been directed toward incorporating recycled and waste-derived materials [5]. Among these, waste tire rubber (WTR) has emerged as an attractive alternative because of its ability to improve deformability, impact resistance, and energy absorption while providing an environmentally sustainable solution for recycling end-of-life tires [6-8]. However, the low stiffness of rubber particles and their weak bond with the cementitious matrix generally reduce the mechanical strength of rubberized cementitious composites [8,9]. Compared with conventional concrete, ECC provides a more compatible matrix for waste tire rubber because its intrinsic strain-hardening behavior better accommodates the deformable nature of rubber particles [10]. Previous studies have shown that rubberized ECC can retain strain-hardening characteristics while improving deformability, impact resistance, and vibration damping [11,12].

Several studies have investigated the incorporation of waste tire rubber in cementitious materials. Sofi [13], Valente et al. [14], Fauzan et al. [15], and Ahmad et al. [16] consistently reported that increasing rubber content generally reduces compressive strength, density, and stiffness, although improvements in crack resistance, abrasion resistance, deformability, and other durability-related properties were observed at moderate replacement levels. Likewise, studies on rubberized ECC have demonstrated that supplementary cementitious materials and fibers can compensate for some of the adverse effects of rubber incorporation while improving rheology, ductility, and durability [17]. Adesina and Das [18] further reported significant improvements in tensile strain and durability despite reductions in compressive strength, whereas Lee et al. [19] demonstrated that ECC produced with locally available materials exhibited superior tensile ductility and compressive strength compared with conventional concrete.

Despite these advances, the combined effects of waste tire rubber and polypropylene (PP) fibers on the mechanical behavior of ECC remain insufficiently understood. Therefore, this study experimentally investigates the mechanical properties of ECC mixtures incorporating PP fibers at dosages of 1.0% and 1.5% together with waste tire rubber as a partial replacement for natural fine aggregate at levels of 10%, 20%, 30%, and 40%.

2 Materials and Methods

2.1 Materials

Type II Portland cement (PC), conforming to ASTM C150 was used as the primary binder. Granulated blast furnace slag (GBFS), with a specific gravity of 2.89, was used as the supplementary cementitious material. The chemical composition and physical properties of both PC and GBFS are presented in Table 1. A polycarboxylate ether-based superplasticizer (SP), commercially identified as Carboxal HF5000, with a specific gravity of 1.10, was used to obtain the desired workability. Natural fine aggregate obtained from the Ghareh-Ghom mine (Marand, East Azerbaijan, Iran) had a maximum particle size of 4.75 mm and a specific gravity of 2.63. WTR, produced from shredded end-of-life automobile tires, was used as a partial replacement for natural fine aggregate. The WTR particles had a size range of 1.18-4.75 mm and a specific gravity of 0.96. Polypropylene fibers, with a specific gravity of 0.91 and an aspect ratio of 863, were used as reinforcement. To ensure uniform dispersion, the fibers were manually separated before mixing. The PP fibers and WTR used in this study are shown in Fig. 1(a) and Fig. 1(b), respectively.

2.2 Mix Proportions and Mixing

As summarized in Table 2, eight ECC mixtures were designed with an approximately constant water-to-binder (w/b) ratio of 0.25. The total binder content was 980.2 kg/m^3 for the mixtures containing 1.0% polypropylene fibers and 975.2 kg/m^3 for those containing 1.5% PP fibers. To enhance environmental sustainability and reduce PC consumption, GGBS was incorporated as a 50% replacement for PC by mass in all mixtures. The experimental variables included two PP fiber volume fractions (1.0% and 1.5%) and five WTR replacement levels (0%, 10%, 20%, 30%, and 40%) as volumetric replacements for natural fine aggregate (FA). The mixtures were prepared using a laboratory-scale mixer following a three-stage mixing procedure to ensure the homogeneous distribution of all constituents, particularly the PP fibers. First, the fine aggregate and one-third of the total mixing water were mixed. Next, the cementitious materials (PC and GBFS) together with another one-third of the mixing water were added and mixed thoroughly. Finally, the PP fibers and WTR particles were gradually incorporated, followed by the remaining mixing water and the superplasticizer, after which mixing continued until a uniform and homogeneous mixture was obtained. After mixing, the fresh ECC mixtures were cast into molds. The specimens were demolded after 24 h and subsequently cured in a water tank maintained at 23 ± 2 °C until the specified testing ages. The mix proportions are summarized in Table 2.

2.3 Testing Procedure

The compressive strength test was performed in accordance with ASTM C109 [20] using 100 × 100 × 100 mm cube specimens. The splitting tensile strength test was conducted in accordance

with ASTM C496 [21] on cylinders measuring 100 mm in diameter and 200 mm in height. Flexural strength was determined according to ASTM C78 [22] using prism specimens with dimensions of 100 × 100 × 450 mm. All mechanical tests were conducted after 7 and 28 days of water curing. For each mixture, three specimens were tested for each mechanical property, and the reported results represent the average values. The experimental setups for the compressive, splitting tensile, and flexural strength tests are presented in Figs. 2, 3, and 4, respectively.

Fig. 2. Compressive strength test setup

Fig. 4. Flexural strength test setup

3 Results and Discussion

3.1 Compressive Strength

The compressive strength results obtained after 7 and 28 days of curing are presented in Fig. 5, while the influence of WTR replacement on the 28-day compressive strength is illustrated in Fig. 6. As shown in Fig. 5, all mixtures exhibited higher compressive strengths at 28 days than at 7 days, reflecting the continued hydration of the PC-GBFS binder system. Regardless of curing age, replacing natural fine aggregate with WTR progressively reduced the compressive strength, and the reduction became more pronounced with increasing WTR content. In contrast, increasing the PP fiber dosage from 1.0% to 1.5% had only a negligible effect on the control mixtures, increasing the 7-day strength from 44.95 MPa to 45.10 MPa (0.33%) and the 28-day strength from 54.53 MPa to 54.70 MPa (0.31%).

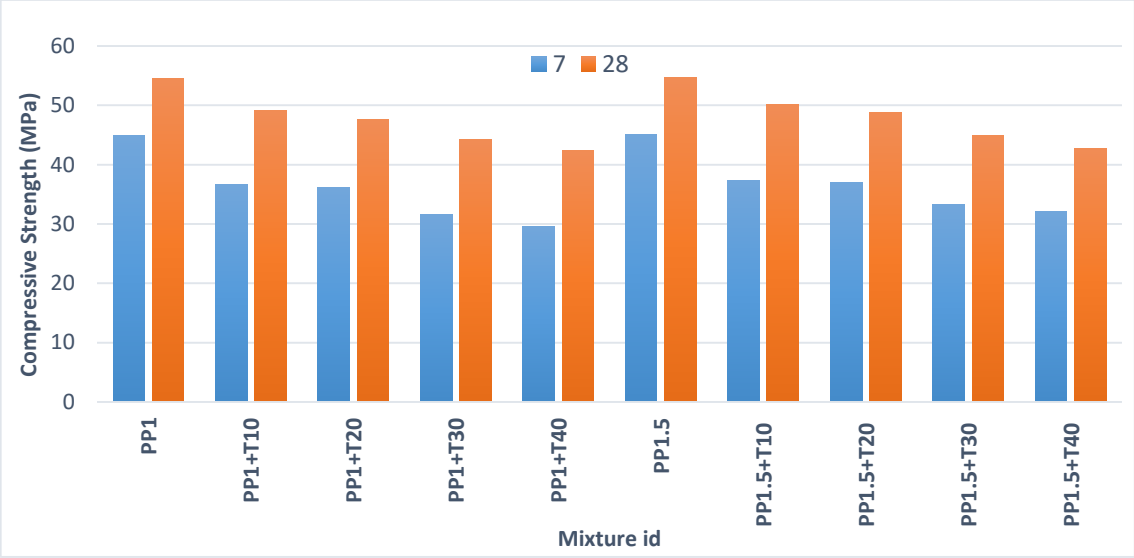

Fig. 5. Compressive strength of ECC specimens at different curing ages.

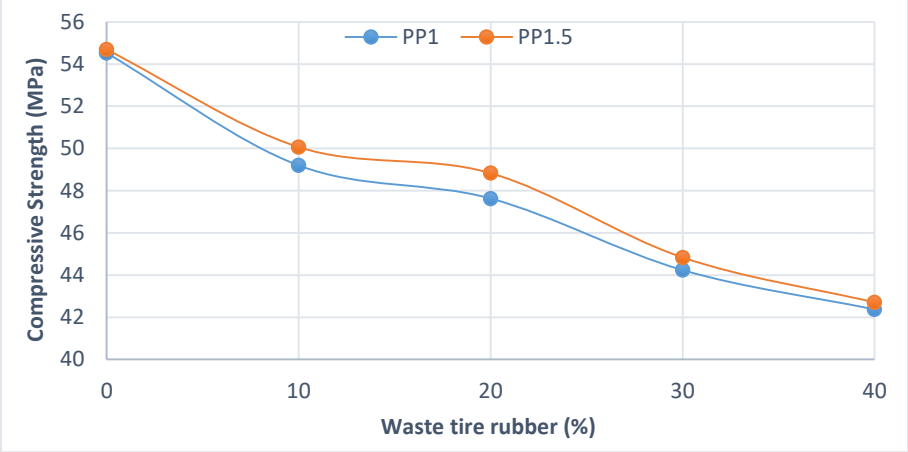

Fig. 6. Compressive strength at 28 days as a function of WTR replacement ratio

The influence of WTR replacement is more clearly observed in Fig. 6. For both fiber dosages, the compressive strength decreased almost linearly as the WTR replacement level increased. The reduction remained relatively moderate up to 20% WTR, whereas a steeper decline occurred between 20% and 40%, indicating that higher rubber contents substantially weaken

the load-carrying capacity of the ECC matrix. At all replacement levels, mixtures reinforced with 1.5% PP fibers exhibited slightly higher compressive strengths than the corresponding 1.0% PP mixtures. For the PP1 mixtures, replacing natural fine aggregate with 10%, 20%, 30%, and 40% WTR reduced the 7-day compressive strength by 18.46%, 19.47%, 29.81%, and 34.37%, respectively, while the corresponding reductions at 28 days were 9.77%, 12.65%, 18.89%, and 22.30%. For the PP1.5 mixtures, the reductions were 17.07%, 18.07%, 26.05%, and 28.71% at 7 days and 8.46%, 10.73%, 18.04%, and 21.94% at 28 days.

The reduction in compressive strength is primarily attributed to the lower stiffness and elastic modulus of WTR compared with natural sand, causing rubber particles to behave as soft inclusions within the cementitious matrix. In addition, the hydrophobic rubber surface results in a weak and porous interfacial transition zone (ITZ), while increased air entrainment further raises the overall porosity of the composite. Similar findings have been reported by Sofi et al. [10] and Valente et al. [11]. Although increasing the PP fiber dosage had little influence on the compressive strength of the control mixtures, it partially compensated for the adverse effect of WTR, particularly at higher replacement levels. At 7 days, the PP1.5 mixtures exhibited compressive strengths 0.33%, 2.05%, 2.07%, 5.71%, and 8.98% higher than the corresponding PP1 mixtures for WTR replacement levels of 0%, 10%, 20%, 30%, and 40%, respectively. The corresponding improvements at 28 days were 0.31%, 1.77%, 2.52%, 1.36%, and 0.78%. Overall, WTR replacement was the dominant parameter governing compressive strength, whereas increasing the PP fiber dosage from 1.0% to 1.5% provided only a modest improvement, particularly at higher WTR contents.

3.2 Splitting Tensile Strength

The splitting tensile strength results obtained after 7 and 28 days are presented in Figs. 7 and 8, respectively. Compared with compressive strength, the tensile behavior of ECC was considerably more sensitive to the PP fiber dosage, whereas the incorporation of WTR produced a non-linear response. As shown in Fig. 7, all mixtures exhibited higher splitting tensile strengths at 28 days than at 7 days because of the continued hydration of the PC-GBFS binder system. Increasing the PP fiber dosage from 1.0% to 1.5% noticeably improved the tensile strength of the control mixtures. The 7-day strength increased from 3.82 MPa to 4.34 MPa (13.6%), while the 28-day strength increased from 4.67 MPa to 5.14 MPa (10%). These results confirm that, unlike compressive strength, the tensile performance of ECC is highly dependent on fiber reinforcement owing to the crack-bridging capability of PP fibers.

The influence of WTR replacement is more clearly illustrated in Fig. 8. For both fiber dosages, the tensile strength decreased when 10% WTR was incorporated, partially recovered at 20% WTR, and then declined again at 30% and 40% WTR. This indicates that an optimum WTR content of approximately 20% exists for tensile performance. For the PP1 mixtures, the 7-day tensile strength decreased by 21.2%, 8.38%, 22.5%, and 26.9% at WTR replacement levels of 10%, 20%, 30%, and 40%, respectively, while the corresponding reductions at 28 days were 17.34%, 5.57%, 19.9%, and 24.4%. A similar trend was observed for the PP1.5 mixtures, where the corresponding reductions at 7 days were 20.74%, 13.13%, 26.04%, and 30.41%, respectively. The temporary recovery observed at 20% WTR is attributed to the elastic nature of the rubber particles, which enhances crack deflection and energy absorption without severely disrupting matrix continuity. However, at higher replacement levels, the low stiffness of WTR together with its weak interfacial bonding with the cementitious matrix leads to stress concentration and premature crack propagation. Similar observations have been reported by Sofi et al. [10] and Valente et al. [11]. For all WTR replacement levels, mixtures reinforced with 1.5% PP fibers consistently exhibited higher tensile strengths than those containing 1.0% PP fibers. At 10%, 20%, 30%, and 40% WTR, increasing the PP fiber dosage improved the 28-

day tensile strength by 7.25%, 4.08%, 6.15%, and 3.97%, respectively. This improvement is attributed to the higher fiber-bridging density, which limits crack opening and delays crack propagation, thereby partially compensating for the weakening effect of WTR.

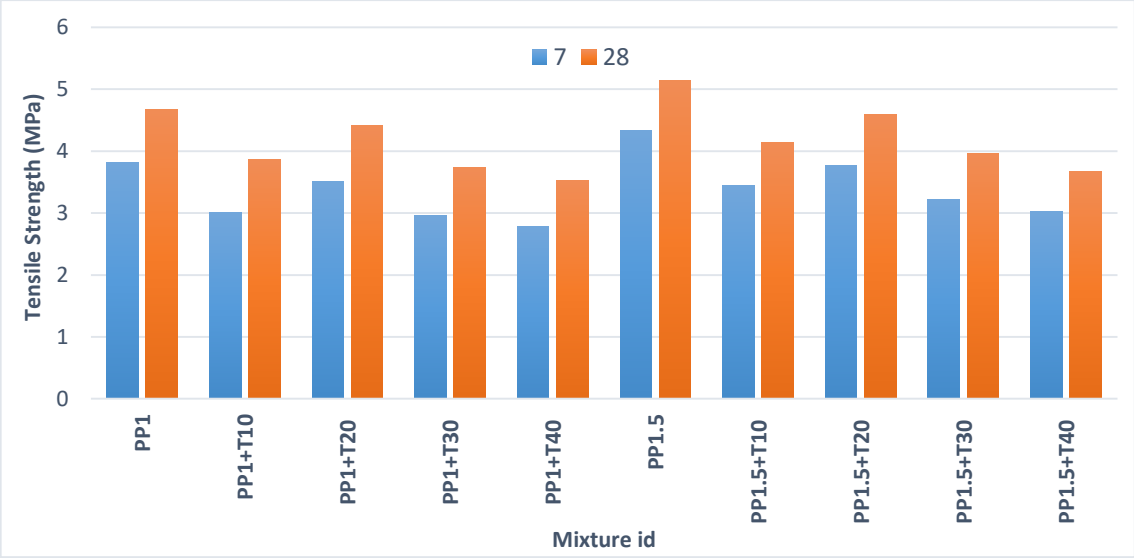

Fig. 7. Splitting tensile strength of ECC specimens at different curing ages

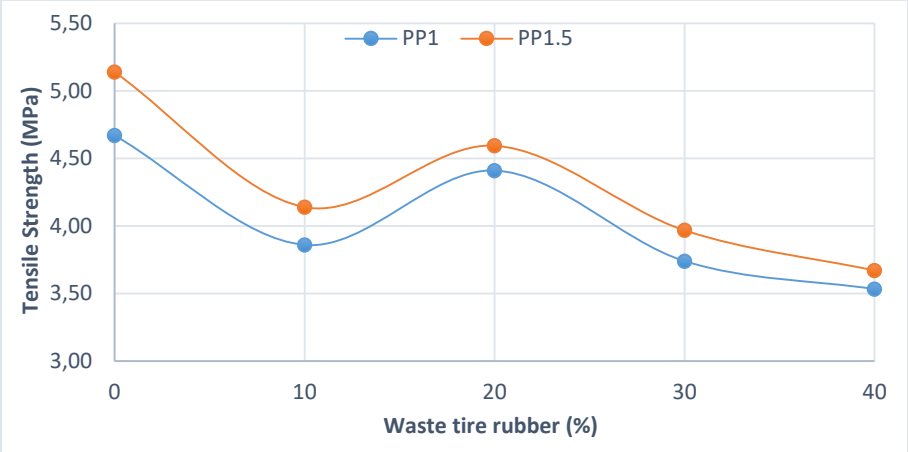

Fig. 8. Splitting tensile strength at 28 days as a function of WTR replacement ratio

3.3 Flexural Strength

The development of flexural strength at 7 and 28 days for the different ECC mixtures is shown in Fig. 9. A clear age-dependent improvement was observed for all mixtures, while the magnitude of flexural strength was governed by both WTR replacement and PP fiber dosage. The WTR-free mixtures exhibited the highest values within each fiber series. At 28 days, increasing the PP fiber content from 1.0% to 1.5% increased the flexural strength from 7.66 to 8.32 MPa, corresponding to an improvement of approximately 8.6%. This enhancement was considerably more pronounced than that observed for compressive strength, reflecting the greater contribution of PP fibers under bending through crack bridging and restriction of crack opening.

The effect of WTR replacement on the 28-day flexural response is presented more clearly in Fig. 10. Unlike the nearly continuous reduction observed in compressive strength, the flexural response followed a non-linear pattern. For the PP1 series, the strength initially decreased from 7.66 MPa to 6.68 MPa at 10% WTR, but subsequently recovered to 7.08 MPa at 20% WTR. A

similar behavior occurred for the PP1.5 series, where the corresponding values were 8.32, 7.23, and 7.50 MPa at 0%, 10%, and 20% WTR, respectively. Further increasing the WTR content to 30% and 40% caused renewed strength reductions in both series. Thus, among the rubber-containing mixtures, 20% WTR consistently provided the most favorable flexural response. The reduction in flexural strength at higher WTR replacement levels can be attributed to the same mechanisms discussed previously for the compressive and splitting tensile strength results. As the WTR content increases, these adverse effects become increasingly dominant, leading to a progressive deterioration in flexural resistance.

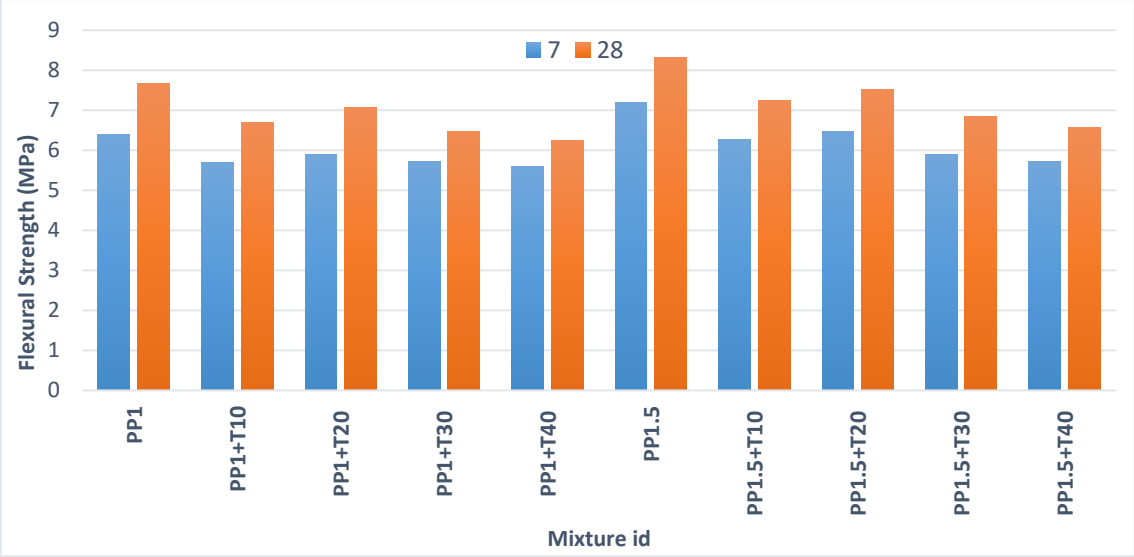

Fig. 9. Flexural strength of ECC specimens at different curing ages.

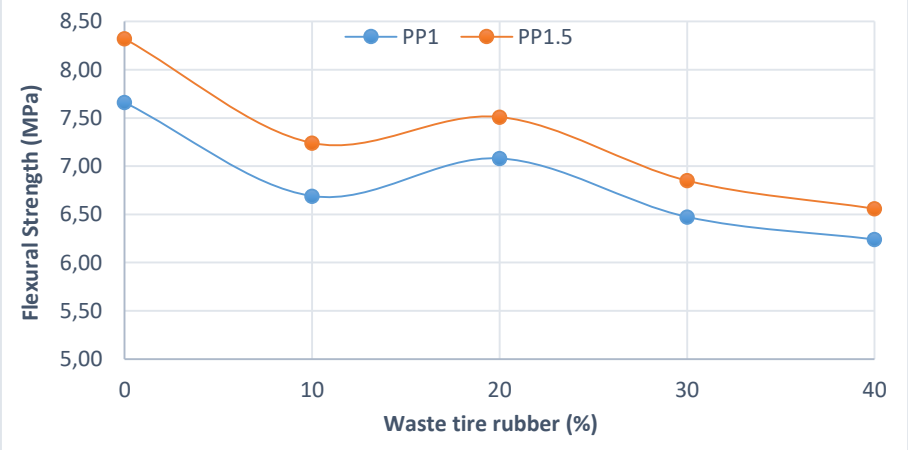

Fig. 10. Flexural strength at 28 days as a function of WTR replacement ratio

Another important feature of Figs. 9 and 10 is the consistently superior flexural performance of the mixtures containing 1.5% PP fibers. Unlike the limited influence of fiber dosage on compressive strength, the higher fiber content provided a noticeable advantage under flexural loading across the entire WTR range. The denser fiber network enhances crack bridging and stress transfer across developing cracks, thereby improving resistance to bending. Nevertheless, this benefit becomes insufficient to fully compensate for the deterioration of the matrix at high WTR contents, particularly at 30% and 40% replacement. From a mechanical-performance perspective, the results indicate that 20% WTR combined with 1.5% PP fibers provides the most favorable configuration among the rubber-containing mixtures investigated. This

combination maintains comparatively high flexural strength while enabling a substantial proportion of natural fine aggregate to be replaced with recycled tire rubber.

4 Conclusions

This study investigated the combined effects of WTR replacement and polypropylene fiber dosage on the mechanical performance of ECC. Based on the experimental results, the following conclusions can be drawn:

- WTR replacement progressively reduced compressive strength, with the greatest reductions occurring at higher replacement levels. At 28 days, incorporating 40% WTR reduced compressive strength by approximately 22%.
- Increasing the PP fiber dosage from 1.0% to 1.5% had only a minor effect on compressive strength but noticeably improved splitting tensile and flexural performance. In the WTR-free mixtures, the corresponding 28-day improvements were approximately 10.0% and 8.6%, respectively.
- Splitting tensile and flexural strengths exhibited a non-linear response to WTR. Following an initial reduction at 10% WTR, both properties partially recovered at 20% WTR, whereas further replacement to 30% and 40% resulted in renewed strength deterioration.
- The higher PP fiber dosage consistently improved tensile and flexural performance in the presence of WTR, indicating that enhanced fiber bridging can partially compensate for the mechanical weakness introduced by rubber particles.
- Among the rubber-containing mixtures, 20% WTR combined with 1.5% PP fibers provided the most favorable mechanical balance, achieving approximately 48.9 MPa compressive strength, 4.59 MPa splitting tensile strength, and 7.50 MPa flexural strength at 28 days.
- The findings demonstrate that an appropriate combination of WTR and PP fibers can enable meaningful replacement of natural fine aggregate while maintaining satisfactory mechanical performance, supporting the development of more resource-efficient ECC mixtures.

Abstract. The use of polypropylene (PP) fibers in cementitious mortars can improve flexural strength and ductility but may reduce compressive strength due to increased porosity and matrix discontinuity. Natural pozzolans such as natural zeolite (NZ) can potentially compensate for this reduction. This study investigates the effects of NZ (5, 10, 15, and 20% cement replacement) and PP fibers (0.1, 0.2, and 0.3%) on the compressive and flexural strengths of mortars cured at -15, 0, 20, and 35 °C for 3, 7, and 28 days. Curing temperature strongly influenced strength development, with -15 °C causing compressive strength losses exceeding 90% relative to 20 °C. Curing at 35 °C accelerated early-age strength development but resulted in an 8-12% reduction in 28-day strength. Although PP fibers alone reduced compressive strength by 10-13%, NZ effectively compensated for this reduction. The optimum performance was obtained with 15% zeolite and 0.3% PP fibers, achieving 25% higher compressive strength and 26% higher flexural strength than the control mixture. The findings highlight the potential of combining NZ and PP fibers to improve mechanical performance under different curing temperatures.

Keywords: Natural zeolite; polypropylene fibers; mechanical properties; curing condition.

1 Introduction

The growing demand for cementitious materials has intensified concerns regarding CO_2 emissions from Portland cement production, making supplementary cementitious materials (SCM) an effective strategy for reducing clinker consumption [1]. Among natural SCMs, natural zeolite (NZ) has attracted attention due to its pozzolanic activity, porous aluminosilicate structure, high specific surface area, and low density, which can improve the hydration and microstructural characteristics of cementitious matrices [2-4]. However, cement-based materials remain inherently brittle, and discrete fibers are commonly incorporated to improve crack control, tensile behavior, ductility, and post-cracking performance [5]. Polypropylene (PP) fibers are particularly attractive because of their low density, corrosion resistance, chemical stability, and cost-effectiveness [6,7], although their performance depends strongly on fiber dosage and the characteristics of the surrounding matrix.

Curing temperature represents another key parameter because it governs the kinetics of cement hydration and pozzolanic reactions and therefore affects the development of the matrix in which the fibers are embedded. Changes in temperature can alter hydration rate, reaction-product formation, interfacial characteristics, and strength evolution [8-10]. This issue is particularly important for zeolite-containing mortars, since the contribution of a pozzolanic material may vary considerably with curing conditions. Consequently, the mechanical response of a mortar containing both NZ and PP fibers cannot necessarily be inferred from studies in which these variables are examined independently. Previous investigations illustrate these individual effects. Alani et al. [11] showed that calcined nano-montmorillonite could modify the strength retention of mortar subjected to elevated temperatures, while Marzouk and Hussein

[12] demonstrated the strong influence of curing temperature and initial moist-curing duration on the strength development of cementitious systems containing silica fume and fly ash. Soriano et al. [13] further reported that pozzolanic additions affected hydration and relative strength development under low-temperature curing. For NZ specifically, Kriptavičius et al. [14] identified a favorable clinoptilolite replacement level of approximately 15% by volume based on flowability, compressive strength, and hydration characteristics. More broadly, SCM incorporation has been shown to significantly modify the fresh and hardened behavior of cement-based materials [15,16].

The role of PP fibers has also been shown to depend strongly on the surrounding matrix and exposure conditions. Richardson reported that increasing PP fiber content could reduce compressive strength and density because of fiber-induced air entrainment [17], whereas Smarzewski [18] demonstrated that PP fibers improved resistance to freeze-thaw deterioration by restricting crack propagation and water ingress. Together, these studies show that neither SCM incorporation nor fiber reinforcement produces a universally beneficial response; their effectiveness depends on dosage, matrix characteristics, and environmental conditions. Despite the extensive literature on natural pozzolans, PP fibers, and temperature-related effects, their combined influence remains insufficiently understood. In particular, limited information is available on how NZ replacement and PP fiber incorporation interact under different curing temperatures to govern the mechanical development of cement mortar. Therefore, the present study investigates the combined effects of NZ as a partial cement replacement, PP fiber dosage, and curing temperature on the mechanical properties of cement mortars. The results are intended to clarify the interaction among these variables and to identify mixture conditions capable of maintaining satisfactory mechanical performance under different curing environments.

2 Experimental and Numerical Methods

2.1 Materials

Type II Portland cement (PC), conforming to ASTM C150, was used as the primary binder, while NZ was incorporated as a supplementary cementitious material. The physical properties and chemical compositions of PC and zeolite are summarized in Table 1. Natural silica sand was used as fine aggregate (FA), with a maximum particle size of 4.75 mm and a saturated surface-dry (SSD) specific gravity of 2.63. A polycarboxylate ether-based high-range water-reducing admixture (HRWR), commercially known as Carboxal HF5000, with a specific gravity of 1.10, was incorporated to achieve the required workability. Polypropylene fibers were used as reinforcement and had a length of 19 mm, a diameter of 22 μm, a specific gravity of 0.91, an aspect ratio (L/d) of approximately 863, and a circular cross-section. Prior to mixing, the PP fibers were manually separated to promote uniform dispersion throughout the mortar and minimize fiber agglomeration.

2.2 Mix proportions and Specimen Preparation

Eight mortar mixtures were designed with a constant water-to-binder (w/b) ratio of 0.46, as summarized in Table 2. The experimental variables were the PP fiber volume fraction (0.1%, 0.2%, and 0.3%) and the zeolite replacement level (5%, 10%, 15%, and 20% by mass of cement). For mixtures containing both NZ and PP fibers, the fiber content was fixed at 0.3% by volume. A three-stage mixing procedure was adopted to achieve uniform distribution of the constituents. First, the fine aggregate was mixed with one-third of the total mixing water. The binder materials (PC and NZ) were then introduced together with the second third of the water. Finally, the PP fibers were gradually added, followed by the remaining water premixed with the HRWR, and mixing was continued until a homogeneous mortar was obtained. After mixing, the mortar was cast into molds and consolidated using a vibrating table. The specimens were demolded after 24 h and subsequently exposed to four curing temperatures: -15, 0, 20, and 35 °C, using controlled curing environments appropriate for each temperature. Representative specimens under the different curing conditions are shown in Fig. 1.

Table 2. Mix proportions of the mortar specimens (kg/m^3)

Fig. 1. Mortar specimens under different curing conditions.

2.3 Mechanical properties

The mechanical performance of the mortar mixtures was evaluated through compressive and flexural strength tests. Compressive strength was determined in accordance with ASTM C109 [19] using 50 mm cubic specimens, while flexural strength was determined in accordance with ASTM C348 [20] using 40×40×160 mm prismatic specimens subjected to three-point bending. The experimental setups for the compressive and flexural strength tests are shown in Figs. 2(a) and 2(b), respectively. For both tests, the reported results represent the average of three specimens. A coefficient of variation (CV) of 4-5% was considered acceptable; tests exceeding this range were repeated to ensure consistency and reliability of the measurements.

3 Results and Discussion

3.1 Compressive Strength

The compressive strength development of the PP fiber-reinforced mortars at 3, 7, and 28 days under different curing temperatures is presented in Fig. 3, while Fig. 4 illustrates the effect of PP fiber dosage on the 28-day strength. The results demonstrate that curing temperature was the dominant parameter governing strength development. Increasing the temperature from -15 to 35 °C substantially enhanced compressive strength, whereas PP fiber incorporation generally reduced the strength relative to the corresponding unreinforced control.

At -15 °C, all mixtures exhibited limited strength development, with 28-day values ranging from 4.1 to 4.9 MPa. Although the 0.2% and 0.3% PP mixtures showed higher 3-day strengths than the control, this advantage disappeared at later ages. At 0 °C, the 28-day strength decreased from 20.8 MPa for the control to 15.5, 17.1, and 17.8 MPa for the 0.1%, 0.2%, and 0.3% PP mixtures, respectively. A similar response occurred at 20 °C, where the control reached 48.4 MPa compared with 36.6-42.3 MPa for the fiber-reinforced mixtures. At 35 °C, the corresponding values were 49.1 MPa for the control and 39.4, 40.2, and 42.9 MPa for the three PP dosages. Thus, although PP fibers generally reduced compressive strength, increasing their content from 0.1% to 0.3% progressively moderated this reduction.

The reduction associated with PP fibers may be attributed to increased air entrapment, disruption of matrix continuity, and the relatively low stiffness of PP fibers under compressive loading. Similar reductions in compressive strength with PP fiber incorporation were reported by Ibrahim et al. [21]. Conversely, higher curing temperatures promoted matrix development and substantially increased strength, consistent with the temperature-dependent behavior reported by Lu et al. [22]. Overall, Figs. 3 and 4 indicate that curing temperature exerted a substantially greater influence on compressive strength than PP fiber dosage.

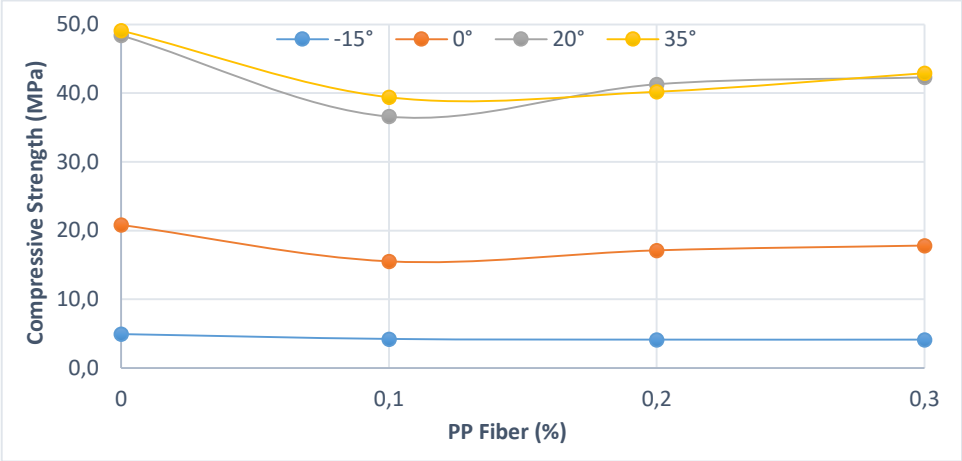
28	4,9	4,2	4,1	4,1	20,8	15,5	17,1	17,8	48,4	36,6	41,3	42,3	49,1	39,4	40,2	42,9

Fig. 3. Compressive strength development of PP fiber-reinforced mortars under different curing temperatures



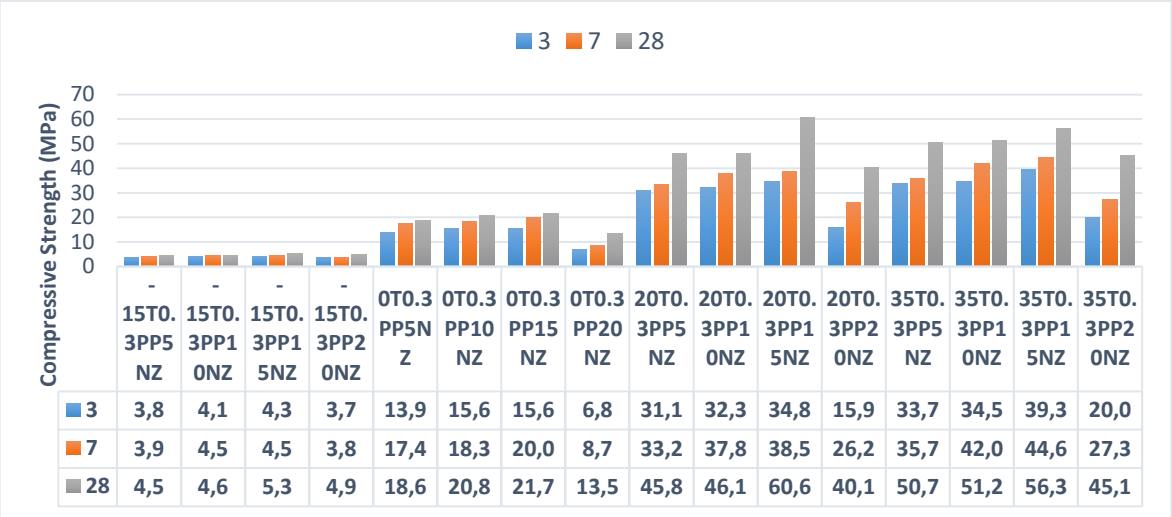


Fig. 4. Effect of PP fiber dosage on 28-day compressive strength under different curing temperatures

The influence of NZ replacement on mortars containing 0.3% PP fiber is presented in Fig. 5, while Fig. 6 shows the corresponding 28-day trends. At -15 °C, NZ content had little influence, with 28-day strengths ranging from 4.1 to 5.3 MPa. At 0 °C, increasing NZ from 0% to 15% increased the 28-day strength from 17.8 to 21.7 MPa, whereas 20% NZ reduced it to 13.5 MPa. The beneficial effect of NZ became considerably more pronounced at 20 °C. The 28-day strength increased from 42.3 MPa without NZ to 45.8, 46.1, and 60.6 MPa at 5%, 10%, and 15% replacement, respectively. Thus, 15% NZ produced a 43.3% improvement, whereas increasing the replacement to 20% reduced the strength to 40.1 MPa. At 35 °C, a similar trend was observed, with strength increasing from 42.9 MPa to 50.7, 51.2, and 56.3 MPa at 5%, 10%, and 15% NZ before decreasing to 45.1 MPa at 20%.

The improvement at moderate NZ contents can be associated with its filler and pozzolanic contributions, whereas excessive replacement may reduce the effective cement content and increase water demand. The favorable performance of mortars incorporating natural zeolite and PP fibers is consistent with the findings of Dabbaghi et al. [3]. Overall, the results reveal a clear interaction between curing temperature and NZ content. Among the investigated combinations, 15% NZ with 0.3% PP fiber provided the highest compressive strength, reaching 60.6 MPa at 28 days under 20 °C curing.

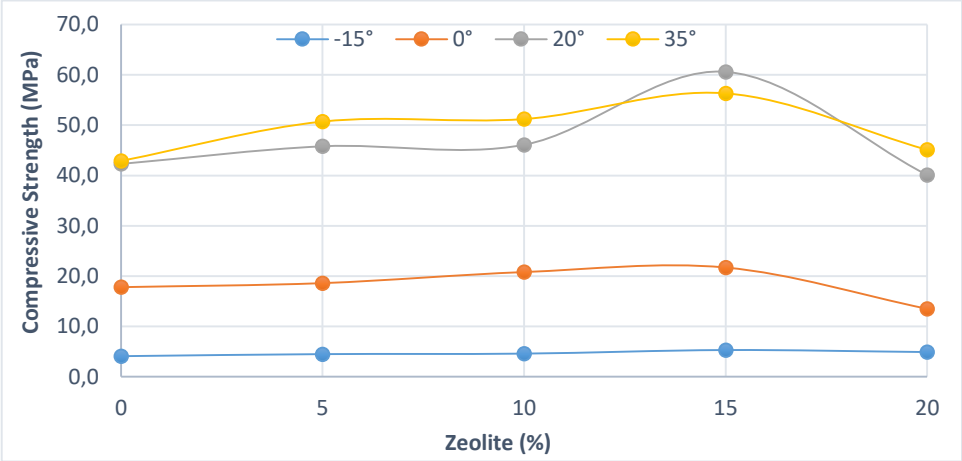
Fig. 5. Compressive strength development of NZ-modified PP fiber-reinforced mortars under different curing temperatures



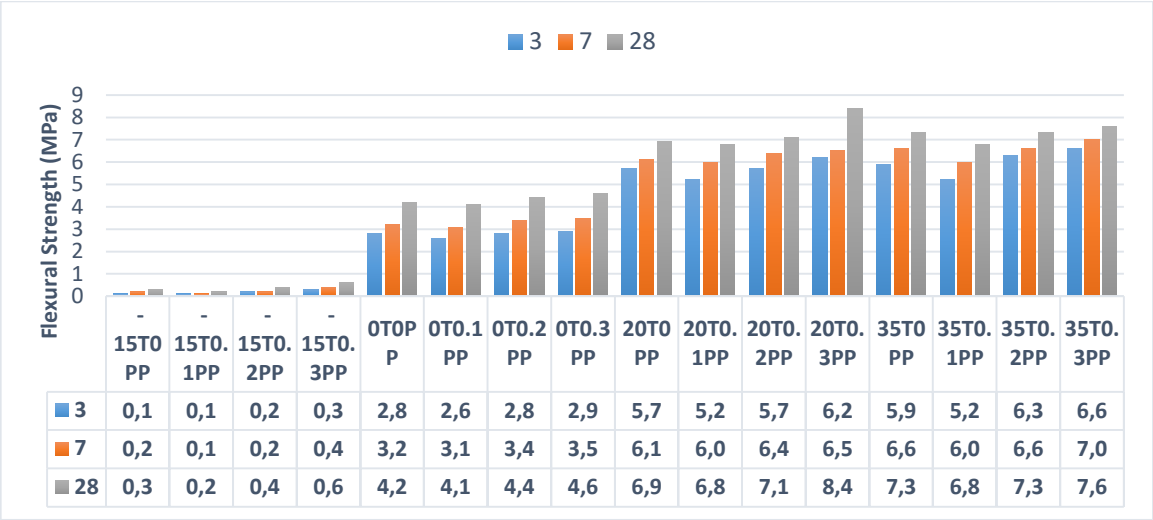


Fig. 6. Effect of NZ replacement level on 28-day compressive strength under different curing temperatures

3.2 Flexural Strength

The flexural strength development of PP fiber-reinforced mortars at 3, 7, and 28 days under different curing temperatures is presented in Fig. 7, while Fig. 8 illustrates the effect of PP fiber dosage on the 28-day strength. Overall, curing temperature strongly influenced flexural strength, while the effect of PP fiber dosage was non-linear and dependent on the curing condition. At -15 °C, flexural strength remained extremely low, with 28-day values ranging from 0.2 to 0.6 MPa, indicating severely restricted matrix development. At 0 °C, the 28-day strength varied from 4.1 to 4.6 MPa for the fiber-reinforced mixtures compared with 4.2 MPa for the control. At higher curing temperatures, the influence of PP fibers became more evident. At 20 °C, the 28-day flexural strengths of the control and mixtures containing 0.1%, 0.2%, and 0.3% PP were 6.9, 6.8, 7.1, and 8.4 MPa, respectively. Thus, 0.3% PP resulted in a 21.7% increase relative to the control. At 35 °C, the corresponding values were 7.3, 6.8, 7.3, and 7.6 MPa, respectively. As further illustrated in Fig. 8, low PP dosages did not necessarily improve flexural strength; however, further increasing the fiber content resulted in strength recovery, with 0.3% PP providing the highest strength at both 20 and 35 °C. The beneficial effect at higher fiber contents can be attributed to enhanced crack bridging, which restricts crack propagation

and increases resistance to flexural failure. Similar beneficial effects of PP fibers on flexural behavior have been reported by Fu et al. [23] and Wei et al. [24].

	-15T0PP	-15T0.1PP	-15T0.2PP	-15T0.3PP	0T0PP	0T0.1PP	0T0.2PP	0T0.3PP	20T0PP	20T0.1PP	20T0.2PP	20T0.3PP	35T0PP	35T0.1PP	35T0.2PP	35T0.3PP

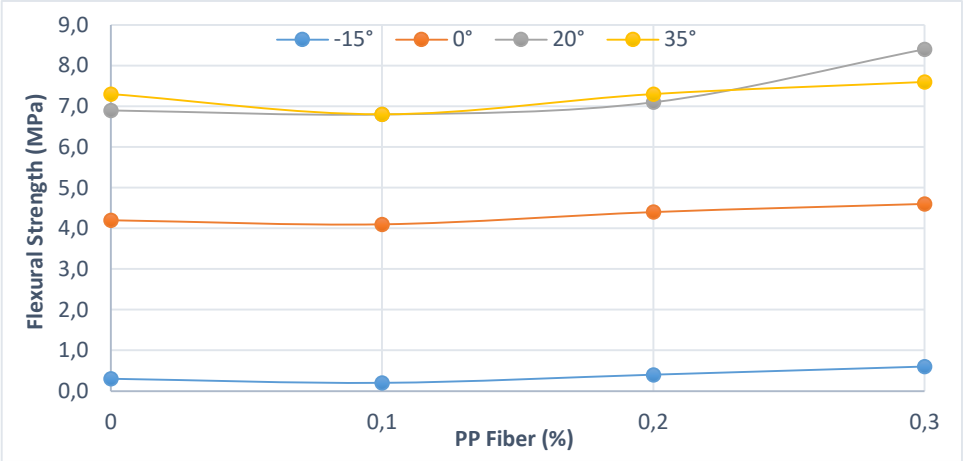
7	0,2	0,1	0,2	0,4	3,2	3,1	3,4	3,5	6,1	6,0	6,4	6,5	6,6	6,0	6,6	7,0
28	0,3	0,2	0,4	0,6	4,2	4,1	4,4	4,6	6,9	6,8	7,1	8,4	7,3	6,8	7,3	7,6

Fig. 7. Flexural strength development of PP fiber-reinforced mortars under different curing temperatures



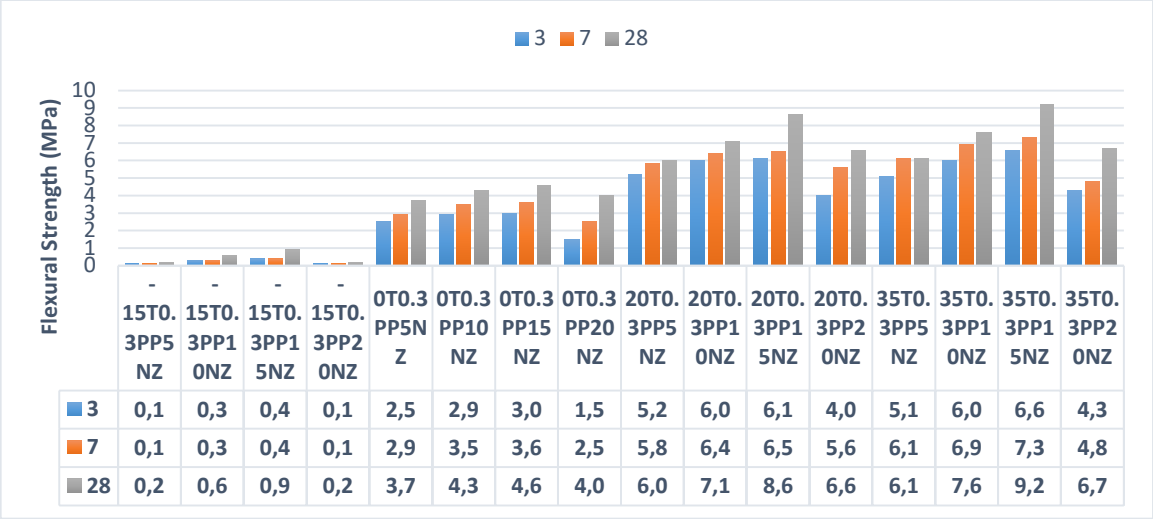


Fig. 8. Effect of PP fiber dosage on the 28-day flexural strength under different curing temperatures

The combined effects of NZ replacement and curing temperature on the flexural strength of mortars containing 0.3% PP fiber are presented in Fig. 9, while the corresponding 28-day trends are shown in Fig. 10. The results reveal a distinctly non-linear response to NZ content. At -15 °C, strength development remained severely restricted; nevertheless, the 15% NZ mixture reached the highest 28-day strength of 0.9 MPa compared with 0.6 MPa for the NZ-free mixture. At 0 °C, the 28-day strengths at 0%, 5%, 10%, 15%, and 20% NZ were 4.6, 3.7, 4.3, 4.6, and 4.0 MPa, respectively, indicating that the contribution of NZ remained limited under low-temperature curing. The influence of NZ became considerably more pronounced at higher temperatures. At 20 °C, the 28-day flexural strength initially decreased from 8.4 MPa without NZ to 6.0 MPa at 5% replacement, followed by an increase to 7.1 and 8.6 MPa at 10% and 15% NZ, respectively. Further increasing the replacement to 20% reduced the strength to 6.6 MPa. A similar trend was observed at 35 °C, where the corresponding strengths were 7.6, 6.1, 7.6, 9.2, and 6.7 MPa. As clearly shown in Fig. 10, 15% NZ represented the optimum replacement level, producing the highest flexural strength at all curing temperatures. The maximum value of 9.2 MPa was obtained at 35 °C, representing an improvement of approximately 21.1% over

the corresponding NZ-free mixture. The favorable performance at 15% NZ may be associated with an effective balance between matrix refinement and fiber matrix interaction, which enhances the crack-bridging efficiency of PP fibers. In contrast, the strength reduction at 20% NZ suggests that excessive cement replacement offsets these beneficial effects through dilution of the cementitious matrix and increased water demand. Overall, the results demonstrate that the flexural response is governed by a coupled interaction among curing temperature, PP fiber dosage, and NZ content. Among the investigated combinations, 0.3% PP fiber with 15% NZ provided the most favorable flexural performance, reaching 9.2 MPa at 28 days under 35 °C curing.

4 Conclusion

This study investigated the combined effects of NZ, PP fibers, and curing temperature on the mechanical performance of cement mortars. The following conclusions can be drawn:

- Curing temperature was the dominant factor controlling mechanical performance. Sub-zero curing at -15 °C severely restricted strength development, whereas higher curing temperatures substantially improved both compressive and flexural strengths.
- PP fibers affected compressive and flexural strengths differently. Fiber incorporation generally reduced compressive strength, while 0.3% PP provided the best performance among the fiber-reinforced mixtures and increased the 28-day flexural strength by 21.7% at 20 °C compared with the unreinforced control.
- The effect of NZ was non-linear and temperature-dependent. A replacement level of 15% consistently provided the most favorable response, whereas increasing NZ to 20% generally resulted in strength deterioration.
- The combination of 15% NZ and 0.3% PP fiber was identified as the optimum mixture within the investigated ranges. It achieved the highest 28-day compressive strength of 60.6 MPa at 20 °C, representing a 43.3% improvement over the corresponding NZ-free mixture.
- The same mixture achieved the highest flexural strength of 9.2 MPa at 35 °C, approximately 21.1% higher than its NZ-free counterpart. This demonstrates that the optimum curing temperature is property-dependent, with maximum compressive and flexural strengths occurring at different temperatures.
- Overall, the findings highlight the importance of jointly optimizing NZ content, PP fiber dosage, and curing temperature, rather than considering their effects independently.

Abstract. The multilayer casting of self-consolidating concrete (SCC) may significantly reduce interlayer bond performance, particularly when successive layers are placed after prolonged casting intervals. However, the influence of fiber reinforcement on mitigating this deterioration has not been comprehensively investigated. This study evaluated the effectiveness of glass fibers (GF) and steel fibers (SF), used in mono and hybrid configurations, for improving the residual bond strength (RBS) of multilayer SCC. Fiber dosages of 0.5%, 1.0%, and 1.5% (by volume) were investigated under casting intervals of 0, 40, 80, 120, and 160 min. Interlayer bond performance was assessed using direct shear strength tests. Fiber incorporation substantially enhanced bond retention compared with the control mixture, with the improvement becoming increasingly pronounced as the casting interval increased. Among the mono-fiber mixtures, 1.5% GF achieved an RBS of approximately 51% after a 160 min delay, whereas 1.5% SF exhibited superior performance with an RBS of about 63%, compared with nearly 37% for the control mixture. Increasing the fiber dosage from 0 to 1.5% improved bond strength by approximately 18% and 20% under monolithic casting for GF- and SF-reinforced mixtures, respectively, while the corresponding enhancements increased to about 62% and 105% after 160 min. Hybrid fiber systems exhibited a clear synergistic effect. The optimum performance was obtained with a 30%GF-70%SF hybrid at a total fiber dosage of 1.5%, achieving approximately 158% higher interlayer bond strength than the control and the highest RBS (about 71%) after 160 min. These findings demonstrate that optimized hybrid fiber reinforcement effectively mitigates time-dependent interlayer bond deterioration in multilayer SCC.

Keywords: Self-consolidating concrete; Residual bond strength; Glass fiber; Steel fibers.

1 Introduction

The use of self-consolidating concrete (SCC) has become increasingly common in large concrete elements where construction is carried out through the sequential placement of multiple lifts. Unlike conventionally vibrated concrete, SCC relies entirely on its self-flowing capability, making the quality of the interface between successive layers highly dependent on the condition of the previously placed concrete. As the elapsed time between placements increases, the lower layer gradually loses its fresh characteristics owing to structural buildup and early hydration, which weakens the interaction between adjacent lifts and promotes the formation of cold joints. Consequently, the interlayer region often becomes the weakest part of the composite element, reducing its structural reliability under service loads [1,2].

The quality of the bond developed at the interface is controlled by both material characteristics and casting conditions. Fresh-state rheology governs the ability of the newly placed layer to penetrate and integrate with the underlying concrete, while prolonged delays

between successive placements increase the likelihood of cold joint formation [3,4]. In addition, mixture design parameters such as fiber type and dosage, binder composition, water-to-powder ratio, supplementary cementitious material (SCM) type and dosage, superplasticizers, and viscosity-modifying admixtures directly influence workability, structural buildup, and ultimately the bond performance between successive layers [5,6]. Although considerable attention has been devoted to improving the mechanical properties of fiber-reinforced SCC [7,8], the combined influence of fiber type, fiber content, and casting delay on the interlayer bond behavior of multilayer SCC has not yet been fully clarified. Addressing this knowledge gap is essential for the reliable design and construction of multilayer SCC structures.

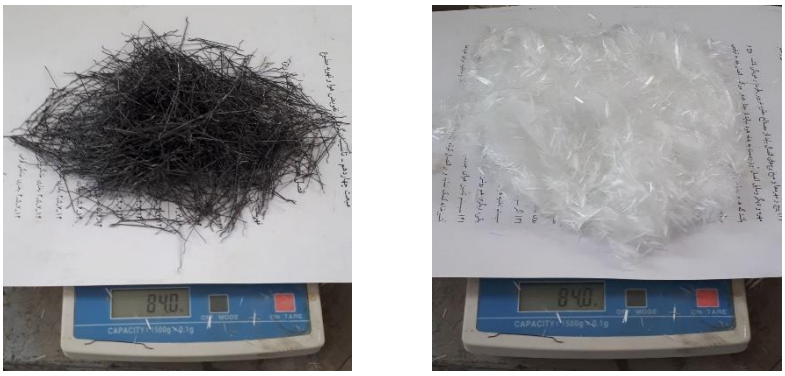
Fiber incorporation is widely recognized as an effective approach for enhancing the tensile strength, crack resistance, toughness, and durability of cementitious materials. However, these benefits are generally accompanied by modifications in the fresh-state behavior of SCC. Previous studies have demonstrated that fiber type, geometry, and dosage significantly affect rheological parameters, including yield stress, plastic viscosity, and flowability. In general, increasing the fiber content increases particle interlocking and mixture cohesiveness, resulting in higher resistance to flow and a more pronounced structural build-up of the fresh matrix [8-10]. Recent investigations have further shown that fiber reinforcement influences the thixotropic behavior and structural recovery of cementitious materials. Since structural build-up governs the evolution of the fresh concrete surface during resting periods, it plays a critical role in determining the degree of intermixing between successive concrete layers. A rapid increase in structural build-up before the placement of a new layer may reduce interface cohesion and promote cold-joint formation, whereas excessive fiber contents may further intensify these effects through increased yield stress and cohesiveness [8-10].

Hybrid fiber reinforcement has attracted increasing attention because combining fibers with different mechanical characteristics can provide performance levels that cannot be achieved using a single fiber type alone. Previous studies have shown that different fiber types contribute differently to the fresh and hardened behavior of cementitious composites, making hybrid fiber systems an attractive approach for improving overall performance [7-10]. The complementary actions of these fibers are expected to enhance stress transfer across the interlayer interface and improve bond integrity under delayed casting conditions. Nevertheless, although hybrid fiber systems have been extensively investigated for improving the mechanical performance of cementitious composites, their influence on the interlayer bond behavior of multilayer SCC has received limited attention.

Despite these advances, existing studies have primarily focused on the influence of fibers on rheological properties, workability, and thixotropic behavior, whereas their direct effect on the interlayer bond performance of multilayer SCC has received considerably less attention. In particular, the combined effects of fiber type, fiber dosage, and casting interval on the residual bond strength between successive layers remain insufficiently understood. Therefore, this study experimentally investigates the effectiveness of glass fibers (GF), steel fibers (SF), and hybrid fiber systems in improving the interlayer bond performance of multilayer SCC subjected to different casting intervals. The findings provide practical guidance for optimizing fiber-reinforced SCC mixtures intended for multilayer construction applications.

2 Experimental procedures

2.1 Materials



The SCC mixtures in this study were prepared using ordinary Portland cement (PC, Type I-425) conforming to ASTM C150 [11] Type I. A Class F fly ash (FA) was used as a supplementary cementitious material by replacing 20 wt.% of the PC. The physical and

chemical properties of the PC and FA are presented in Table 1. Two types of discontinuous fibers, namely alkali-resistant E-glass fibers (GF) and steel fibers (SF), were used as reinforcing materials. The fibers were incorporated individually and in hybrid combinations at total fiber contents of 0.5%, 1.0%, and 1.5% by mass of the total cementitious materials. For the hybrid mixtures, the total fiber dosage was divided either equally between glass and steel fibers (50% GF-50% SF) or at a ratio of 30% glass fibers and 70% steel fibers. Photographs of the glass and steel fibers are presented in Fig. 1. Natural river aggregates with a maximum particle size of 15 mm for coarse aggregate and 5 mm for fine aggregate were utilized. The bulk specific gravity of the coarse and fine aggregates was 2.62 and 2.59, respectively, with absorption capacities of 2.04% and 3.22%. A polycarboxylate ether-based high-range water-reducing admixture (HRWR), commercially designated as CARBOXAL SRF521, conforming to ASTM C494 Type F [12] and having a specific gravity of 1.08, was employed to obtain the desired workability.

2.2 Mix proportions and mixing

Table 2 summarizes the mixture proportions, which consisted of one control SCC mixture without fibers and twelve fiber-reinforced mixtures incorporating different fiber types and dosages. All mixtures were produced with a water-to-binder ratio of 0.36 and a binder content of 500 kg/m^3. The fine-to-total aggregate ratio by mass was maintained at approximately 0.52. For each mixture, the dosage of the HRWR was adjusted to achieve a slump flow of 650 ± 10 mm, ensuring that all fresh concretes satisfied the self-consolidation requirements specified in the EFNARC European Guidelines [13]. Mixing was carried out using a 20 L rotary planetary mixer following a five-step sequence: (i) the aggregates were mixed with 35% of the mixing water for 1 min; (ii) the cementitious materials and 40% of the remaining water were added and mixed for 2 min; (iii) the HRWR, previously diluted in the remaining water, was gradually introduced over 2 min; (iv) the mixture was allowed to rest for 2 min; and (v) the designated fibers were gradually added to the fresh mixture, which was then mixed for an additional 2 min to ensure their uniform dispersion. The temperature during mixing was maintained at 21 ± 2 °C.

2.3 Evaluation of fresh properties and interlayer bond strength

Fresh-property testing was initiated approximately 11 min after the initial contact between water and the cementitious materials, corresponding to approximately 3 min after completion of the mixing procedure. The slump-flow test was conducted in accordance with the EFNARC European Guidelines [13]. The slump-flow value was determined as the average of two spread diameters measured in perpendicular directions.

Interlayer bond performance was evaluated using the direct shear test. Prismatic specimens of identical dimensions were cast in two successive layers with a horizontal interface. Casting intervals of 0, 40, 80, 120, and 160 min were considered between the placement of the first and second layers. For the 0-min condition, the second layer was placed immediately after the first layer without any intentional casting delay. After curing, the specimens were positioned so that the bond interface was vertically oriented during testing, as illustrated in Fig. 2.

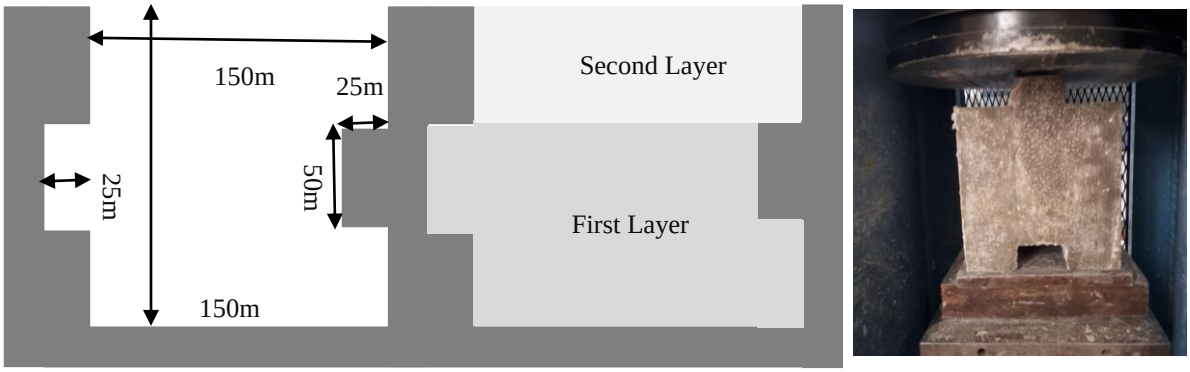

Fig. 2. Direct shear strength mold arrangement and sample under testing

The direct interlayer shear strength, V, was calculated using Eq. (1):

$$V = \frac{P}{2bd} \quad (1)$$

where V is the direct interlayer shear strength (MPa), P is the maximum failure load (N), and b and d are the width and depth of the prism specimen (mm), respectively. The residual bond strength (RBS) was used to quantify the time-dependent reduction in interlayer performance. For each mixture, the bond strength measured at casting intervals of 40, 80, 120, and 160 min

was normalized with respect to the corresponding bond strength obtained at 0 min, according to Eq. (2):

$$\text{RBS (\%)} = \frac{Bond\ strength\ at\ each\ time\ interval}{Bond\ strength\ at\ 0\ min} \times 100 \quad (2)$$

The 0-min condition was used as the reference and therefore corresponded to an RBS of 100%.

3 Results and Discussion

3.1 HRWR demand

The variation in the required HRWR dosage to maintain the target slump flow of 650 ± 10 mm is presented in Fig. 3. As summarized in Table 2, the HRWR demand generally increased with increasing fiber dosage regardless of fiber type. Among the mono-fiber mixtures, the required HRWR dosage increased from 4.2 kg/m^3 for the control mixture to 8.5 kg/m^3 for mixtures containing 1.5% GF or 1.5% SF. A similar trend was observed for the hybrid fiber systems, where most mixtures required progressively higher HRWR dosages as the total fiber content increased. The mixture containing 1.0% total fiber with a 30%GF-70%SF hybrid combination required 7.8 kg/m^3 of HRWR, whereas the corresponding 1.5% hybrid mixture required the highest dosage of 8.5 kg/m^3. Overall, these results indicate that increasing the total fiber content increased the demand for HRWR, although the required dosage was also influenced by the hybrid fiber composition.

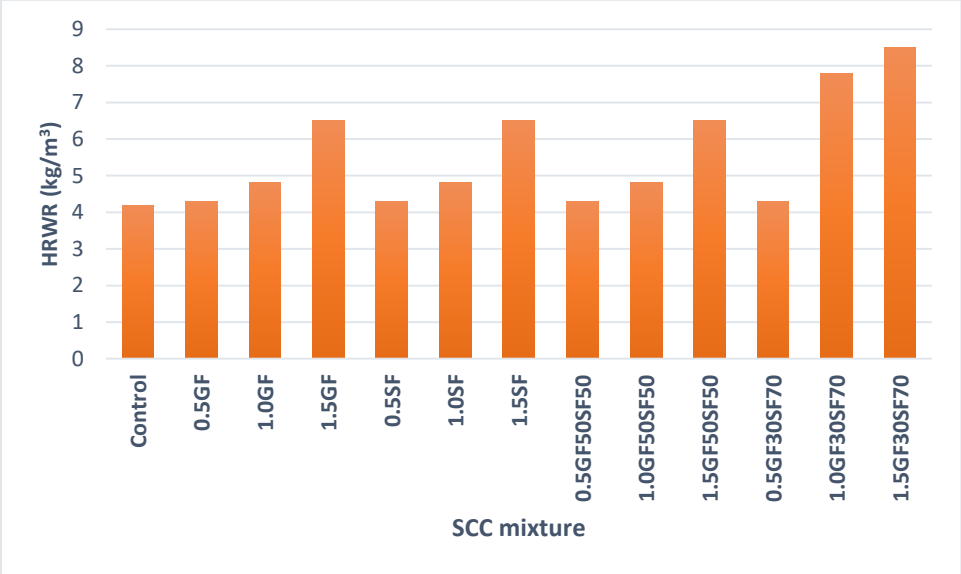

Fig. 3. Variation in the HRWR dosage required to achieve a constant slump flow of 650 ± 10 mm for different SCC mixtures.

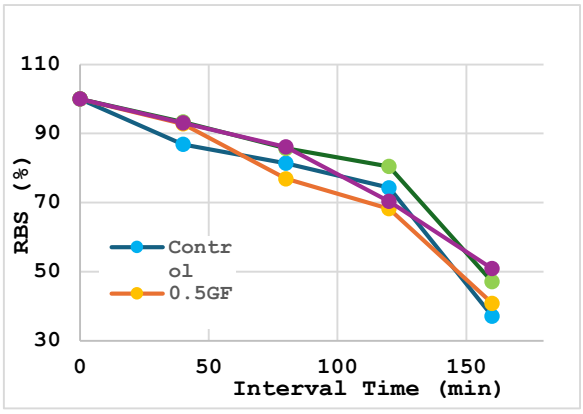
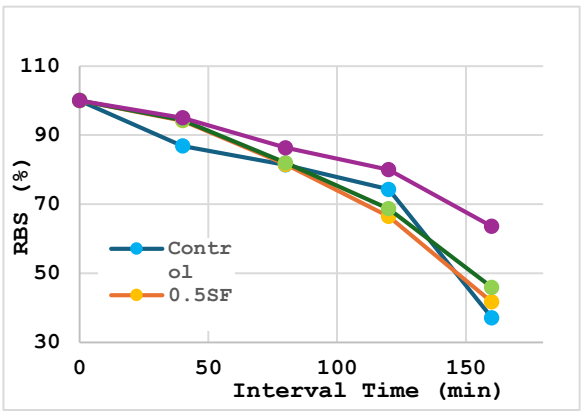
The increase in HRWR demand is mainly attributed to the larger specific surface area introduced by the fibers and the intensified fiber-fiber and fiber-aggregate interactions, which restrict the free movement of solid particles and reduce the flowability of fresh SCC. Consequently, additional superplasticizer was required to compensate for the increased internal friction and maintain the self-consolidating characteristics of the mixtures. Similar trends have been reported in previous studies, where increasing fiber dosage resulted in higher yield stress and plastic viscosity, thereby increasing the superplasticizer demand required to achieve the

desired workability [8,10]. Furthermore, previous investigations have shown that once the fiber content exceeds a critical threshold, particle interactions become more pronounced, leading to a significant deterioration in the rheological performance of fiber-reinforced SCC [8].



3.2 Effect of interval time on residual bond strength

The influence of casting interval on the residual bond strength of fiber-reinforced SCC mixtures is presented in Fig. 4(a-d). Regardless of fiber type or dosage, increasing the interval time between successive concrete layers resulted in a continuous reduction in RBS, confirming that the progressive structural build-up and early hydration of the previously placed layer significantly weaken the interlayer bond. During the resting period, the fresh SCC gradually loses its ability to remix with the subsequently placed layer, leading to a weaker interface and lower bond strength [1,2]. However, both the magnitude and rate of bond deterioration were strongly affected by the fiber reinforcement system.



For the GF-reinforced mixtures (Fig. 4(a)), the reduction in RBS was relatively limited during the first 40 min, after which bond deterioration became more pronounced, particularly beyond 120 min. Increasing the GF dosage consistently improved bond retention throughout the investigated interval range. At the longest casting interval, the mixture containing 1.5% GF retained approximately 51% of its initial bond strength, whereas the corresponding value for the control mixture was only about 37%. Although glass fibers reduced the adverse influence of prolonged casting intervals, the improvement remained relatively moderate compared with the other fiber systems.

A similar decreasing trend was observed for the steel fiber-reinforced mixtures (Fig. 4(b)); however, the beneficial effect of fiber incorporation was considerably greater. Increasing the steel fiber dosage progressively improved the residual bond strength, particularly at longer casting intervals. At 160 min, the mixture reinforced with 1.5% SF retained approximately 64% of its original bond strength, representing a substantial improvement over both the control mixture and the corresponding glass fiber mixture. These results indicate that steel fibers become increasingly effective as the interlayer region progressively weakens.

The hybrid fiber systems exhibited the highest resistance to time-dependent bond degradation (Fig. 4(c-d)). Hybrid mixtures containing equal proportions of glass and steel fibers consistently outperformed the mono-fiber mixtures, indicating a beneficial interaction between the two fiber types. A further improvement was achieved by increasing the proportion of steel fibers in the hybrid system. Among all investigated mixtures, the hybrid system incorporating 30% glass fibers and 70% steel fibers at a total fiber content of 1.5% exhibited the highest RBS throughout the investigated interval range and retained approximately 71% of its initial bond strength after 160 min. In comparison, the corresponding value for the equal-ratio hybrid mixture was approximately 66%, while the control mixture retained only about 37% of its initial bond strength.

(a)

(b)

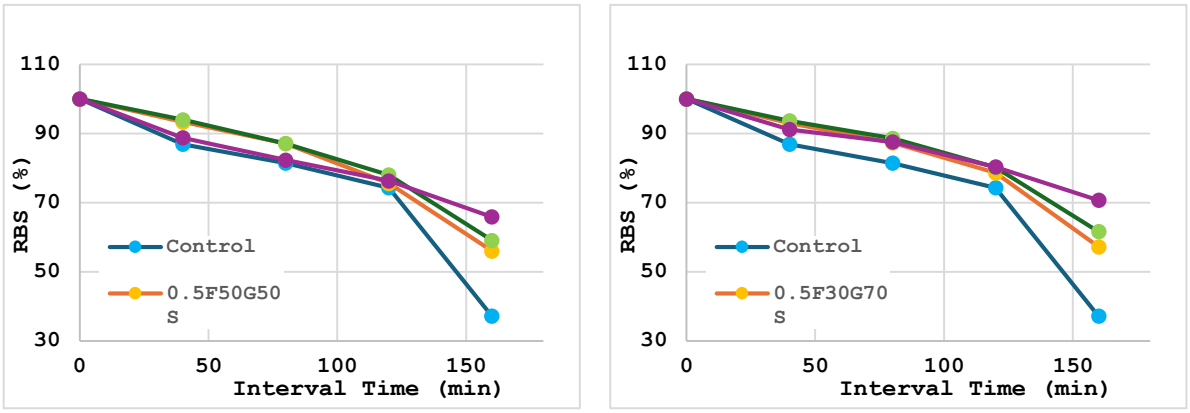


Fig. 4. Effect of casting interval on the RBS of fiber-reinforced SCC mixtures: (a) GF, (b) SF, (c) 50% GF-50% SF, and (d) 30% GF-70% SF.

Overall, the results demonstrate that although increasing the casting interval inevitably leads to interlayer bond deterioration, fiber reinforcement substantially mitigates this adverse effect. Moreover, the beneficial contribution of fibers became increasingly pronounced with increasing casting interval, indicating that fiber bridging across the developing interface plays a progressively more important role as the mechanical continuity between successive concrete layers decreases. Among the investigated reinforcement systems, the hybrid mixture containing 30% glass fibers and 70% steel fibers at a total fiber dosage of 1.5% exhibited the most effective resistance against time-dependent interlayer bond deterioration.

3.3 Effect of fiber dosage on residual bond strength

The influence of fiber dosage on the residual bond strength of SCC mixtures subjected to different casting intervals is presented in Fig. 5(a-d). For all fiber systems, increasing the fiber dosage resulted in higher residual bond strength, although the magnitude of improvement depended strongly on the casting interval. At short placement intervals (0-80 min), increasing the fiber content produced only moderate improvements because the interface remained relatively fresh and sufficient mechanical continuity already existed between successive layers. In contrast, the beneficial effect of fiber incorporation became considerably more pronounced at longer casting intervals, particularly after 160 min, where the interlayer bond had significantly deteriorated.

For the glass fiber mixtures (Fig. 5(a)), increasing the fiber dosage from 0.5% to 1.5% produced a gradual increase in RBS at all casting intervals. The improvement was relatively limited at 0 min, where the normalized bond strength increased from approximately 114% to 118%, but became substantially greater after prolonged delays. At 160 min, increasing the glass fiber content from 0.5% to 1.5% increased the normalized bond strength from approximately 125% to 162%, demonstrating that higher glass fiber contents are more effective in maintaining bond integrity after extended resting periods. A similar but more pronounced trend was observed for the steel fiber mixtures (Fig. 5(b)). Increasing the steel fiber dosage consistently enhanced the residual bond strength at all casting intervals, with the greatest improvement again occurring after 160 min. At this interval, the normalized RBS increased from approximately 126% for the mixture containing 0.5% SF to nearly 206% for the mixture incorporating 1.5% SF, indicating that steel fibers provided more efficient crack bridging and stress transfer across the weakened interface than glass fibers. The hybrid fiber systems exhibited the greatest sensitivity to fiber dosage (Fig. 5(c-d)). For the equal-ratio hybrid mixtures (50% GF-50% SF), increasing the total fiber dosage resulted in a continuous increase in RBS, particularly at the longest casting interval, where the normalized bond strength reached approximately 241% for the mixture containing 1.5% total fibers.

An even greater improvement was obtained by increasing the proportion of steel fibers to 70% (Fig. 5(d)). Under this configuration, the normalized RBS increased from approximately 193% at 0.5% fiber content to nearly 259% at 1.5% fiber content after 160 min, representing the highest bond enhancement among all investigated mixtures.

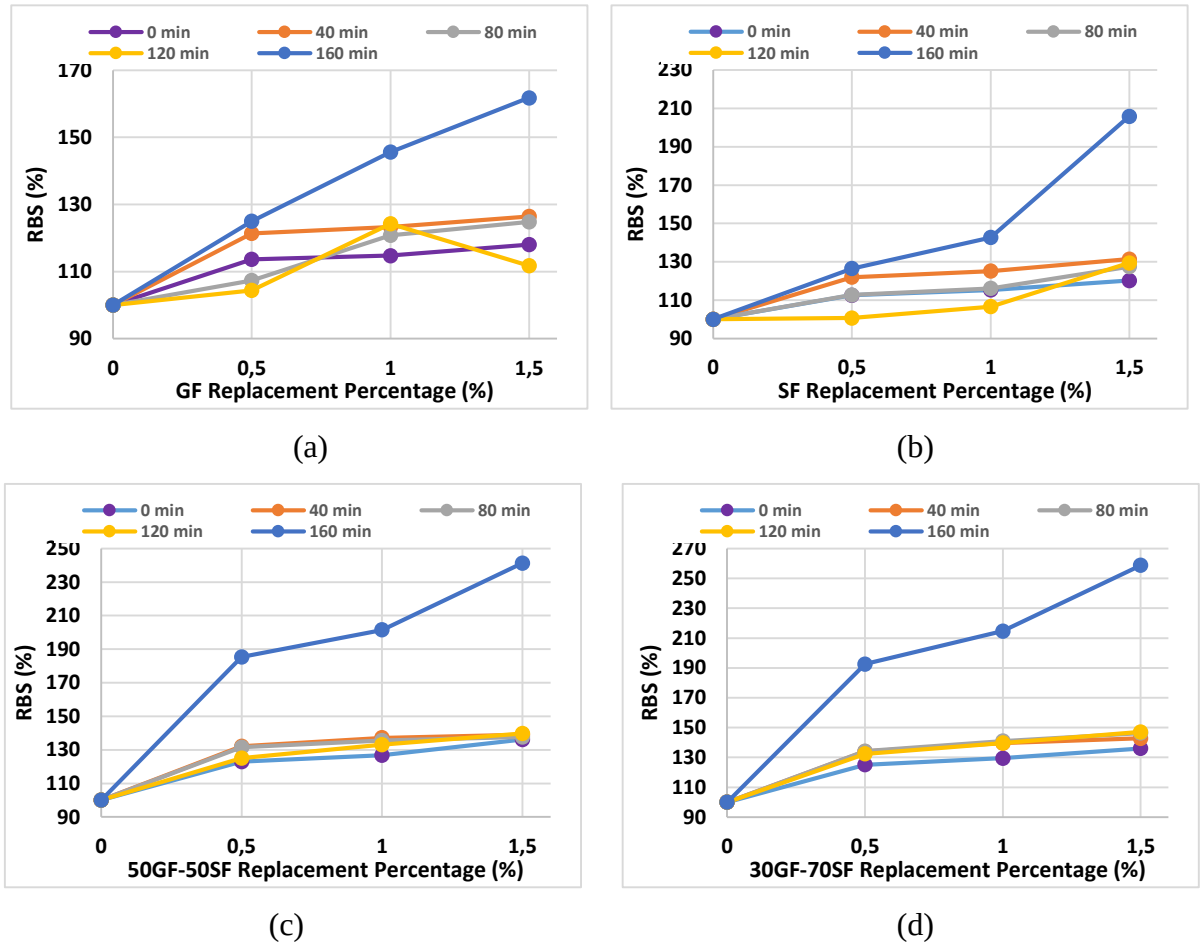

Fig. 5. Influence of fiber dosage on the RBS of SCC mixtures under different casting intervals: (a) GF, (b) SF, (c) 50% GF-50% SF, and (d) 30% GF-70% SF.

These results demonstrate that the effectiveness of fiber dosage depends strongly on the condition of the interlayer interface. When the casting interval was short, increasing the fiber content produced only modest improvements because bond formation was primarily governed by the fresh-state cohesion between adjacent layers. However, as the casting interval increased and the interface progressively weakened, the contribution of fibers became increasingly dominant. Consequently, mixtures incorporating higher fiber dosages, particularly the hybrid system containing 30% glass fibers and 70% steel fibers, exhibited the greatest resistance to interlayer bond deterioration under prolonged casting delays.

4 Conclusions

This study experimentally evaluated the influence of fiber type, fiber dosage, and casting interval on the interlayer bond performance of multilayer SCC using direct shear tests. Based on the obtained results, the following conclusions can be drawn:

- Increasing the fiber dosage increased the demand for HRWR required to maintain the target slump flow of 650 ± 10 mm. This increase was primarily attributed to the greater

specific surface area of the fibers and the intensified fiber-fiber and fiber-aggregate interactions, which reduced the flowability of fresh SCC.

- Increasing the casting interval progressively reduced the RBS of all SCC mixtures owing to the time-dependent structural build-up and reduced intermixing between successive concrete layers. The deterioration became particularly pronounced after 120 min.
- Incorporating fibers effectively mitigated the loss of interlayer bond strength, with the beneficial effect becoming increasingly significant as the casting interval increased.
- Among the mono-fiber systems, steel fibers provided greater improvements in residual bond strength than glass fibers, especially at prolonged casting intervals. At 160 min, mixtures containing 1.5% steel fibers maintained approximately 64% of their initial bond strength, whereas the corresponding value for 1.5% glass fibers was approximately 51%.
- Hybrid fiber reinforcement exhibited a clear synergistic effect. The hybrid system containing equal proportions of glass and steel fibers improved the interlayer bond more effectively than the mono-fiber mixtures, while increasing the steel fiber proportion to 70% produced the highest bond performance.
- The hybrid mixture incorporating 30% glass fibers and 70% steel fibers at a total fiber dosage of 1.5% demonstrated the best overall performance, maintaining approximately 71% of its initial bond strength after a casting interval of 160 min.
- The results demonstrate that optimizing both the fiber dosage and hybrid fiber composition is an effective strategy for reducing time-dependent interlayer bond deterioration in multilayer SCC, thereby improving the reliability of concrete elements constructed using delayed sequential casting.

Acknowledgments

The authors wish to express their sincere appreciation to Çimsa Çimento Sanayi ve Ticaret A.Ş. for its valuable support of this research. The authors also extend their special thanks to Mr. Serhat Sarıkaya, Turkey Sales Manager at Çimsa Çimento Sanayi ve Ticaret A.Ş., for his continuous support, kind cooperation, and valuable assistance throughout the course of this study.

Abstract. The effectiveness of nano-silica in cementitious composites depends not only on its dosage but also on its physical form and dispersion within the matrix. This study experimentally investigates the effects of powder (pNS) and colloidal nano-silica (cNS) on the workability and mechanical performance of cement mortars. Mixtures containing 0, 1, 1.5, 2, 2.5, and 3% nano-silica by weight of binder were produced under comparable mixture proportions and curing conditions. The pNS was dispersed in mixing water using mechanical stirring followed by ultrasonic homogenization, whereas cNS was directly incorporated by accounting for its water content while maintaining the same water-to-binder ratio. Compressive and flexural strengths were evaluated at 7 and 28 days, together with fresh-state flow measurements. The pNS mixtures generally exhibited improved mechanical performance with increasing dosage, reaching maximum 28-day compressive and flexural strengths of 80.4 and 11.74 MPa, respectively, at 3% pNS. In contrast, cNS exhibited its highest performance at approximately 1%, reaching 68.3 MPa compressive strength and 10.55 MPa flexural strength at 28 days, while higher dosages resulted in reduced strengths. Moreover, cNS mixtures exhibited a lower average flow (160 ± 10 mm) than pNS mixtures (200 ± 10 mm). These findings demonstrate that the physical form and particle characteristics of nano-silica significantly influence both fresh-state and hardened performance and should be considered when determining the optimum nano-silica dosage.

Keywords: Colloidal nano-silica; Powder nano-silica; Slump flow.

1 Introduction

Cement-based materials are the most widely used construction materials owing to their versatility, availability, and relatively low production cost. However, conventional cementitious composites often exhibit limitations in terms of mechanical performance, durability, and fresh-state workability. Consequently, considerable research has focused on the incorporation of nano-scale additives to enhance both the fresh and hardened properties of cement-based materials [1–4].

Among the various nano-materials investigated, nano-silica has received significant attention because of its exceptionally high specific surface area, amorphous structure, and high pozzolanic reactivity. Nano-silica accelerates cement hydration, promotes the formation of additional calcium silicate hydrate (C–S–H) gel, and refines the pore structure through both nucleation and nano-filler effects. These mechanisms have been reported to enhance compressive strength, flexural strength, durability, and the interfacial transition zone (ITZ) in cementitious composites [2–6]. Despite these advantages, the effectiveness of nano-silica depends not only on its dosage but also on its particle size, physical form, and dispersion quality within the cementitious matrix. Due to their high surface energy, nano-sized particles tend to

agglomerate during mixing, which may considerably reduce their beneficial effects. Therefore, several dispersion techniques, including ultrasonic homogenization, have been proposed to improve particle distribution and maximize the effectiveness of nano-silica [5–8].
Commercial nano-silica is generally available in two different forms, namely powder and colloidal suspensions. Although both forms have been individually investigated, direct experimental comparisons under identical mixture proportions and curing conditions remain relatively limited [7–10]. Furthermore, the influence of nano-silica's physical form on both fresh-state workability and mechanical performance has not yet been fully clarified.
Therefore, the present study experimentally investigates the effects of pNS and cNS on the fresh-state and mechanical properties of cement mortar mixtures. pNS was dispersed using a combination of magnetic stirring and ultrasonic homogenization before mixing, whereas cNS mixtures were prepared by maintaining identical mixture proportions and adjusting the effective mixing water according to the suspension's solid content. The findings are expected to contribute to the optimization of nano-silica incorporation in cementitious composites and provide a foundation for future studies on extrusion-based cementitious materials and three-dimensional concrete printing applications.

2 Experimental Program

2.1 Materials

CEM II/A-M(S-L) 42.5 R cement with a specific gravity of 3.11 g/cm³ was used as the primary binder in this study. throughout the experimental program. Natural silica sand with a maximum particle size of 2 mm and a specific gravity of 2.64 g/cm³ was used as the fine aggregate. A modified polycarboxylic ether (PCE)-based high-range water-reducing admixture (Sika ViscoCrete GL 51) was incorporated to obtain the desired workability while maintaining a constant water-to-binder ratio.

pNS with an amorphous structure, a purity greater than 98.5%, and a particle size ranging between 55 and 75 nm was employed in the first stage of the study. Prior to mixing, the pNS was dispersed in mixing water using magnetic stirring followed by ultrasonic homogenization to minimize particle agglomeration and improve particle distribution within the cementitious matrix. In the second stage, cNS, obtained from the same manufacturer as pNS, with a particle size of 8–33 nm and a solid content of 26 wt.%, was utilized to investigate the influence of nano-silica physical form. The amount of colloidal suspension was calculated based on the required solid nano-silica content, and the water introduced by the suspension was deducted from the total mixing water to maintain a constant water-to-binder ratio in all mixtures. Physical properties of the materials are given in Table 1.

Table 1. Physical properties of the materials.

Material	**Specification**
Binder	CEM II/A-M(S-L) 42.5 R, 3.11 g/cm^3
Fine aggregate	Natural Silica Sand (0-2mm), 2.64 g/cm^3*
Superplasticizer	Modified Polycarboxylic ether based, 1.1 g/cm^3*
pNS	55–75 nm, amorphous, 2.4 g/cm^3*
cNS	8–33 nm, amorphous, 26 wt.% solids, 2.4 g/cm^3*

*: Values declared by the manufacturer.

2.2 Mixture Proportions

Two experimental programs were conducted in this study. The first program investigated the influence of pNS, whereas the second focused on cNS. Six different mixtures containing 0, 1, 1.5, 2, 2.5 and 3% nano-silica (by binder weight) were prepared for each experimental program. Nano-silica was added to the mixture directly, in an amount equal to the cement percentage, rather than substituting it.

To ensure a meaningful comparison, identical binder content, sand-to-binder ratio, water-to-binder ratio and superplasticizer dosage were adopted for both pNS and cNS mixtures. The superplasticizer amount is increased with increasing the nano-silica amount to obtain a 200±10 mm flow value for all of the pNS mixtures. After that, the superplasticizer amounts used for pNS mixtures remained the same for the cNS mixtures to prevent the effect of superplasticizer on the mechanical properties. In the colloidal mixtures, only the physical form of nano-silica was altered. The additional water contained in the colloidal suspension was deducted from the mixing water to preserve a constant water-to-binder ratio throughout the study. Mix proportions of the pNS and cNS mixtures are given in Table 2.

Table 2. Mix proportions of pNS and cNS mixtures by binder weight.

	pNS0/ cNS0	**pNS1/ cNS1**	**pNS1.5/ cNS1.5**	**pNS2/ cNS2**	**pNS2.5/ cNS2.5**	**pNS3/ cNS3**
Cement	1					
Sand	1.50					
Water	0.45					
Superplasticizer, %	0.6	0.9	1.0	1.3	1.4	1.6
Nano-silica, %	0	1.0	1.5	2.0	2.5	3.0

2.3 Specimen Preparation and Test Methods

To improve the dispersion of pNS within the cementitious matrix, the nanoparticles were first dispersed in approximately two-thirds of the mixing water containing the required amount of superplasticizer using magnetic stirring, followed by ultrasonic homogenization for 10 min. The remaining mixing water was then mixed with cement before incorporating the nano-silica suspension into the mortar mixture.

After the mixing procedure was completed, a flow table test was performed according to TS EN 1015-3. After determining the flow value, the mortar was mixed at low speed for an additional 30 s and then placed into molds. During the molding process, the mortar was first placed up to half the mold height, and the mold was dropped 60 times on a jolting table. The same procedure was repeated after filling the remaining half of the mold. A total of six prismatic specimens (40 × 40 × 160 mm) were cast in accordance with TS EN 196-1 and demolded after 24 h. Subsequently, the specimens were cured in lime-saturated water until the testing ages of 7 and 28 days. Figure 1 illustrates the preparation procedure of the mortar specimens, including fresh-state flow measurement, casting into prism molds, and curing in a water tank.

For the cNS mixtures, identical mixture proportions, water-to-binder ratio, and superplasticizer dosage were maintained to enable a direct comparison between pNS and cNS. This procedure ensured that any observed differences originated primarily from the physical characteristics of nano-silica rather than variations in mixture composition.

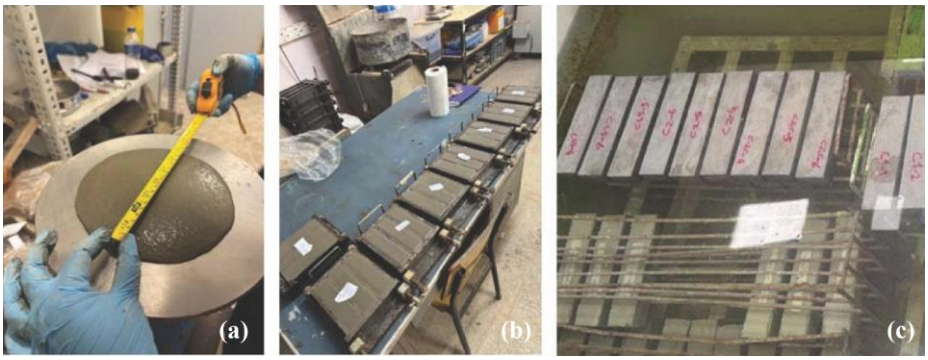

Fig. 1. Preparation of nano-silica mortar mixtures: (a) slump flow measurement, (b) casting of mortar specimens, and (c) water curing of prism specimens.

3 Results and Discussion

3.1 Fresh-State Properties

Figure 2 presents the slump flow results of the pNS and cNS mixtures. For the pNS series, the dosage of the superplasticizer was adjusted to maintain a nearly constant slump flow of approximately 200 ± 10 mm, regardless of the nano-silica dosage. This approach enabled the mechanical performance of the different mixtures to be compared under similar fresh-state workability conditions.

In contrast, the colloidal nano-silica mixtures exhibited an average slump flow of approximately 160 ± 10 mm, although identical mixture proportions, water-to-binder ratio, and superplasticizer dosages were employed. The reduced workability of the cNS mixtures may be associated with their smaller particle size (8–33 nm) and consequently higher specific surface area compared with the powder form (55–75 nm). The higher surface area of finer nano-silica particles can increase water demand and particle interactions within the fresh cementitious matrix, thereby reducing flowability. Similar reductions in workability and changes in the rheological behavior of nano-silica-modified cementitious materials have been reported in previous studies [2,15]. These preliminary findings indicate that the physical form and particle size of nano-silica may significantly influence the fresh-state behavior of cementitious composites even when identical mixture proportions are maintained.

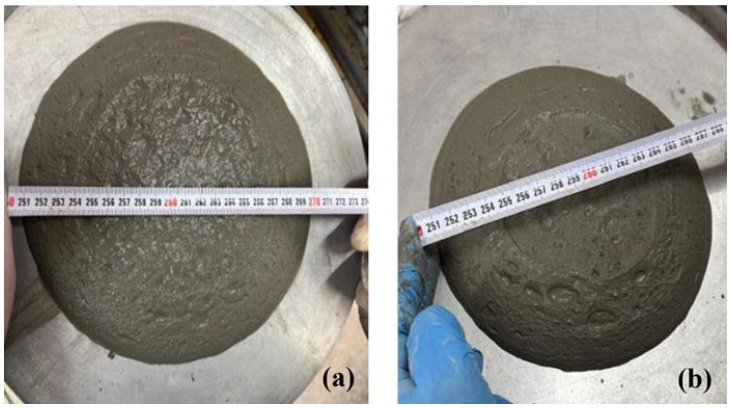

Fig. 2. Slump flow comparison of pNS (a), and cNS (b) mixtures for same mix design.

3.2 Mechanical Properties

Flexural Strength. Prior to compressive strength testing, prism specimens were subjected to three-point bending under displacement control at a loading rate of 0.2 mm/min, as illustrated in Figure 3. The flexural strength results of the pNS and cNS mixtures after 7 and 28 days of curing are presented in Figure 4 and Figure 5.

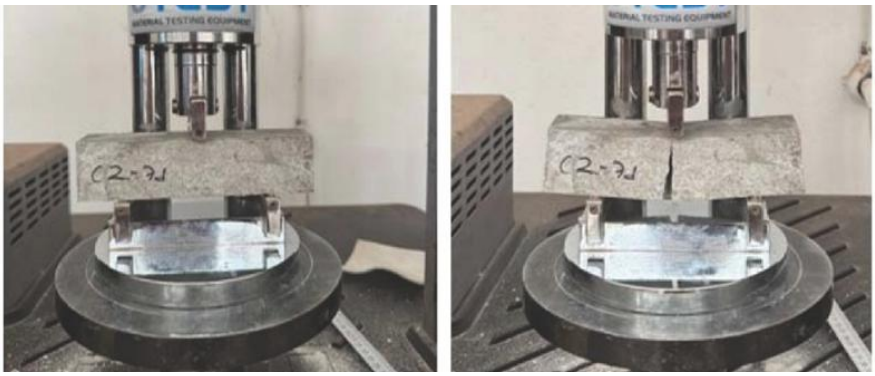

Fig. 3. Flexural test set-up.

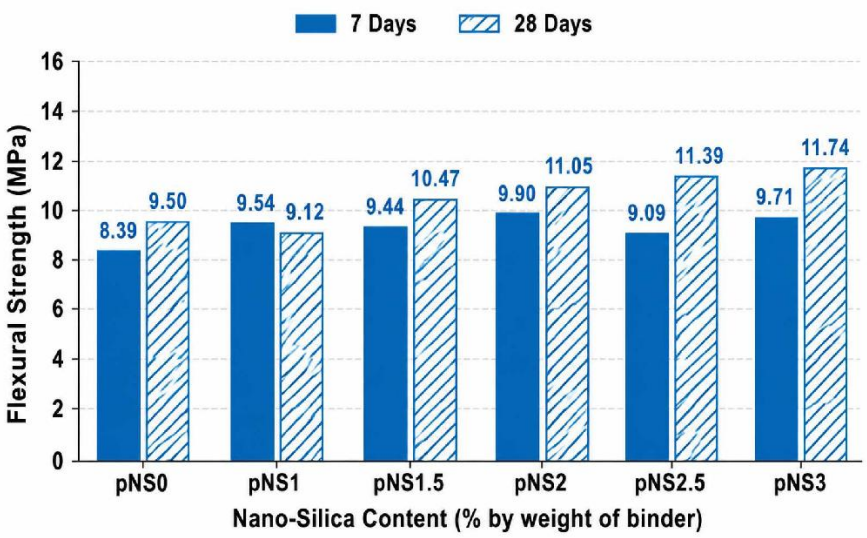

Fig. 4. Flexural strength of pNS mortar mixtures after 7 and 28 days of curing.

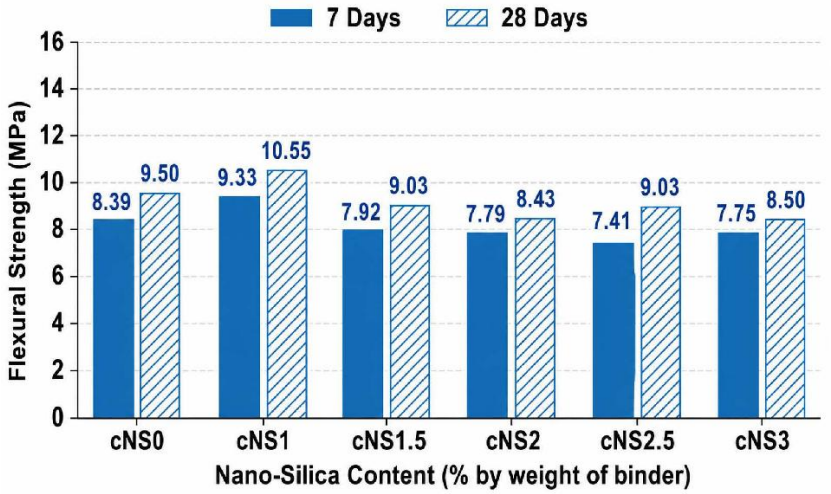

Fig. 5. Flexural strength of cNS mortar mixtures after 7 and 28 days of curing.

For the pNS mixtures, flexural strength generally increased with increasing nano-silica content, particularly after 28 days of curing. The highest flexural strength was obtained for the mixture containing 3% pNS, reaching 11.74 MPa at 28 days. This improvement is consistent with previous studies reporting that nano-silica incorporation can enhance the mechanical

performance of cementitious materials through matrix densification and pore-structurerefinement [2,4].

3.2.1 Compressive Strength

Figures 6-8 present the compressive strength testing and results of the pNS and cNS mixtures after 7 and 28 days of curing, respectively.

The pNS mixtures exhibited a continuous improvement in compressive strength with increasing nano-silica content, particularly after 28 days of curing. Compared with the reference mixture, the beneficial effect of pNS became more pronounced at later curing ages, indicating that the pozzolanic activity and nano-filler effect continued to contribute to cement hydration. Within the investigated dosage range, the highest compressive strength was obtained for the mixture containing 3% pNS, reaching 80.4 MPa after 28 days of curing.

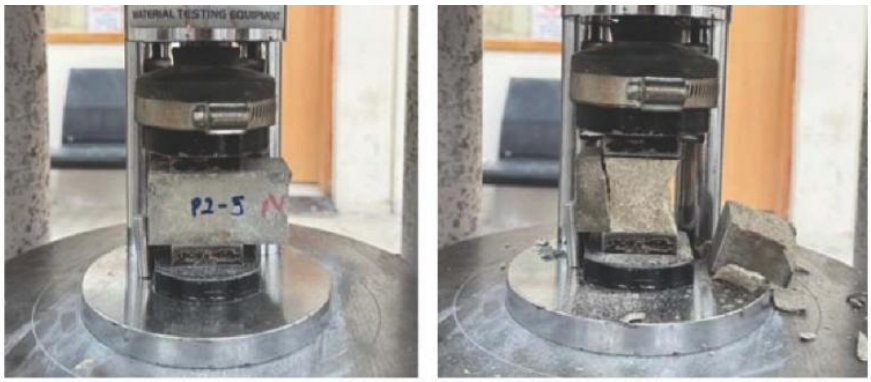

Fig. 6. Compressive test set-up.

In contrast, the cNS mixtures exhibited a different strength development trend. While the incorporation of 1% cNS resulted in the highest compressive strength among the colloidal mixtures (68.3 MPa at 28 days), further increases in nano-silica dosage led to a noticeable reduction in compressive strength. This behavior indicates that the optimum nano-silica dosage depends not only on the replacement level but also on the physical characteristics of the nano-silica employed.

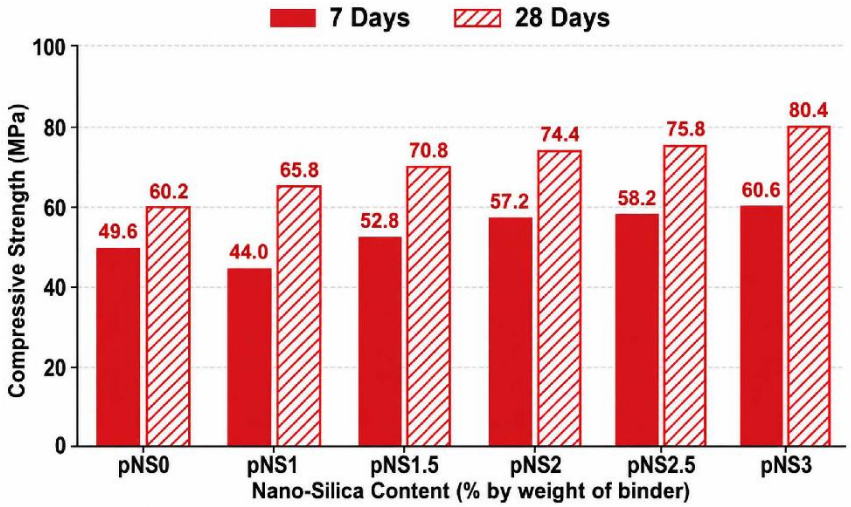

Fig. 7. Compressive strength of pNS mortar mixtures after 7 and 28 days of curing.

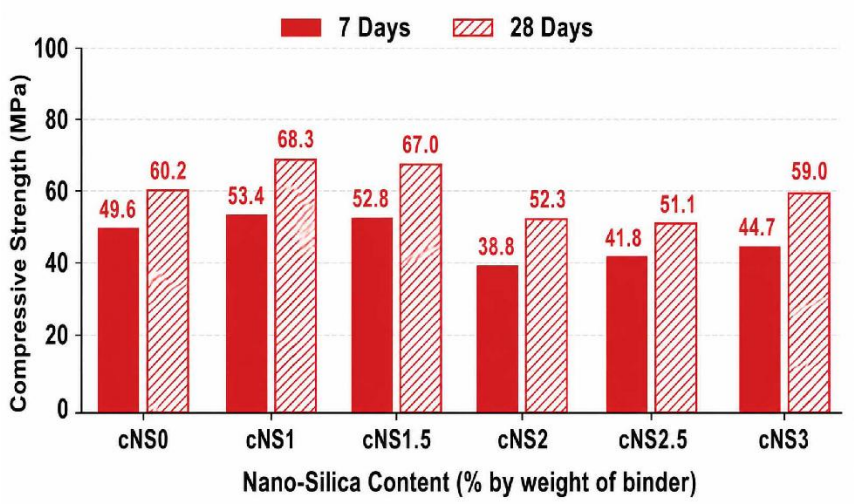

Fig. 8. Compressive strength of cNS mortar mixtures after 7 and 28 days of curing.

Overall, the pNS mixtures demonstrated superior compressive performance at higher nano-silica contents compared with the colloidal mixtures. The different strength development observed between the two nano-silica forms is likely associated with differences in particle size, specific surface area, and their interaction with the cementitious matrix. Detailed microstructural analyses using SEM and XRD will be performed in the subsequent stage of this study to further explain the observed mechanical behavior.

3.3 Comparison of Powder and Colloidal Nano-Silica

The results obtained in this study demonstrate that the physical form of nano-silica plays an important role in determining both the fresh-state and hardened properties of cementitious composites. Although identical mixture proportions, water-to-binder ratio, and superplasticizer dosages were adopted for both experimental series, the two nano-silica forms exhibited noticeably different mechanical responses.

The pNS mixtures showed a progressive improvement in mechanical performance with increasing nano-silica content, particularly at 28 days. The highest 28-day compressive strength was obtained with 3% pNS (80.4 MPa), corresponding to an increase of approximately 33.7% compared with the control mixture (60.2 MPa). The same mixture exhibited an increase of approximately 32.7% from 7 to 28 days. In contrast, the highest compressive strength within the cNS series was obtained with 1% cNS (68.3 MPa at 28 days), representing an improvement of approximately 13.5% over the control. The maximum 28-day compressive strength obtained with pNS was approximately 17.8% higher than the maximum value obtained with cNS.

A similar distinction was observed in flexural performance. The highest 28-day flexural strength of the pNS series was 11.74 MPa at 3% pNS, whereas the highest value for the cNS series was 10.55 MPa at 1% cNS. These results indicate that the optimum dosage and resulting mechanical performance depend on the form and characteristics of the nano-silica.

Furthermore, the cNS mixtures produced a lower average slump flow (160 ± 10 mm) than the pNS mixtures (200 ± 10 mm) despite identical mixture proportions. This difference may be associated with the different physical characteristics of the two nano-silica products, including their particle-size ranges (8–33 nm for cNS and 55–75 nm for pNS), which can influence particle interactions and water demand within the fresh cementitious matrix. Further microstructural investigations are expected to provide additional insight into the mechanisms responsible for the observed differences.

4 Conclusions

The effects of powder and colloidal nano-silica on the fresh-state behavior and mechanical performance of cement mortar mixtures were experimentally investigated. Based on the findings of this study, the following conclusions can be drawn:

- The incorporation of pNS improved both compressive and flexural strengths, particularly after 28 days of curing. The highest mechanical performance was achieved with 3% pNS, reaching 80.4 MPa in compressive strength and 11.74 MPa in flexural strength at 28 days. The 28-day compressive strength was approximately 33.7% higher than that of the control mixture, confirming the beneficial contribution of nano-silica to the mechanical performance of cementitious materials [2,4,11].
- The cNS mixtures exhibited a different mechanical response, with the highest performance generally observed at approximately 1% cNS. At this dosage, the 28-day compressive strength reached 68.3 MPa, corresponding to an increase of approximately 13.5% compared with the control mixture. Higher cNS dosages resulted in reduced mechanical performance, indicating that the optimum nano-silica dosage depends on its physical form and interaction with the cementitious matrix [9,12].
- Comparison of the two nano-silica forms revealed that the maximum 28-day compressive strength obtained with pNS was approximately 17.8% higher than the maximum value obtained with cNS. Similarly, the highest 28-day flexural strengths were 11.74 MPa for pNS and 10.55 MPa for cNS, further demonstrating the different mechanical responses of the two nano-silica forms.
- Despite identical mixture proportions, water-to-binder ratio, and superplasticizer dosage, the cNS mixtures exhibited a lower average slump flow (160 ± 10 mm) than the pNS mixtures (200 ± 10 mm). This difference indicates that the physical characteristics of nano-silica can considerably influence the fresh-state behavior of cementitious composites [3,6,13].
- Overall, pNS exhibited a more consistent improvement in mechanical performance with increasing dosage within the investigated range, whereas cNS showed greater sensitivity to dosage variation. These findings highlight the importance of considering the physical form and characteristics of nano-silica when determining its optimum incorporation level.

Further investigations involving SEM and XRD analyses are underway to better understand the relationship between nano-silica characteristics, hydration products, and the observed mechanical behavior. The optimized mixtures identified in this study will also provide a basis for future investigations involving extrusion-based cementitious materials and three-dimensional concrete printing applications [8,14,15].

Abstract. The combined influence of curing regime and mold release agent on the strength development of concretes incorporating ground granulated blast-furnace slag (GGBFS) remains insufficiently understood. This study evaluates the compressive and splitting tensile strength of plain and GGBFS-blended concretes belonging to two strength classes (C25/30 and C40/50) under continuous water curing and intermittent sprinkler curing. Two mold release agents, a conventional mineral-oil-based product and a paraffin-containing non-ionic product, were also investigated. The results showed that GGBFS incorporation reduced early-age strength but enhanced later-age strength development, leading to comparable or higher 28-day strengths than the corresponding plain mixtures. The effectiveness of the curing regime depended on both concrete class and binder composition. While intermittent sprinkler curing generally lowered early-age strength, its effect on 28-day performance was limited and, in several slag-containing mixtures, comparable to that of continuous water curing. The type of mold release agent had no systematic influence on either compressive or splitting tensile strength. Overall, binder composition and curing conditions were found to govern strength development to a much greater extent than mold surface treatment. The findings highlight the importance of considering the interaction between binder type and curing practice when optimizing the mechanical performance of plain and slag-blended concretes.

Keywords: Ground granulated blast-furnace slag (GGBFS); curing regime; sprinkler curing; mold release agent; compressive strength; splitting tensile strength.

1 Introduction

Curing is the process of maintaining adequate moisture and temperature conditions in concrete for a sufficient period after casting to allow cement hydration to proceed to the extent required by design. It is well established that inadequate or interrupted curing reduces the degree of hydration and leads to a coarser and more interconnected pore structure, adversely affecting strength, permeability, and durability. Rahal [1] reported reductions of up to 39% in compressive strength for concrete exposed to unfavorable curing conditions compared with laboratory-cured specimens.

The response of concrete to curing conditions depends strongly on binder composition. Ground granulated blast-furnace slag (GGBFS) contributes to hydration through a latent

hydraulic mechanism and generally exhibits slower early-age reactivity than Portland cement. Consequently, the development of mechanical properties in slag-containing systems is highly dependent on sustained moisture availability. Previous studies have shown that insufficient curing may significantly reduce the later-age performance of GGBFS concretes, with the severity of the effect increasing as the slag replacement level increases [2-5].

Another factor that may influence concrete performance is the type of mold release agent applied to the formwork surface. Conventional mineral-oil-based products and non-ionic paraffin-based release agents differ in their wetting characteristics and interfacial behavior. Djelal et al. [6] reported that certain mineral-oil-based formulations may interact with the alkaline pore solution of fresh concrete, whereas non-ionic release agents are generally considered chemically inert and function primarily as physical separation layers. Similarly, Abbas et al. [7] described modern non-ionic emulsion-based release agents as materials designed to improve demolding efficiency and surface quality without participating in cement hydration reactions. Despite these observations, limited information is available regarding their performance under interrupted curing conditions.

Although the individual effects of curing conditions, binder composition, and mold release agent characteristics have been widely investigated, their combined influence on the mechanical performance of concretes with different strength classes remains insufficiently understood. Therefore, the present study evaluates two concrete classes (C25/30 and C40/50), two binder systems (plain Portland cement and GGBFS-blended concrete), two curing regimes (water curing and intermittent sprinkler curing), and two mold release agents (conventional mineral-oil-based and paraffin-containing non-ionic formulations) within a unified experimental program. The study aims to clarify the interaction between binder composition and curing regime while also assessing whether mold release agent type influences the mechanical performance of concretes with different strength classes and binder systems.

2 Materials and Experimental Programme

2.1 Cement and Slag Characterization

A CEM I 42.5 R Portland cement and a ground granulated blast-furnace slag (GGBFS) were used as binder materials. Characterization tests confirmed compliance with TS EN 197-1 and TS EN 15167-1 requirements, respectively. The GGBFS exhibited a higher fineness than the cement. The chemical, physical and mechanical properties of both materials are presented in Table 1.

Table 1. Chemical and physical properties of the CEM I 42.5 R cement and the GGBFS.

Parameter	CEM I 42.5 R	Standard limit	GGBFS	EN 15167-1 limit
SiO_2 (%)	18.69	–	40.93	–
Al_2O_3 (%)	4.92	–	10.84	–
Fe_2O_3 (%)	3.28	–	1.17	–
CaO (%)	62.76	–	36.85	–
MgO (%)	0.97	–	6.73	≤ 18

2.2 Mixture Proportions

Four concrete mixtures, representing two strength classes (C25/30 and C40/50) and two binder systems (plain Portland cement and GGBFS-blended cement), were designed for the experimental programme. To minimize the influence of variables other than binder composition and strength level, the aggregate grading and chemical admixture type were kept constant across the mixtures. The complete mixture proportions are given in Table 2.

Table 2. Mixture proportions (kg/m^3) (P = plain, S = slag-blended).

Constituent (kg/m^3)	C25-P	C25-S	C40-P	C40-S
CEM I 42.5 R	270	210	370	310
GGBFS	0	75	0	75
GGBFS / binder (%)	0	26.3	0	19.5
Water	162	162	155.4	155.4
Superplasticizer	(0.94%)	(0.85%)	(1.0%)	(1.0%)
Fine aggregate (0–4 mm)	469	465	452	448
Coarse aggregate #1 (4–11.2 mm)	455	451	457	453
Coarse aggregate #2 (11.2–22.4 mm)	538	533	499	494
Natural sand	501	496	482	478

2.3 Curing Regimes and Mold Release Agents

After demolding at 24 h, the 100 × 100 × 100 mm cube specimens were subjected to the designated curing regimes and maintained under the respective curing conditions until the relevant testing age. The curing program comprised two methods: continuous water curing at 20 ± 2 °C and intermittent sprinkler curing. Under the intermittent curing regime, specimens were exposed to ambient laboratory conditions and wetted by water spraying for 2 min at 10 min intervals throughout the curing period. Furthermore, to investigate the potential influence of mold release agent characteristics on concrete performance, two commercially available release agents were used during casting: a conventional mineral oil-based mold release agent and a paraffin-containing non-ionic mold release agent.

2.4 Testing Methods

Slump was measured on each fresh batch in accordance with TS EN 12350-2. Compressive strength was determined at 2, 7 and 28 days, and splitting tensile strength at 28 days, each as the mean of three specimens, in accordance with TS EN 12390-3 and TS EN 12390-6, respectively.

3 Results

3.1 Fresh Properties

Slump was maintained at 23.0 ± 1 cm across all sixteen batches, confirming that workability was successfully equalized between the plain and slag-blended mixtures and was not a confounding variable in the strength comparisons that follow. Superplasticizer demand, expressed as a percentage of binder mass, was slightly lower for the slag-blended mixtures than for their plain counterparts within each strength class (0.85% vs 0.94% for the C25 series; 0.96% vs 1.00% for the C40 series), consistent with the smoother particle morphology and higher fineness of the ground slag improving paste rheology at equal or lower free water content.

3.2 Compressive and Splitting Tensile Strength Development

Table 3 presents the full compressive and splitting tensile strength results for the eight mixture/mold-agent combinations under standard (continuous water immersion) curing, and Table 4 the equivalent results under intermittent sprinkler curing.

Table 3. Fresh and hardened properties – standard curing.

Mixture	Mold agent	Slump (cm)	SP (%)	$f_{c,2d}$ (MPa)	$f_{c,7d}$ (MPa)	$f_{c,28d}$ (MPa)	$f_{sp,28d}$ (MPa)
C25-P (plain)	Conventional	22.0	0.94	22.9	28.8	32.8	2.63
C25-P (plain)	Paraffin	22.0	0.94	22.0	29.5	33.3	2.53
C25-S (slag)	Conventional	22.5	0.85	15.2	24.0	35.6	2.73

C40-S (slag)	Paraffin	23.0	0.96	32.0	46.1	58.7	3.33

Regardless of the curing regime, slag replacement led to lower early-age compressive strength, with the reduction being more pronounced in the C25 mixtures than in the C40 mixtures. Under

standard curing, the strength reduction ranged from 28.5% to 33.7% in the C25 mixtures and from 14.0% to 14.8% in the C40 mixtures. Similar reductions were observed under sprinkler curing, corresponding to 20.9–31.4% and 10.3–11.6% for the C25 and C40 series, respectively. At 28 days, the slag mixtures exhibited comparable or higher strengths than the corresponding plain mixtures. Under standard curing, the 28-day compressive strength increased by 8.1–8.5% in the C25 series, whereas the differences in the C40 series remained within ±2%. Under sprinkler curing, the beneficial effect of slag became more pronounced, with strength gains of 4.8–7.3% for the C25 mixtures and 9.9–15.7% for the C40 mixtures relative to their plain counterparts.

The influence of mold release agent type on compressive strength was generally limited. Nevertheless, the paraffin-containing non-ionic release agent tended to provide slightly higher 28-day strengths, particularly in the slag-containing C40 mixtures subjected to sprinkler curing, where the highest compressive strength of the study (58.7 MPa) was achieved. Overall, curing condition and binder composition had a much greater effect on strength development than the mold release agent type.

The 28-day splitting tensile strength results indicate that slag incorporation had a generally positive effect on tensile performance. Under standard curing, tensile strength increased by up to 7.9% and 9.8% in the C25 and C40 series, respectively, while under sprinkler curing the highest improvement reached 8.8% in the C40 mixtures. In contrast, the effect of mold release agent type remained relatively minor, with only small differences observed between the conventional and paraffin-containing non-ionic products.

4 Discussion

The observed strength development confirms the well-established influence of GGBFS on hydration kinetics and microstructural evolution. The slower early-age performance of the slag-containing mixtures can be attributed to the lower clinker content and the delayed hydraulic reactivity of slag compared with ordinary Portland cement [3, 5, 8]. As hydration progresses, the contribution of slag becomes increasingly significant due to the continued formation of secondary C-S-H gel and the refinement of pore structure. This process promotes matrix densification and enhances long-term mechanical performance [4, 9].

The findings further indicate that the effectiveness of GGBFS depends strongly on curing conditions. Previous studies have shown that supplementary cementitious materials require sufficient moisture availability to sustain hydration and achieve their full performance potential [3, 5]. In the present study, the intermittent sprinkler regime appears to have provided adequate moisture for continued hydration. Similar conclusions were reported by Wang et al. [10], who demonstrated that curing regime substantially affects strength development and microstructural quality, and by Guo et al. [11], who observed that moisture-retaining curing systems can effectively support concrete hydration by reducing excessive surface water loss.

Additionally, sprinkler curing did not consistently produce lower later-age strengths than continuous water curing. This suggests that curing efficiency should not be evaluated solely based on the curing method itself but rather in conjunction with binder composition and mixture characteristics. Similar correlations between curing conditions and supplementary cementitious materials have been reported by Sherwani et al. [12] and Ahmad et al. [4].

The influence of mold release agent type was considerably less pronounced than the effects of binder composition and curing regime. Although the paraffin-containing non-ionic release agent occasionally resulted in slightly higher mechanical properties, no systematic trend was observed.

The splitting tensile strength results exhibited trends broadly comparable to those observed for compressive strength. The improvement in tensile performance observed in several slag-containing mixtures may be associated with continued microstructural refinement and

enhancement of the aggregate-paste interfacial transition zone. Comparable findings have been reported by Sang and Khoa [13], Vincent et al. [9], and Ahmad et al. [4], who identified positive relationships between slag hydration, matrix densification, and tensile strength development.

Overall, the present findings indicate that binder composition was the dominant factor governing strength development, followed by curing regime, whereas mold release agent type exerted only a secondary influence. These findings suggest that optimization of binder design and curing practice is more critical to long-term mechanical performance than the selection of the mold release agent.

5 Conclusions

Based on the experimental results obtained from sixteen concrete mixtures incorporating different binder systems, curing regimes, and mold release agents, the following conclusions can be drawn:

1. GGBFS incorporation delayed early-age strength development but contributed positively to later-age mechanical performance. The results confirm that slag-blended concretes can compensate for their initial strength deficit and achieve comparable or superior 28-day compressive and splitting tensile strengths when adequate curing conditions are provided.
2. The effect of curing regime depended on both concrete class and binder type. Intermittent sprinkler curing was generally effective in sustaining the hydration of slag-containing mixtures and produced 28-day strengths comparable to those obtained under continuous water curing. However, its effectiveness was less pronounced for the high-strength plain Portland cement mixtures.
3. The paraffin-containing non-ionic mold release agent did not adversely affect either compressive or splitting tensile strength. The differences between the two mold release agents remained limited throughout the study, indicating that mold release agent type has only a secondary influence on the mechanical performance of concrete compared with binder composition and curing practice.

Overall, the findings highlight the strong interaction between binder composition and curing regime in governing concrete strength development. Continuous water curing remained the most reliable condition for ensuring adequate hydration; however, the sprinkler curing regime investigated in this study also provided satisfactory performance in several mixtures, particularly those containing GGBFS. These results suggest that curing efficiency should be assessed in relation to the characteristics of the concrete system rather than solely on the basis of the curing method employed. Further studies incorporating microstructural characterization techniques and long-term durability assessments are recommended to better understand the interaction between GGBFS hydration and curing conditions governing strength development.

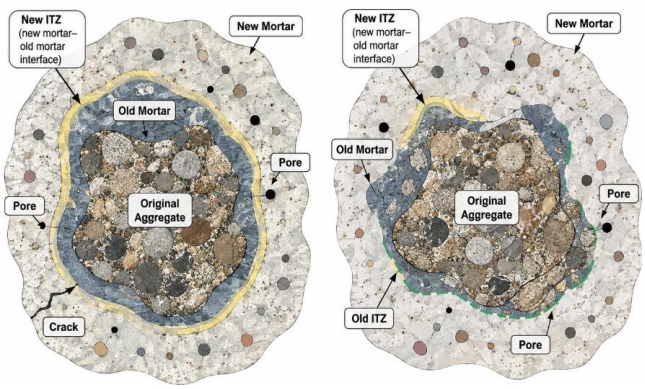
Abstract. The growing volume of concrete waste, which constitutes a major fraction of construction and demolition (C&D) waste, highlights the need for sustainable reuse in high-value applications. Road construction is a promising pathway, particularly for roller-compacted concrete (RCC), where compaction control is critical for field performance. This study investigated the moisture–density behavior of RCC mixtures incorporating recycled concrete aggregate (RCA) and concrete waste powder (CWP), a finely ground residual fraction generated during RCA processing. Nine mixture designs combining three RCA replacement levels (0%, 50%, and 100%) and three CWP contents (0%, 30%, and 50%) were evaluated at five effective water contents (4.5–8.5%) on a saturated surface-dry (SSD) condition, resulting in 45 mixture conditions. The mixtures were prepared with oven-dry aggregates, and additional water was included to compensate for aggregate absorption. Although the SSD-based optimum moisture content (OMC) remained approximately 6.5%, the total water demand under oven-dry batching increased from 8.4% for RCA0 to 9.7% for RCA50 and 11.2% for RCA100 because of the additional absorption water required by RCA. Increasing RCA content also reduced maximum dry density (MDD) by approximately 5.4% and 10.8% at RCA50 and RCA100, respectively, while the influence of CWP was considerably smaller. VeBe measurements further indicated a stiffer fresh consistency with increasing recycled constituents. From a practical perspective, the results indicate that the conventional RCC OMC can be used as an initial moisture target for RCA-containing mixtures, provided that the additional water required for RCA absorption is added separately. However, because RCA substantially reduces the achievable dry density and may result in a stiffer fresh consistency, field compaction control should be based on mixture-specific MDD values, together with careful monitoring of placement and compaction.

Keywords: Roller-compacted concrete; pavements; recycled concrete aggregate; concrete waste powder; optimum moisture content.



1 Introduction

Roller-compacted concrete (RCC) is a zero-slump concrete placed with paving equipment and compacted by rollers, combining rapid construction with the structural capacity and durability of concrete pavements. Because RCC contains relatively low paste and water contents and relies on external compaction, its performance is highly sensitive to aggregate grading, moisture condition, compactive effort, and curing. The moisture–density relationship is therefore central to RCC mixture design. Insufficient water limits particle rearrangement and results in excessive voids, whereas excess water prevents the formation of a densely packed structure. For a given compaction method and effort, the optimum moisture content (OMC) corresponds to the water content at which the maximum dry density (MDD) is achieved. Since both OMC and MDD are influenced by mixture composition and compaction procedure, they should be considered mixture- and method-specific parameters [1–3].

The use of recycled concrete aggregate (RCA) in RCC provides an opportunity to reduce both the consumption of natural aggregate (NA) and the quantity of concrete waste requiring disposal. Pavement construction is particularly suitable for such large-volume recycling because aggregates constitute the majority of an RCC mixture. However, RCA differs extensively from NA. An RCA particle is generally a composite consisting of the original NA and varying amounts of residual mortar remaining after crushing and processing. This adhered mortar typically has a lower density, greater porosity, higher water absorption, and more microcracking than the original aggregate. Increasing RCA content can therefore reduce the compacted density of RCC while increasing the quantity of water required to achieve adequate particle movement and consolidation. Recent experimental studies on RCA-containing RCC have similarly reported higher moisture demand and lower density as the replacement level increases, although the magnitude of these changes depends on the source and quality of the RCA, its grading, initial moisture state, and processing method [4,5].

The composite structure of RCA creates a more complex interfacial system than NA. As shown in *Fig. 1* (a), when the original aggregate remains covered by adhered mortar, the old ITZ is located between the original aggregate and old mortar, while a new ITZ forms between the old and new mortar. If part of the adhered mortar is removed during processing, the original aggregate becomes locally exposed and an additional new ITZ may form directly between the aggregate and new mortar, as illustrated in *Fig. 1* (b). Thus, several ITZs may coexist within a single RCA particle [6,7]. More importantly for RCC compaction, the porous and microcracked adhered mortar absorbs part of the mixing water and reduces the free water available for particle rearrangement. This effect is particularly significant when oven-dry RCA is used. Therefore, the effective water content expressed on an SSD condition should be distinguished from the total water added under oven-dry conditions, which also includes aggregate absorption. RCA-containing mixtures may consequently exhibit similar SSD-based OMC values but substantially different total water demands, making experimental determination of the moisture–density relationship necessary for each mixture [4-8].

RCA processing also produces a residual fine fraction composed of ground cement paste, mortar, and minor aggregate particles. This material can be reused in RCC as concrete waste powder (CWP). Although its fine particles may improve void filling, its porous nature and high surface area may also affect water demand and compaction. However, limited research has separately examined the effects of RCA and CWP on the OMC and MDD of RCC mixtures over complete moisture–density relationships [9,10].

(a) (b)

Fig. 1. Schematic ITZ configurations in RCA concrete: (a) new ITZ between old and new mortar; (b) additional aggregate–new mortar ITZ after partial removal of adhered mortar. Adapted from [11].

This study therefore investigates the moisture–density behavior of RCC pavement mixtures containing RCA and CWP. Nine mixture designs were formulated by combining RCA replacement levels of 0%, 50%, and 100% with CWP contents of 0%, 30%, and 50% as a partial replacement of Ordinary Portland cement (OPC). For each design, five effective water contents—4.5%, 5.5%, 6.5%, 7.5%, and 8.5%—were evaluated on an SSD condition, resulting in 45 mixture conditions. The mixtures were prepared using oven-dry aggregates, with additional water included to compensate for aggregate absorption. This approach allowed the additional water demand associated with RCA absorption to be distinguished from the effective moisture required for optimum compaction. It also enabled the relative effects of RCA and CWP on OMC and MDD to be evaluated separately.

2 Materials and Moisture–Density Experimental Program

OPC, NA, RCA, and CWP were used in the mixtures. RCA was produced by crushing previously used concrete cubes (*Fig.2*), followed by sieving to obtain the required aggregate gradation. The resulting RCA covered particle sizes from 0.063 to 16 mm. The fine residual fraction generated during RCA processing was further ground to a cement-like powder and used as CWP as a partial replacement of OPC. For volumetric mixture calculations, a particle specific gravity of 2.70 was adopted for CWP.

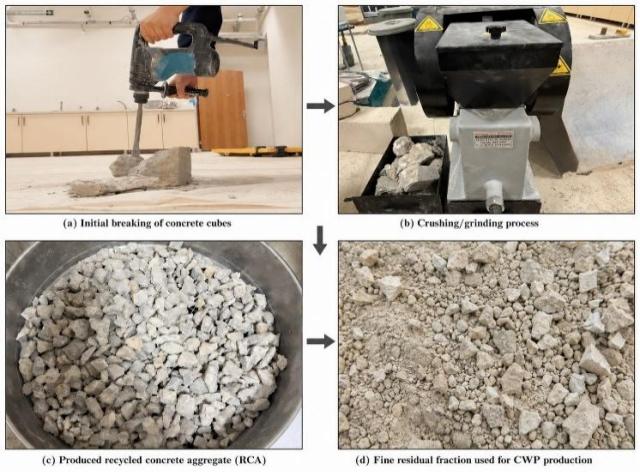


Fig. 2. Production process of RCA and CWP from crushed concrete waste [12].

The main physical properties of the natural and aggregate are summarized in Table 1. Aggregate gradations were selected in accordance with the General Technical Specification for "*Roller-Compacted Concrete Roads"* published by the Turkish Ministry of Environment, Urbanization and Climate Change [13].

Table 1. Physical properties of the RCA and NA used in study [14].

Agg. types	Agg. sieve size	Apparent Particle density (g/cm³)	Oven-Dry Particle Density (g/cm³)	SSD Particle Density (g/cm³)	Water Abs. Capacity (%)
RCA	16–32 mm	2.67	2.41	2.53	2.93
	8–16 mm	2.65	2.37	2.48	4.38
	4–8 mm	2.63	2.33	2.44	5.00
	2–4 mm	2.51	2.08	2.25	8.30
	1–2 mm	2.45	2.02	2.19	8.74
NA	16–32 mm	2.84	2.83	2.83	0.18
	8–16 mm	2.71	2.71	2.72	0.28
	4–8 mm	2.81	2.77	2.78	0.52
	2–4 mm	2.85	2.78	2.81	0.88
	1–2 mm	2.53	2.12	2.28	4.00

Nine RCC mixture designs were developed by combining three RCA replacement levels (0%, 50%, and 100%) with three CWP contents (0%, 30%, and 50%), with CWP replacing OPC by mass. For each mixture design, five effective water contents (4.5%, 5.5%, 6.5%, 7.5%, and 8.5%) were investigated on an SSD condition, resulting in 45 mixture conditions, as summarized in Table 2. The mixtures were prepared using oven-dry aggregates, and additional water was added to account for aggregate absorption. Aggregate quantities were adjusted according to the selected RCA replacement level and water content.

Table 2. Experimental matrix of RCC mixtures.

Note: CWP replacement is expressed as a percentage of total binder mass.

The selected water contents were defined on SSD condition. However, the aggregates were used in the oven-dry (OD) condition during mixture preparation; therefore, additional water corresponding to aggregate absorption was included in the actual batch water. This distinction

was particularly important for RCA because of its considerably higher absorption associated with adhered mortar. The mixtures were compacted using the adopted Proctor procedure, and moisture–density curves were established for each mixture. The SSD-based OMC and corresponding MDD were obtained from these curves. In addition, the total water demand under OD conditions was calculated to evaluate the additional water requirement resulting from RCA absorption.

Moisture–density relationships were determined using the standard Proctor procedure in accordance with ASTM D698. Each RCC mixture was compacted in a 945 cm^3 mold in three equal layers, with 25 blows applied to each layer using the standard Proctor rammer, corresponding to a compactive effort of approximately 600 $kN \cdot m/m^3$. Five effective water contents were evaluated for each mixture on an SSD condition; because the aggregates were batched in the oven-dry condition, additional water was included to account for aggregate absorption. Following compaction, representative samples were oven-dried at 110 °C for 24 h to determine the actual moisture content and dry density. The moisture–density curves were then used to determine the SSD-based OMC and corresponding MDD for each mixture. Vebe consistency was also measured in accordance with ASTM C1170 to characterize the fresh consistency of the RCC mixtures. The Proctor compaction, moisture determination, and Vebe consistency procedures are illustrated in *Fig. 3*.

Fig. 3. Experimental procedures used for moisture–density and consistency evaluation of RCC mixtures [12].

3 Results and Discussion

3.1 Moisture–Density Relationships and OMC

Fig. 4 shows the moisture–density relationships expressed on an SSD condition. Despite substantial changes in RCA and CWP contents, the investigated mixtures exhibited a similar OMC of approximately 6.5%. This indicates that the effective moisture required to achieve optimum compaction remained relatively stable when aggregate absorption was accounted for. Although the position of the density peak changed little, the corresponding MDD decreased

noticeably with increasing RCA content, indicating the lower particle density and porous adhered mortar associated with RCA.

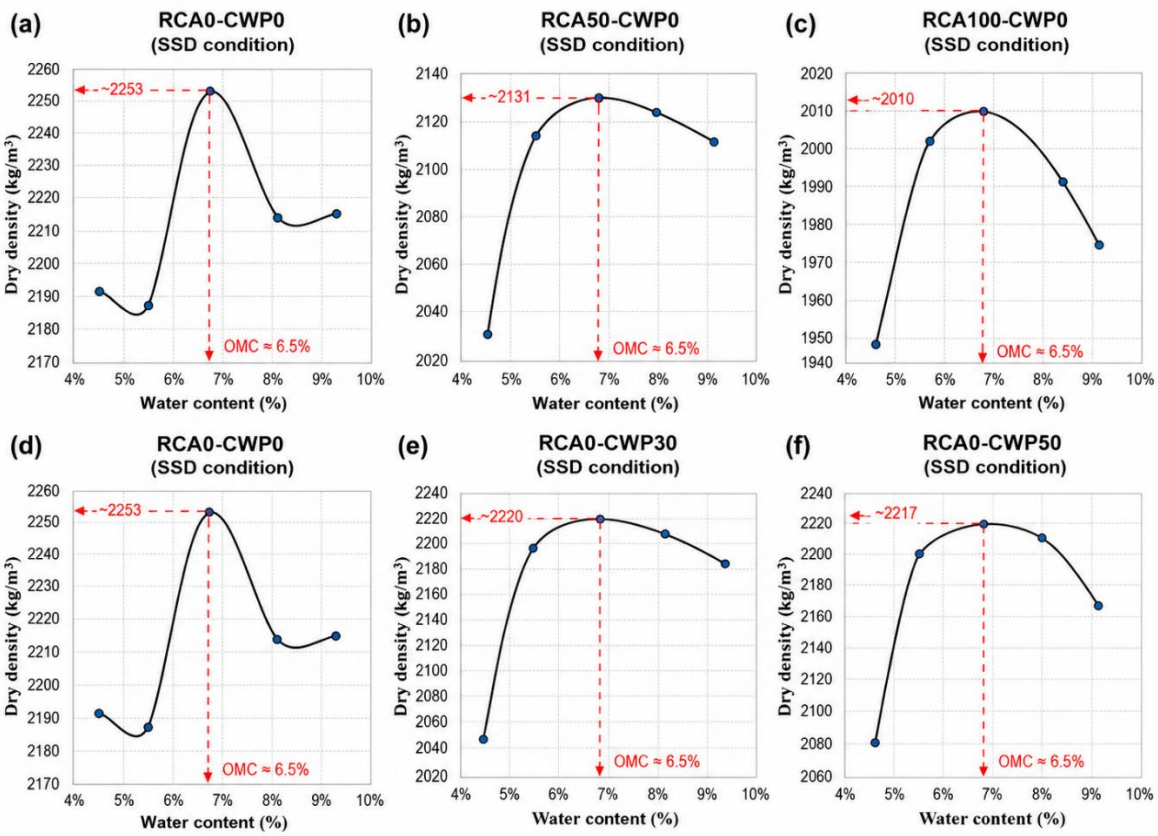

Fig. 4. Moisture–density relationships and SSD-based OMC of RCC mixtures.

A different trend becomes evident when the water content is expressed for mixtures prepared with oven-dry aggregates (*Fig.5*). For the CWP0 series, the total water content corresponding to MDD increased from approximately 8.4% for RCA0 to 9.7% for RCA50 and 11.2% for RCA100. In comparison, changing the CWP content produced considerably smaller shifts in total water demand. For example, at RCA0, the corresponding values remained within approximately 8.4–8.9%. Mixtures containing both RCA and CWP followed the same general pattern, with total water demand governed primarily by the RCA replacement level.

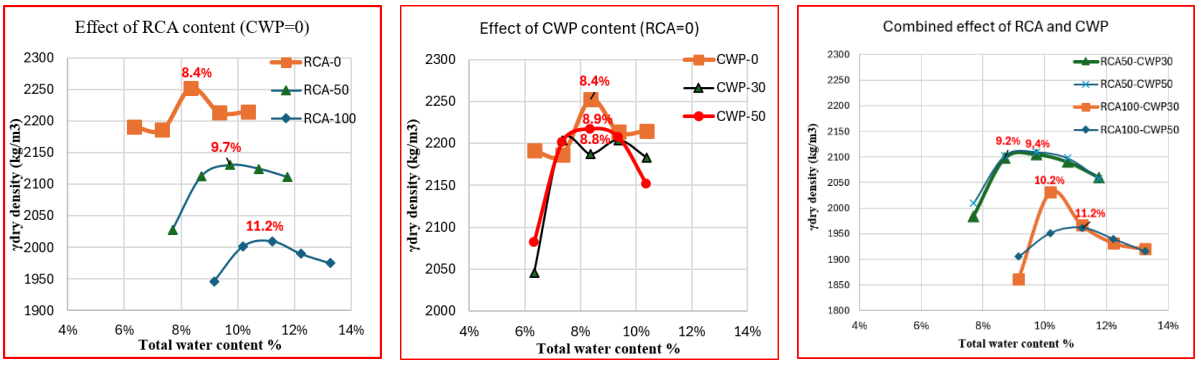

Fig. 5. Total water demand of RCC mixtures under oven-dry conditions.

The comparison between *Fig. 3* and *Fig.4* is particularly important: RCA did not substantially alter the SSD-based OMC, but it markedly increased the total amount of water required when oven-dry aggregates were used. This additional requirement is mainly associated with water

absorbed by the porous adhered mortar in RCA rather than an equivalent increase in the effective moisture needed for compaction. Therefore, SSD-based OMC and total water demand under oven-dry conditions should be clearly distinguished when proportioning RCA-containing RCC mixtures.

Although the mixture constituents affected the magnitude of the achieved dry density, they caused only minor changes in the location of the SSD-based optimum moisture level. This suggests that the primary effect of RCA was not a shift in the effective moisture required for compaction, but an increase in the additional water required to satisfy aggregate absorption when the material was batched in the oven-dry condition.

To complement the moisture–density evaluation, Vebe consistency was measured for three representative mixtures at the SSD-based OMC of approximately 6.5%. The Vebe time increased from 35 s for RCA0-CWP0 to 42 s for RCA0-CWP50 and 47 s for RCA100-CWP0, indicating a progressively stiffer fresh consistency with increasing recycled constituents. Nevertheless, all mixtures remained compactable under the adopted laboratory procedure. From a practical perspective, the higher Vebe times suggest that RCA-containing RCC mixtures may require greater attention to compaction during placement to achieve the target density, even though the SSD-based OMC remained nearly unchanged.

3.2 Effect of RCA and CWP on Maximum Dry Density

Fig.6 summarizes the MDD values of the investigated RCC mixtures. The results show that RCA content had a pronounced effect on MDD. For the mixtures without CWP, MDD decreased from approximately 2253 kg/m^3 for RCA0-CWP0 to 2131 kg/m^3 for RCA50-CWP0 and 2010 kg/m^3 for RCA100-CWP0, corresponding to reductions of approximately 5.4% and 10.8%, respectively. This reduction is consistent with the lower particle density and higher porosity associated with the adhered mortar in RCA. In contrast, the effect of CWP on MDD was considerably smaller. At RCA0, increasing CWP content to 30% and 50% reduced MDD from approximately 2253 to 2220 and 2217 kg/m^3, corresponding to reductions of only 1.5% and 1.6%, respectively. A similarly limited influence of CWP was observed at higher RCA contents. Overall, the results indicate that RCA replacement was the primary factor controlling the reduction in MDD, whereas the influence of CWP was secondary.

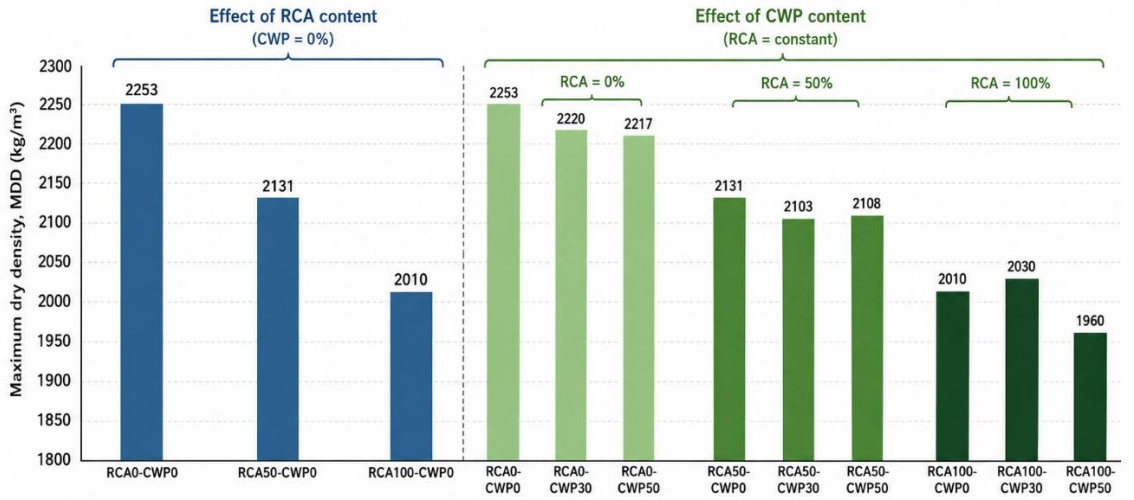

Fig. 6. Effect of RCA and CWP contents on MDD of RCC mixtures

From a practical perspective, the results indicate that the SSD-based OMC of conventional RCC may provide a reasonable initial moisture target for RCA-containing mixtures when aggregate absorption is properly accounted for, since the optimum effective moisture remained close to 6.5% across the investigated mixtures. However, a similar OMC does not imply a similar maximum achievable density or fresh consistency. The MDD decreased substantially with increasing RCA content, indicating that field density acceptance should be based on the mixture-specific laboratory MDD rather than on the reference value of conventional RCC. In addition, the increase in Vebe time with recycled constituents shows that mixtures may become stiffer even at a similar SSD-based OMC, suggesting greater resistance to consolidation and a need for closer compaction control during field placement.

4 Conclusion

The moisture–density behavior of RCC mixtures containing RCA and CWP was evaluated with particular emphasis on distinguishing SSD-based effective moisture from the total water demand of mixtures prepared with oven-dry aggregates. The main conclusions are:

- The SSD-based OMC remained approximately 6.5% across the investigated mixtures, despite substantial changes in RCA and CWP contents. This indicates that the conventional RCC OMC can be used as an initial target for RCA-containing mixtures, provided that the additional water required for RCA absorption is added separately.
- In contrast, the total water demand under oven-dry conditions increased significantly with RCA content, rising from approximately 8.4% for RCA0 to 9.7% for RCA50 and 11.2% for RCA100 in mixtures without CWP. This increase was mainly associated with RCA absorption rather than a corresponding increase in effective compaction moisture.
- RCA had a pronounced effect on MDD. Relative to RCA0-CWP0, MDD decreased by approximately 5.4% at RCA50 and 10.8% at RCA100, whereas the effect of CWP was considerably smaller. Therefore, field density acceptance for RCA-containing RCC should be based on the mixture-specific laboratory MDD rather than the MDD of conventional RCC.
- Similar OMC values did not result in identical fresh consistency. Vebe time increased from 35 s for RCA0-CWP0 to 47 s for RCA100-CWP0, indicating a stiffer consistency with increasing recycled constituents. Thus, RCA-containing RCC may require closer attention to compaction during field placement even when the SSD-based OMC remains nearly unchanged.

Overall, the results show that the principal effect of RCA on RCC mixture design is not a substantial shift in SSD-based OMC, but rather an increase in total water demand, a reduction in achievable dry density, and a stiffer fresh consistency.

Abstract. Electric arc furnace slag (EAFS) is increasingly generated as electric arc furnace-based steel production grows. Its use as an alternative aggregate in cementitious composites may reduce natural aggregate consumption while valorizing an industrial by-product. In this study, EAFS was investigated as a partial fine aggregate replacement in cement mortar. Mortar mixtures were prepared by replacing CEN standard sand with EAFS at 25, 50 and 75%, and their fresh-state behavior and compressive strength development were evaluated. The EAFS exhibited a water absorption capacity of 2.61%, indicating a higher water demand than conventional standard sand. Increasing the EAFS content resulted in a gradual reduction in mortar flow, with the highest replacement level causing approximately 26% lower flow than the reference mixture. This reduction was mainly associated with the rough texture, angular particle shape, and higher absorption capacity of EAFS. At 28 days, the mixture containing 25% EAFS achieved the highest compressive strength as 52.0 MPa, corresponding to about 9% improvement compared with the reference mortar. This improvement was attributed to the rough and angular morphology of EAFS particles, which may enhance mechanical interlocking and paste–aggregate bonding at moderate replacement levels. The 50% replacement level showed comparable strength, whereas 75% replacement led to a strength reduction due to reduced workability and lower effective free water availability. A preliminary life cycle assessment further indicated that EAFS replacement reduced the total global warming potential by up to approximately 6.8%, while 25% replacement provided the best technical–environmental balance.

Keywords: Electric arc furnace slag; fine aggregate replacement; cement mortar; compressive strength; life cycle assessment

1 Introduction

The construction sector consumes large amounts of natural aggregates, particularly fine aggregates used in mortar and concrete production. Continuous extraction of natural sand creates environmental concerns and increases the need for alternative aggregate sources. At the same time, the steel industry generates large quantities of slag, and electric arc furnace slag (EAFS) is becoming increasingly important with the growing share of scrap-based steelmaking. Recent studies have emphasized that EAFS can be considered a potential secondary raw material for concrete and mortar production, supporting resource efficiency and circular construction practices [1,2].

EAFS has several physical characteristics that make it suitable as an alternative aggregate, including high density, angular particle shape, rough surface texture and high mechanical

hardness. These characteristics may improve the aggregate skeleton and paste–aggregate interaction when EAFS is used at suitable replacement levels. However, they may also reduce workability because angular and rough slag particles increase internal friction and may increase water demand. Recent reviews and experimental studies have shown that the effect of steel slag aggregates on mortar and concrete is strongly dependent on slag type, particle size, replacement ratio and mixture design [1–3].

In addition to technical performance, the environmental implication of EAFS use should also be considered. Previous studies have reported that replacing natural aggregates with EAFS can reduce environmental impacts or improve sustainability performance, especially when avoided natural aggregate extraction and reduced slag landfilling are included in the system boundary [2,4]. However, transportation, processing and the dominant contribution of cement may limit the overall reduction in global warming potential. Therefore, a combined evaluation of workability, compressive strength and preliminary environmental performance is needed to identify a balanced replacement level.

In this study, EAFS was evaluated as a partial fine aggregate replacement in cement mortar. CEN standard sand was replaced with EAFS at 25%, 50% and 75% by mass, while a reference mortar without EAFS was also prepared. The fresh behavior was assessed using the flow table test, and compressive strength was measured at 3, 7 and 28 days. In addition, a preliminary cradle-to-gate global warming potential screening was carried out to evaluate the environmental implication of EAFS replacement.

2 Materials and Methodology

2.1 Materials

Ordinary Portland cement, CEN standard sand, tap water and processed electric arc furnace slag (EAFS) were used for the preparation of cement mortar mixtures. The cement was used as the sole binder in all mixtures, while CEN standard sand was used as the reference fine aggregate. EAFS was used as a partial replacement for standard sand. Before mixture preparation, the EAFS was processed as a fine aggregate and its particle size distribution was determined by sieve analysis as shown in Fig. 1. The water absorption capacity of EAFS was measured as 2.61%, indicating a higher absorption potential compared with standard sand. This property was considered important because it may reduce the amount of free mixing water available in the fresh mortar and affect both flowability and strength development.

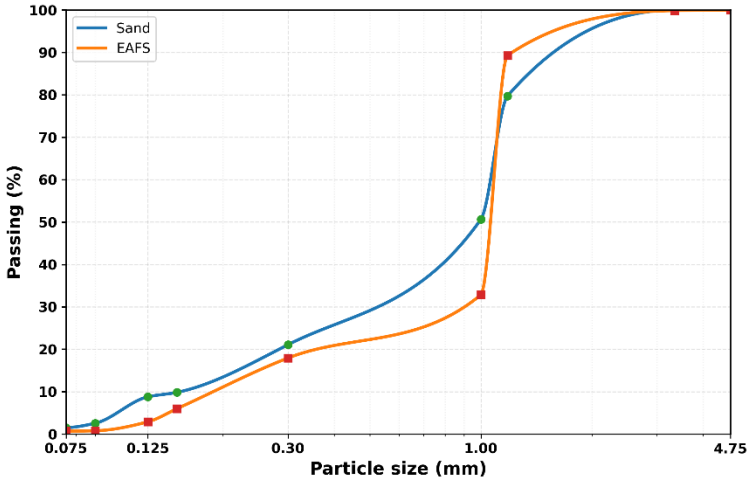

Fig. 1. Particle size distribution of the sand and EAFS

2.2 Mixture Proportions

Four mortar mixtures were prepared with different EAFS replacement levels. The reference mixture contained only CEN standard sand, while the remaining mixtures contained 25%, 50% and 75% EAFS as sand replacement by mass. In all mixtures, the cement content was kept constant at 225 g and the water content was kept constant at 112.5 g, corresponding to a water-to-cement ratio of 0.50. The total fine aggregate content was fixed at 675 g, giving a cement-to-aggregate ratio of 1:3 by mass. The detailed mixture proportions are given in Table 1.

Table 1. Mixture proportions

Mix ID	EAFS replacement (%)	Cement (g)	Water (g)	Standard sand (g)	EAFS (g)
M0	0	225	112.5	675.00	0.00
M25	25	225	112.5	506.25	168.75
M50	50	225	112.5	337.50	337.50
M75	75	225	112.5	168.75	506.25

2.3 Preparation, Curing and Testing

The dry materials were first weighed according to the mixture proportions. Cement, standard sand and/or EAFS were then placed in the mixing bowl and mixed to obtain a uniform dry blend. Water was added gradually, and mixing was continued until a homogeneous mortar was obtained. After mixing, the fresh mortar was used immediately for the flow table test. The remaining mortar was cast into 50 × 50 × 50 mm cube moulds for compressive strength testing. The specimens were compacted to reduce entrapped air and then covered to prevent early moisture loss. After 24 h, the specimens were demoulded and cured in water until the testing ages.

The fresh-state behavior of the mortar mixtures was evaluated using the flow table test in accordance with ASTM C1437. After placing the fresh mortar into the flow mould, the mould was lifted vertically and the flow table was operated according to the standard procedure. The spread diameter of the mortar was measured in two perpendicular directions, and the average value was recorded as the flow diameter. Compressive strength tests were conducted on 50 × 50 × 50 mm mortar cube specimens at 3, 7 and 28 days. Before testing, the specimens were removed from the curing tank and surface-dried. Each specimen was placed centrally in the compression testing machine, and load was applied until failure. The compressive strength was calculated by dividing the maximum failure load by the loaded area of the cube.

2.4 Life cycle assessment

A simplified life cycle assessment (LCA) was carried out to evaluate the global warming potential (GWP) of the mortar mixtures. The assessment was limited to GWP and was conducted with a cradle-to-gate system boundary. The functional unit was defined as 1 m^3 of mortar. The system included the production of cement, standard sand and water, EAFS processing, mixing electricity, transportation of raw materials, and the landfilling of unused EAFS. The environmental data for cement, water, standard sand and transportation were obtained from the Ecoinvent database. Since EAFS was considered as an industrial by-product, no upstream burden from steel production was assigned to it. However, the electricity consumption associated with crushing and size reduction was included for EAFS processing. Transportation distances were assumed as 15 km for cement, 39 km for sand, and 80 km for EAFS. For the landfilling scenario, a transport distance of 50 km was considered.

Multifunctionality related to EAFS utilization was handled by using the M75 mixture as the reference maximum-utilization scenario. Accordingly, for mixtures containing lower amounts of EAFS, the unused EAFS amount relative to M75 was assumed to be sent to landfill and was added to the system inventory. This approach allowed the environmental benefit of increasing EAFS utilization to be reflected in the preliminary GWP comparison.

3 Results and Discussion

3.1 Compressive strength and flow results

The compressive strength and flow results of the mortar mixtures are presented in Fig. 2. The reference mixture (M0) exhibited a flow diameter of 215 mm. With increasing EAFS replacement, the flow values decreased progressively to 195, 178 and 160 mm for M25, M50 and M75, respectively. This corresponds to flow reductions of approximately 9.3%, 17.2% and 25.6% compared with the reference mixture. The decrease in flow can mainly be attributed to the angular shape, rough surface texture and higher water absorption capacity of EAFS particles. Similar reductions in workability have been reported in previous studies where steel slag or EAF slag was used as natural fine aggregate replacement [1,5]. The rough and sharp-edged surface of EAF slag particles increases internal friction within the fresh mortar and reduces the lubricating effect normally provided by rounded or more regular sand particles [5].

The compressive strength results showed that moderate EAFS replacement improved or maintained the mechanical performance of the mortar. At 3 days, M25 achieved the highest strength among the mixtures, with 22.5 MPa compared with 20 MPa for the reference mixture. A similar trend was observed at 7 days, where M25 and M50 reached 32 and 30 MPa, respectively, both slightly higher than the reference mortar. At 28 days, M25 again provided the highest compressive strength, reaching 52 MPa, corresponding to an increase of about 9.1% compared with the reference mixture. The M50 mixture showed a comparable 28-day strength of 48 MPa, while the M75 mixture decreased to 41 MPa. The strength improvement observed at 25% EAFS replacement may be related to the rough and angular morphology of the slag particles, which can enhance mechanical interlocking and improve paste–aggregate bonding. In addition, the high hardness and density of EAFS may contribute to a more resistant aggregate skeleton under compression. Previous studies have similarly reported that EAF slag aggregate can improve compressive strength when used as a partial replacement for natural aggregate [5,6]. However, at high replacement levels, the reduction in workability and the higher absorption capacity of EAFS may reduce the effective free water available in the mixture and make compaction more difficult. This can increase entrapped voids and weaken the matrix, explaining the lower 28-day strength of M75.

Overall, the results indicate that EAFS content has a combined effect on fresh and hardened properties. Increasing EAFS replacement improves the utilization of an industrial by-product but gradually reduces flow. From a mechanical performance point of view, 25% EAFS replacement appears to be the most effective level, providing the highest 28-day compressive strength while maintaining acceptable workability. The 50% replacement level can also be considered feasible because it produced a strength comparable to the reference mixture. In contrast, 75% replacement resulted in a clear loss of workability and lower compressive strength, indicating that high-volume EAFS replacement may require additional mixture optimization, such as pre-wetting or the use of water-reducing admixtures.

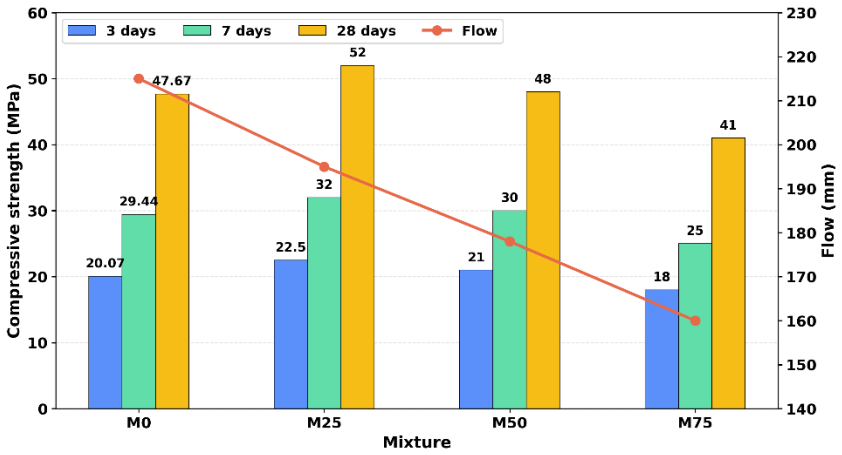

Fig. 2. Compressive strength and flow results of the mixtures

3.2 Life cycle assessment

A preliminary LCA was carried out to evaluate the environmental implication of replacing standard sand with EAFS. The total GWP values of M0, M25, M50 and M75 were calculated as 705.8, 694.0, 682.3 and 658.0 kg CO_2-eq/m³, respectively (Fig. 3.). Compared with the reference mixture, this corresponds to reductions of approximately 1.7%, 3.3% and 6.8% for M25, M50 and M75. The results show that cement was the dominant contributor to total GWP in all mixtures. Since the cement content was kept constant, the overall reduction remained moderate. The environmental benefit of EAFS replacement was mainly associated with the reduction in standard sand consumption and the decrease in the amount of unused EAFS assumed to be sent to landfill [7]. However, this benefit was partly offset by the additional transportation and processing-related emissions associated with EAFS use.

Although M75 provided the lowest total GWP, it also showed the lowest flow and a reduction in 28-day compressive strength. Therefore, the mixture with the lowest environmental impact was not necessarily the best technical option. When mechanical performance and GWP are considered together, M25 appears to be the most balanced mixture, as it reduced the total GWP slightly while providing the highest 28-day compressive strength. M50 also offered a reasonable compromise, with lower GWP than the reference mixture and comparable compressive strength. Overall, the LCA screening indicates that moderate EAFS replacement can improve the resource efficiency of cement mortar without compromising mechanical performance.

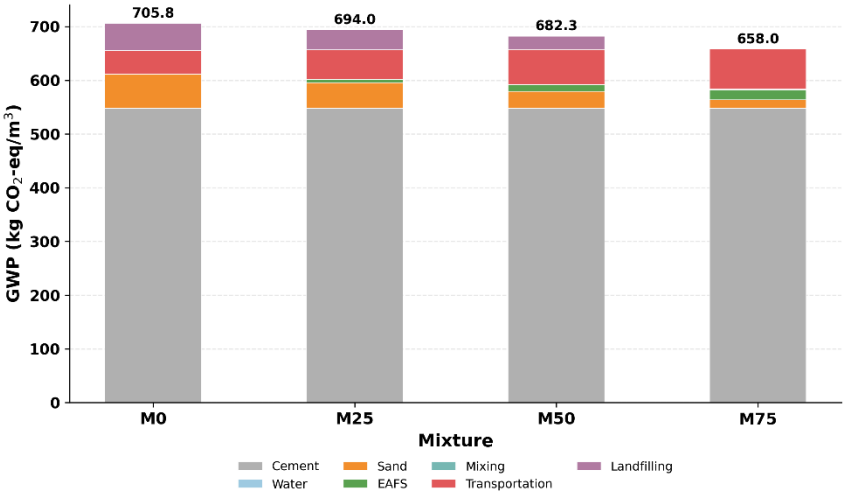

Fig. 3. Life cycle assessment of the mixtures

4 Conclusions

This study investigated the feasibility of using electric arc furnace slag (EAFS) as a partial fine aggregate replacement in cement mortar. Mortar mixtures containing 25%, 50% and 75% EAFS were evaluated in terms of fresh-state behavior, compressive strength development and preliminary GWP performance. The results showed that increasing EAFS content gradually reduced workability, with flow losses of approximately 9.3%, 17.2% and 25.6% for M25, M50 and M75, respectively. However, the 25% replacement level provided the best mechanical performance, increasing the 28-day compressive strength by about 9.1% compared with the reference mortar. The M50 mixture showed comparable strength, whereas M75 resulted in a 14.0% strength reduction. The preliminary GWP screening also indicated environmental benefits, with total GWP reductions of approximately 1.7%, 3.3% and 6.8% for M25, M50 and M75, respectively. Overall, 25% EAFS replacement appears to be the most balanced option, combining improved compressive strength, acceptable workability and a slight reduction in environmental impact.

Abstract. Calcined clays are promising aluminosilicate precursors for low-carbon one-part geopolymer binders, but their performance is strongly controlled by activator chemistry and dosage. This study investigates a low-grade natural clay from the Şile region of Istanbul, Türkiye, as a precursor for one-part geopolymer mortars. The clay is considered waste because its relatively high Fe_2O_3 content makes it unsuitable for ceramic and paper applications. The raw clay was characterized using X-ray fluorescence (XRF) and thermogravimetric analysis (TGA), while X-ray diffraction (XRD) analysis was performed before and after calcination at 700 °C. The calcination temperature of 700 °C was selected based on the Strength Activity Index results obtained at 600, 700, and 800 °C. The calcined clay was activated with six solid activators, sodium hydroxide, potassium hydroxide, sodium silicate, potassium silicate, sodium carbonate, and sodium sulfate, each at activator-to-clay ratios of 15, 30, 45, 60, and 75%. The silicate activators were synthesized from recycled waste glass and the corresponding hydroxides. Mortars were cured at 23±1 °C and 55±5% relative humidity and tested for flexural and compressive strength at 7, 14, and 28 days. Spearman's rank correlation related the 28-day compressive strength to the mix-design and chemical parameters. Silicate activators outperformed the hydroxide, carbonate, and sulfate systems, with sodium silicate giving the highest compressive strength. The correlation analysis linked 28-day strength most closely to alkali availability and the Si/Al and Ca-based ratios.

Keywords: One-Part Geopolymer; Calcined Clay; Mechanical Strength; Alkali Activation.

1 Introduction

Portland cement remains the most widely used construction material because its performance is proven and it is cheap and available, but its production is energy-intensive and generates considerable CO_2, mainly from fuel combustion and the calcination of limestone during clinker manufacture [1]. The cement and concrete sectors are estimated to contribute around 7-8% of global CO_2 emissions [2], and industry roadmaps set steep reduction targets [3], underlining the need for lower-carbon binder systems.

A widely studied route is to replace part of the clinker with supplementary cementitious materials (SCMs) such as ground granulated blast-furnace slag, fly ash, silica fume, and metakaolin, which lower clinker content while preserving or improving performance. However, the supply of conventional SCMs is a growing concern: fly ash will decline as coal plants are phased out, slag depends on the steel industry and may not meet future demand [4], and silica fume is limited by cost and low feasible replacement levels [5]. Attention has therefore shifted toward alternative aluminosilicate resources, especially calcined clays, which are locally

abundant and rich in reactive aluminosilicate phases, and which show potential both as SCMs and as precursors for geopolymer binders [6-9].

Geopolymers form when an aluminosilicate precursor dissolves in a highly alkaline environment and the released Si and Al reorganize through polycondensation into a three-dimensional gel network of N-A-S-H, C-A-S-H, or coexisting phases (Fig. 1). Their performance depends not only on the alkaline activator but also on the precursor's mineralogy, amorphous content, Si/Al ratio, and calcination conditions.

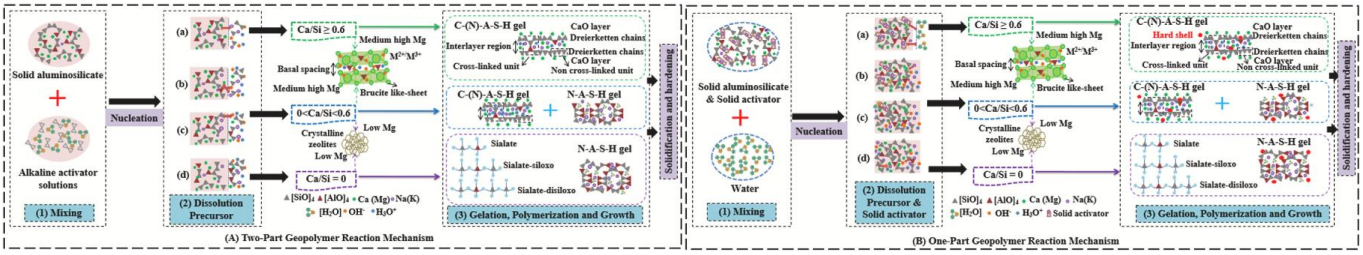

Fig. 1. Schematic illustration of hydration process and reaction mechanism of one-part geopolymer and conventional two-part geopolymer [8]

Geopolymers are produced by two routes. In two-part systems the precursor is mixed with a pre-prepared liquid activator, whereas one-part systems are made by dry-blending the precursor with a solid activator, with reaction beginning only when water is added. This "just-add-water" route is more practical and closer to ordinary cement use, and it avoids preparing, transporting, and handling corrosive alkaline solutions. Its performance, however, depends strongly on the compatibility between precursor and solid activator, since the activator's dissolution rate, setting behavior, and degree of gel formation govern the fresh and hardened properties. Selecting a suitable precursor-activator combination is therefore essential [7-8].

This study investigates a low-grade, iron-rich clay of limited ceramic value as a precursor for one-part geopolymer mortars. The clay was characterized and calcined at 700 °C, then activated with six solid activators at five dosages, and the mortars were evaluated by mechanical testing.

2 Materials and Methods

2.1 Raw Clay, Calcination, and Characterization

The raw material used in this study was a natural clay from the Şile region of Istanbul, Türkiye. The clay is a low-grade material with high iron content. Its iron oxide level produces coloration on firing and excludes it from ceramic and paper use [10]. Iron is a normal constituent of cement, so this is not a barrier to use as a precursor material [11]. The bulk oxide composition was measured by X-ray fluorescence (XRF) and is given in Table 1. The combined SiO_2, Al_2O_3, and Fe_2O_3 content was 84.1 wt.%. This value exceeds the 70 wt.% minimum set by ASTM C618 for Class N pozzolan. The raw clay was dried at 105 °C to a constant dry mass. The dried clay was ground in a ball mill at 70 rpm for 30 min. The specific gravity and the Blaine fineness were 2.77 and 12560 cm²/g, respectively.

Table 1. Chemical composition of raw clay and waste glass determined by XRF (wt.%)

	Na_2O	MgO	Al_2O_3	SiO_2	K_2O	CaO	TiO_2	Fe_2O_3	SO_3	*LOI
Raw Clay	0.10	1.12	22.31	52.49	3.50	0.26	1.34	9.29	0.19	9.11
Waste Glass	8.87	1.51	1.65	72.43	0.53	13.22	0.13	1.08	0.10	0.10

Thermogravimetric analysis (TGA) was carried out under a nitrogen atmosphere at a heating rate of 10 °C/min from room temperature to 950 °C. Fig. 2 shows a minor mass loss below 150 °C attributed to free water. The DTG curve showed a small peak between 200 and 400 °C, which may be related to decomposition of iron oxyhydroxide phases, consistent with the high Fe_2O_3 content of the clay [12]. The main mass loss occurred between 350-650 °C, corresponding to dehydroxylation of the clay minerals [13]. The DTG curve showed a shoulder near 400-450 °C, which might reflect the partially overlapping dehydroxylation of kaolinite and illite in the mixed-mineral clay [14]. The TGA curve stabilized beyond approximately 700 °C, indicating that dehydroxylation was essentially complete by this temperature.

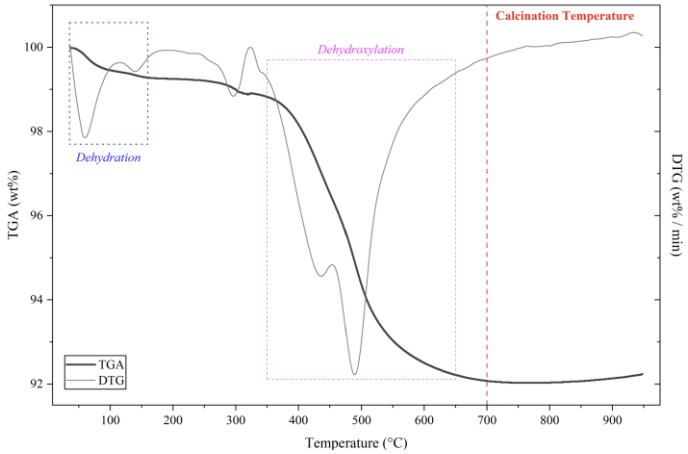

Fig. 2. TGA/DTG curves of the raw clay showing dehydration, dehydroxylation, and the selected calcination temperature of 700 °C.

Based on the TGA results, calcination temperatures at and beyond the completion of dehydroxylation were selected for evaluation. The clay was calcined at 600, 700, and 800 °C and tested as a 20 wt.% cement replacement using the Strength Activity Index (SAI). Calcination at 700 °C gave the highest activity for this clay and was adopted for the present study. The clay was calcined in a preheated muffle furnace at 700 °C for 1 h and then cooled rapidly to room temperature to preserve the disordered, reactive structure.

X-ray diffraction (XRD) was carried out on the raw and the 700 °C clay. Fig. 3 shows the raw clay with reflections of kaolinite, illite, quartz, and feldspar. After calcination at 700 °C, the kaolinite reflection had disappeared. This indicates the breakdown of kaolinite and its conversion to metakaolinite. The quartz and feldspar reflections remained. The change confirmed the formation of a more reactive aluminosilicate.

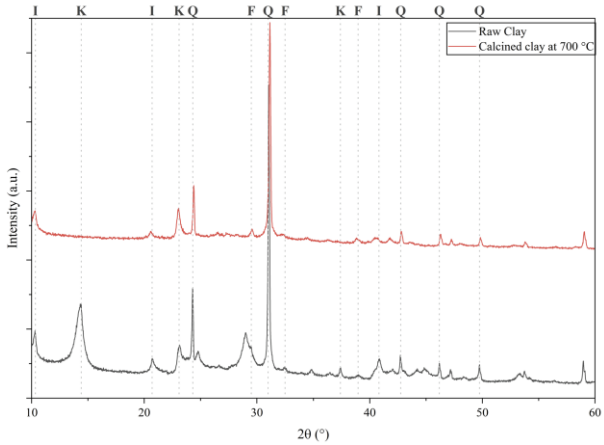

Fig. 3. XRD patterns of raw clay and clay calcined at 700 °C. The calcined clay pattern was vertically shifted for clarity. K: kaolinite; I: illite; Q: quartz; F: feldspar.

The particle size distribution and physical properties of the raw and calcined clay are summarized with the distribution curves in Fig. 4. After calcination, the clay showed a coarser particle size distribution, along with a slight increase in specific gravity and specific surface area.

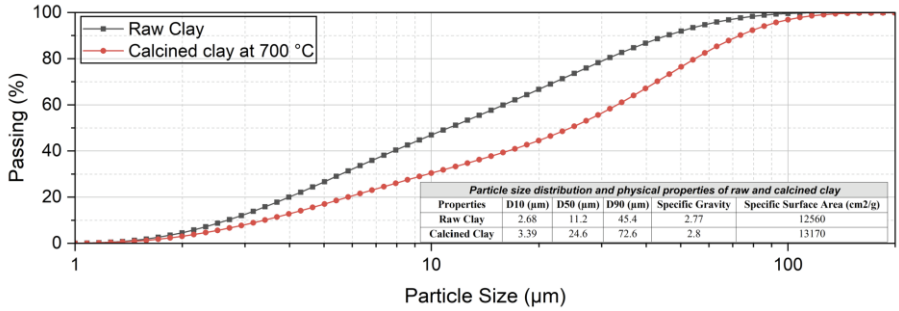

Fig. 4. Particle size distribution of raw and calcined clay determined by laser diffraction

2.2 Activators

Six solid activators were used in this study: sodium hydroxide, potassium hydroxide, sodium carbonate, sodium sulfate, sodium silicate, and potassium silicate. Their chemical formulas and densities are summarized in Table 2. NaOH, KOH, Na_2CO_3, and Na_2SO_4 were obtained commercially as solid reagents.

Table 2. Solid activators used in the study.

Activators	Na_2CO_3	NaOH	KOH	Na_2SO_4	Na_2SiO_3 (Ms*=1)	K_2SiO_3 (Ms*=1)
Code	NC	NH	KH	NSO	NS	KS
Density (g/cm³)	2.54	2.13	2.04	2.66	2.43	2.52

*Ms: silica modulus.

The sodium and potassium silicate activators (Ms = 1, where Ms is the molar SiO_2/M_2O ratio) were synthesized in the laboratory from recycled waste glass, providing a more sustainable alternative to commercial silicate activators. The waste glass was obtained from the Şişecam factory in Istanbul. It was ground in a mill for 5000 revolutions to a specific surface area of 7820 cm²/g. Its bulk oxide composition (XRF) is given in Table 1, and confirmed a high silica content, with SiO_2 as the dominant oxide. Sodium silicate was produced by a hydrothermal synthesis method, reacting the ground glass with NaOH and a small addition of water, heated at 250 °C for 2 h. Potassium silicate was produced by a thermochemical synthesis method, reacting the ground glass with KOH without water addition, heated at 400 °C for 2 h. Both products were obtained as solids and ground to powder for use as activators.

2.3 Mix Design

Natural sand was used as the fine aggregate in all geopolymer mortar mixtures. The specific gravity and fineness modulus of the sand were 2.64 and 2.69, respectively. The sand content was kept constant at 1188 g for all mixtures. The particle size distribution of the sand was determined by sieve analysis in accordance with EN 933-1. The characteristic particle sizes were D_{10} = 0.31 mm, D_{30} = 0.59 mm, and D_{60} = 1.57 mm, corresponding to a coefficient of uniformity (C_u) of 5.06 and a coefficient of curvature (C_c) of 0.72.

Thirty mixtures were prepared, combining the six activators at five activator-to-clay ratios (15, 30, 45, 60, and 75 wt.%). Each mix is identified by its activator code followed by its activator-to-clay ratio (e.g., NS-60). The binder was defined as the combined mass of calcined clay and activator. The water-to-binder ratio (w/b) was adjusted for each mix between 0.50 and 0.65 to maintain workability and is reported for each mix in Table 3. The flow of the fresh mortars was determined using a flow table following ASTM C1437. The flow value was taken

as the average spread diameter of the mortar. Mixture proportions and fresh-state properties are also summarized in Table 3.

Table 3. Mixture proportions and fresh-state properties of calcined clay geopolymer mortars

*A hyphen indicates that the value was not determined. Flow values marked as 25+ indicate that the spread exceeded the reported scale.

Mortar specimens were cast in accordance with EN 196-1, using 40 × 40 × 160 mm prismatic molds. Mixing followed a modified EN 196-1 procedure, adapted to the one-part approach used in this study, in which the solid activator was dry-blended with the calcined clay before water and sand were added. Specimens were demolded after a minimum of 24 h, or later if the mortar had not yet hardened sufficiently. All specimens were cured at ambient laboratory temperature 23±1 °C and 55±5 % relative humidity until testing.

2.4 Mechanical Testing and Statistical Analysis

Flexural and compressive strength were determined in accordance with EN 196-1. Prismatic specimens (40 × 40 × 160 mm) were tested in three-point bending at a loading rate of 0.4

mm/min to determine flexural strength. The resulting halves from each specimen were then tested in compression at a loading rate of 1 mm/min. Testing was carried out at 7, 14, and 28 days for each mix.

Statistical analysis was carried out using IBM SPSS Statistics. Spearman's rank correlation was used to assess the strength and direction of the association between the 28-day compressive strength and the mix-design and chemical parameters of the mixtures, with correlations taken as significant at $p < 0.05$.

3 Results

3.1 Compressive Strength

Compressive strength was controlled by the type of activator rather than only by its dosage. The compressive strength of all mixtures at 7 and 28 days are shown in Fig. 5, with the full 7, 14, and 28-day values listed in Table 4.

Table 4. Flexural and Compressive strength of one-part calcined clay geopolymer mortars at 7, 14, and 28 days.

*A hyphen indicates that the strength value was not available.

In these one-part systems, the silicate activated mortars reached strengths well above the hydroxide and sulfate systems, peaking at 27.13 MPa for sodium silicate (NS-75) at 7 days, whereas no hydroxide or sulfate mix exceeded 3.85 MPa (NH-30) at any age (Table 4). A hydroxide activator raises the pore solution pH and dissolves the aluminosilicate precursor [15], but it contributes no silica of its own, so gel growth depends entirely on silicon released from the clay. A soluble silicate activator instead delivers reactive silicate directly into the pore solution, which enhances the condensation process and introduces additional silicon into the aluminosilicate chain, producing a denser and better-connected gel [16].

With sodium silicate, strength did not climb gradually with dosage. At 15% and 30% the 28-day strength stayed near 1 MPa, then jumped to 14.28 MPa at 45% (Fig. 5). Below this dosage there is too little dissolved silicate to form a continuous gel; above it a connected network forms and strength develops. This is consistent with reports on one-part geopolymers, where an insufficient activator dosage leaves the precursor incompletely dissolved and prevents the formation of an interconnected gel network, so strength remains low until dosage is high enough to build a continuous matrix [17].

Sodium carbonate at 45%, 60%, and 75%, together with sodium silicate at 75%, were strongest at 7 days yet lost strength by 28 days, whereas sodium silicate at 45% and 60% continued to gain with age. This behavior may be associated with over-activation, in which the activator supplies more alkali than the forming gel can bind, so the excess remains mobile in the pore solution rather than incorporated into the network [18]. Visible efflorescence was observed on these specimens, the surface expression of that free alkali migrating and carbonating, and the accompanying leaching increases porosity and destabilizes the gel, lowering strength over time [17-18-19]. Where the alkali is instead more fully consumed into the gel, the mortars densify and strengthen with age. Early-age and long-term strength therefore diverge only once dosage exceeds what the gel can bind, so for sodium silicate the best dosage was not the one with the highest early strength.

Potassium silicate produced the most consistent dosage response of the set: strength rose to a maximum at 45% dosage and held that level, changing little between 7 and 28 days at any dosage. This age stability indicates that its gel forms early and does not continue to restructure, so the binder is essentially complete by the first test age. The choice of alkali cation is known to affect precursor dissolution, gel structure, and aluminum incorporation, with the potassium cation, being larger and of lower charge density, associating more easily with silicate and aluminosilicate in solution [15].

Among the non-silicate activators, sodium carbonate produced the highest strength, its 28-day values rising steadily with dosage from about 0.8 MPa at 15% to 7.86 MPa at 75%. This gradual gain, rather than the sharp threshold seen with sodium silicate, may be related to sodium carbonate being a weaker activator whose lower pore-solution alkalinity slows precursor dissolution [20].

The hydroxide and sulfate activators formed only weak binders. Sodium hydroxide reached its highest 28-day strength of 3.85 MPa at 30% and fell as dosage rose, failing to harden at all at 75%; this might be due to the absence of a silicate source, which leaves the gel silica starved so that adding more alkali does not improve condensation [16]. Potassium hydroxide developed almost no strength, not exceeding 0.35 MPa through 45% and reaching only 0.63 to 0.64 MPa at 60% and 75% by the final test age, where its late strength gain points to slow, incomplete gel formation. Sodium sulfate gave low but stable strengths, staying near 2.2 MPa at its higher dosages. It is a weak activator whose solution is only mildly alkaline, around pH 9 to 10, so it dissolves little of the precursor; its activation also depends largely on reaction with calcium, which a calcined clay contains very little of, leaving little gel to form [21].

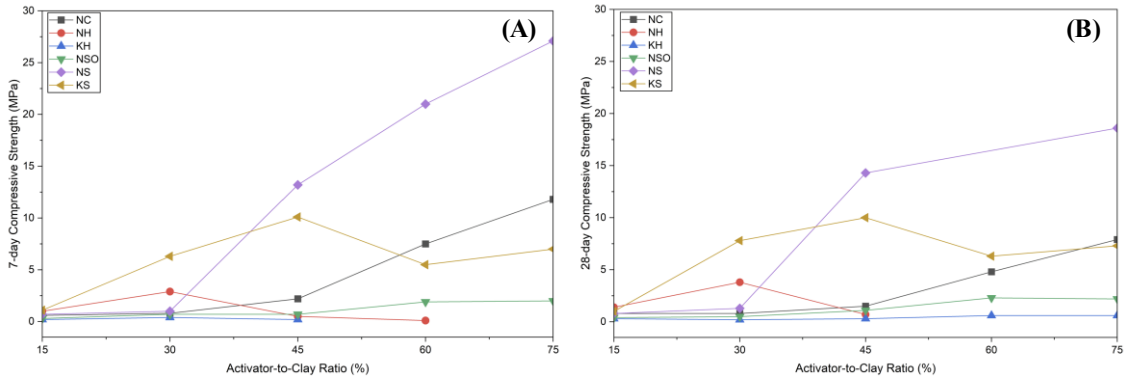

Fig. 5. Compressive strength of the calcined clay geopolymer mortars versus activator-to-clay ratio at (A) 7 days, (B) 28 days.

3.2 Flexural Strength

Flexural strength followed the same pattern as compressive strength. Sodium silicate gave the highest flexural strengths, reaching 6.74 MPa (NS-75) at 7 days, while no hydroxide or sulfate mix exceeded 1.11 MPa (NH-30) at any age (Table 4); the soluble silicate that builds a well-connected gel is also what carries tensile load and resists cracking [16].

Potassium silicate did not follow its compressive trend. At 28 days its compressive strength peaked at 45% (10.0 MPa), yet its flexural strength at that dosage was only 0.53 MPa, one of its lowest. Sodium silicate behaved oppositely: its flexural and compressive strengths increased together, and both peaked at 75% (6.28 and 18.56 MPa at 28 days). Sodium silicate reaching higher flexural strength than potassium silicate is consistent with metakaolin-based geopolymers, where sodium metasilicate has given higher flexural strength than potassium formulations [22].

3.3 Correlation Analysis

Spearman's rank correlation analysis presented in Table 5 showed the 28-day compressive strength was significantly related to several chemical parameters. The strongest positive relationships were found for the Si/Al, Ca/Si and Ca/(Si+Al) ratios, all of which were positively associated with 28-day strength at the same level of correlation. Significant positive correlations were also identified for Na/Al, Na_2O content, and activator ratio. These findings suggest that alkali availability, particularly together with the Si/Al ratio, was closely linked to strength development.

By contrast, clay content was negatively correlated with 28-day compressive strength. Since a higher clay ratio corresponds to a lower activator content, this negative correlation reflects the lower strength observed at higher clay replacement levels. A significant negative correlation was also observed between K_2O and compressive strength. For SiO_2, SO_3, CaO, MgO, S/Al and K/Al, however, the correlations were not statistically significant. Overall, the analysis indicates that Si/Al, the Ca-based molar ratios, Na/Al, Na_2O content and activator ratio were the parameters most closely associated with 28-day compressive strength in the mixtures investigated. These findings are in line with previous studies indicating that strength development in geopolymer binders is strongly influenced by alkali availability, Si/Al balance, and the contribution of Ca-bearing reaction products to the binding matrix [8-9].

Table 5. Spearman correlations of selected parameters with 28-day compressive strength

Parameter	Si/Al	Ca/Si	Ca/(Si+Al)	Na/Al	Na_2O	Activator Ratio	Clay Ratio	K_2O
Spearman's ρ	0.598	0.598	0.598	0.508	0.499	0.473	-0.467	-0.394
p-value	<0.001	<0.001	<0.001	0.007	0.008	0.013	0.014	0.042

4 Conclusions

This study evaluated six solid activators, each at five dosages, for one-part geopolymer mortars made from a low-grade Şile calcined clay. Activator type controlled strength more than dosage. The silicate activators gave by far the highest strengths, because a soluble silicate supplies the reactive silicate that drives gel condensation, whereas the hydroxide, carbonate, and sulfate systems depend on silicon released from the calcined clay alone. Sodium silicate developed strength as a threshold response, remaining weak at low dosage and rising sharply once enough soluble silicate was present, while the highest silicate and carbonate dosages lost strength with age as excess alkali effloresced. Sodium carbonate produced the highest strengths among the non-silicate activators, developing gradually with dosage. Potassium silicate reached high compressive strength but low flexural strength, and the hydroxide and sulfate activators formed only weak binders. Each activator had its own effective dosage window, so no single activator-to-clay ratio suited them all. The statistical analysis supported these trends, with alkali availability and the Si/Al and Ca-based ratios most closely associated with 28-day compressive strength. Overall, sodium silicate was the most effective activator tested, with activator type having a greater influence on one-part geopolymer performance than dosage.

Further work is needed to link these mechanical trends to the binder microstructure, to clarify the compression to flexure gap of the potassium silicate system and the calcium dependent behavior of the sulfate activator, and to assess the long-term durability of the most promising mixes.

Abstract. This study examined the influence of waste marble powder and polyvinyl alcohol (PVA) fibers on the fresh, physical, mechanical, thermal, and high-temperature properties of blast furnace slag-based geopolymer foam concrete. Nine different mixes were created by replacing marble powder with blast furnace slag at 0%, 20%, and 40% by weight, and adding PVA fibers at 0%, 0.6%, and 1.2% by volume. A standard amount of SLS-based foam, incorporating expanded perlite and activated with sodium metasilicate, was used, and the samples were cured at 75 °C for 24 h. Increasing the marble powder substitution resulted in a larger flow diameter, higher apparent porosity and water absorption, and reduced density and mechanical strength. The addition of PVA fibers reduced workability; however, a fiber content of 0.6% notably enhanced the structural integrity and mechanical strength of foam. The MP0-F0.6 mixture had the lowest apparent porosity of 16.43%, the highest density of 883 kg/m³, and achieved the greatest 28-day compressive and flexural strengths of 6.585 MPa and 0.78 MPa, respectively. The thermal conductivity ranged from 0.143 to 0.229 W/(m·K), with the lowest value observed in the MP40-F1.2 mixture. After high-temperature testing, MP0-F0.6 retained the highest strength, and MP20-F0.6 maintained approximately 61.5% of its original strength at 600 °C. Overall, 0.6% PVA was identified as the optimal fiber content for the best combination of physical, mechanical, and high-temperature properties of the composites.

Keywords: Geopolymer foamed concrete; waste marble powder; PVA fiber; thermal conductivity; high-temperature resistance.

1. Introduction

Rapid population growth and relentless urbanization worldwide have driven the demand for building materials in the construction sector to enormous levels. Currently, ordinary Portland cement (OPC), the most common and basic binder material, is responsible for approximately 8% of global carbon dioxide (CO_2) emissions due to limestone calcination and high fossil fuel consumption during its production [1,2]. In addition, cement production consumes natural resources and energy at extraordinary rates, causing irreversible damage to the ecosystems [3,4]. To promote environmental sustainability in construction and reduce the industry's carbon footprint, there has been an increasing shift towards eco-friendly binders that consume less energy and can replace OPCs. Geopolymer technology, introduced by French scientist Davidovits in the 1970s, has emerged as a leading and revolutionary alternative owing to its amorphous and semi-crystalline inorganic polymeric network [4,5]. Geopolymers are synthesized by reacting aluminosilicate-rich industrial wastes or byproducts, such as blast furnace slag, fly ash, silica fume, and metakaolin, with alkaline activators such as sodium

hydroxide and sodium silicate [6,7]. This polycondensation reaction (geopolymerization) can occur at low temperatures and has the potential to reduce CO_2 emissions by 70% to 80% compared to OPC production [8]. Geopolymer systems derived from blast furnace slag (BFS) can cure rapidly at room temperature owing to their high calcium levels. They develop a dense gel network of C-A-S-H/N-A-S-H, providing excellent early strength and resistance to chemical corrosion [6,9].

Advances in traditional concrete technology have paved the way for the development of geopolymer foam concrete (GFC) to meet the need for lightweight, highly insulating building elements. GFC is an innovative, ultra-lightweight material in which controlled air voids are trapped within its cellular structure using chemical (e.g., hydrogen peroxide) or mechanical foaming agents [10,11]. Geopolymer foam concretes are specialized composites that combine the low dry density (typically 280–1000 kg/m^3), superior thermal insulation, and high acoustic damping capacity of traditional lightweight concretes with the chemical, mechanical, and thermal stability of geopolymers [12]. GFC offers an ideal range of solutions for partition walls, roof insulation panels, sound barriers, and lightweight building elements in sustainable architecture and energy-efficient buildings [13–15]. However, the intentionally high void ratio in the matrix significantly decreases the mechanical strength of the material, including its compressive and flexural capacities. Additionally, the spongy characteristics of the matrix make it more brittle [16,17]. Maintaining the stability of fresh foam without collapse and without loss of load-bearing capacity in the hardened material are the most significant drawbacks of the widespread commercial-scale production of GFCs [3,17].

To address the mechanical limitations of GFC and advance environmental sustainability alongside economic benefits, it is crucial to incorporate industrial waste (solid waste materials) into geopolymer production systems, in addition to using binders or aggregates [8,11]. In this context, recent academic research has focused on the use of waste marble powder (MP) [18]. Worldwide, quarrying and the marble sector produce millions of tons of marble slurry and fine dust each year from cutting and polishing. The mismanagement of such waste causes groundwater contamination, reduces soil permeability, destroys agricultural soil, and poses considerable health problems due to air pollution [15,19]. The use of marble dust as an additive or replacement for some precursors in fly ash geopolymer cement (GFC) matrices solves the problem of environmental waste management and minimizes ecological impact [14,15]. Because of its very small particle size, the main role of the marble powder is as a micro-filler, filling the interparticle voids and resulting in denser foam walls [18]. In addition, because of its high calcium carbonate content, it may promote gel nucleation at an early age [18]. On the other hand, marble powder possesses low reactivity; in larger amounts, it might result in the dilution of aluminosilicate gels, thus preventing the process of geopolymerization and decreasing the amount of the main binder [20]. Determining the optimal waste substitution ratio is essential for balancing fresh workability, such as rheological fluidity, with hardened physical strength [14,19].

However, the problem of matrix is brittle owing to the stress concentration inherent to the mechanical voids and cellular structure. This problem can be addressed by introducing reinforcing fibers into the composite material [21,22]. There are three types of fibers: synthetic, inorganic, and natural. However, Polyvinyl Alcohol (PVA) fibers constitute a unique reinforcing element for alkali-activated geopolymeric systems owing to their high tensile strength, high modulus of elasticity, and high resistance to corrosion in alkali environments [23]. The main feature of PVA fibers is the possibility of creating a reliable chemical bond and a high-friction interface (interfacial transition zone—ITZ) between the fibers and inorganic

matrix owing to the presence of hydroxyl groups on the PVA fiber surface [24]. PVA fibers can prevent crack formation in the matrix, limit matrix movements, and physically stop crack propagation with the help of the fiber bridging mechanism when using a specific volume fraction of fibers (from 0.2% to 1.2%) [21,22]. This avoids sudden brittle fractures in GFC, making the composite more ductile and capable of absorbing deformations [21]. Thus, the compressive, flexural, and splitting tensile strengths of the material increased, whereas its impact toughness improved dramatically [21]. However, owing to the hydrophilic nature of PVA fibers, excessive use can significantly reduce the workability of fresh mortar by absorbing free water. This can result in fiber balling and the formation of additional voids, which ultimately cause mechanical performance issues [23]. Therefore, to optimize the integrity of the foam walls, analyses of the fiber size and volumetric dosage must be performed with extreme precision.

Geopolymer technology clearly demonstrates the extraordinary benefits and opportunities for recovering inorganic industrial wastes. However, there is a significant lack of systematic research in the literature that addresses the synergistic and antagonistic interactions created simultaneously by high substitution rates of waste marble powder (20% and 40%) and various dosages of PVA fiber (0.6% and 1.2%) in slag-based geopolymer foam concrete. The volumetric threshold values at which potential strength reductions caused by the dilution effect of waste marble dust can be offset by the energy-absorbing bridging mechanisms of PVA fibers, and how the material preserves its structural stability under different thermal and mechanical stresses, such as high-temperature shocks up to 600 °C, in a complex cellular system with lightweight aggregates (expanded perlite), have not yet been thoroughly documented. This study aims to determine the optimal mix design for an innovative geopolymer foam concrete that uses blast furnace slag and waste marble powder as binders, expanded perlite as aggregate, and PVA fiber for reinforcement. This study explores how varying marble powder and PVA fiber ratios affect the workability, physical properties such as porosity and water absorption, mechanical strengths such as compressive and flexural strength, and resistance to high temperatures. The aim was to create a sustainable insulation and building material characterized by low carbon emissions, an ultra-lightweight design, high fire resistance, and improved ductility. This approach promotes a circular economy by repurposing industrial marble waste into valuable products.

2. A Subsection Sample

2.1.Raw materials

In this experiment, BFS was used as the primary source of aluminosilicates, with waste marble powder (MP) as its partial replacement. BFS is a waste material known for its glassy phase and large amounts of CaO, SiO_2, Al_2O_3, and MgO, as well as its high reactivity in alkaline media. Alkali activation allows the dissolution of the slag and the formation of binders' reaction products, namely C-(A)-S-H, which helps the foam concrete gain mechanical strength through pore wall reinforcement. MP is a finely divided waste material that primarily contains calcite from the processing of marble blocks. For alkali-activated systems, its role is primarily to fill empty spaces, increase grain packing, and provide nucleation centers to create a more homogeneous matrix and dense pore walls. Higher amounts of MP may have a diluting effect and decrease the volume of the binder gel due to the lower reactive slag content. Therefore, waste marble powder was used to replace BFS at 20% and 40% by weight in this study. The chemical compositions of BFS and MP, determined by XRF, are presented in Table 1, and their mineralogical properties, determined by XRD, are presented in Figure 1.

Table 1. Chemical composition of BFS and MP

	SiO_2	Al_2O_3	Fe_2O_3	CaO	Na_2O	K_2O	MgO	SO_3	LOI
BFS	37.5	10.1	3.5	35.6	0.2	0.6	11.5	0.3	0.6
MP	0.2	0.2	0.1	54.3	0.1	0.2	0.4	0.1	44.3

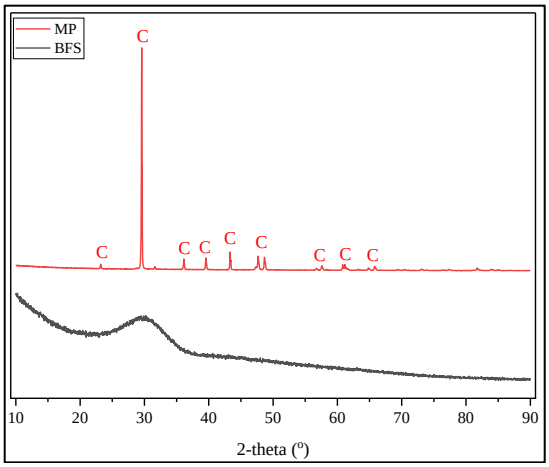

Fig. 1. Mineralogical properties of BFS and MP (C: Calcite)

In this study, expanded perlite with a particle size of 0-4 mm was used as a lightweight aggregate. The bulk density of perlite is 0.22 g/cm³, while the water absorption rate by weight is 147%, owing to its open and interlinked porous nature. The low specific gravity of perlite decreases the volume weight of the composite and improves the lightweight concrete properties of the composite. Simultaneously, the porosity of perlite provides more thermal insulation. The solid alkali activator sodium metasilicate (Na_2SiO_3) was used for the geopolymerization process; its specific gravity was 2.61, and it contained 53% SiO_2 and 46% Na_2O. Sodium lauryl sulfate (SLS), also known as sodium dodecyl sulfate (SDS), served as the foaming surfactant. SLS is a synthetic anionic surfactant with the chemical formula $C_{12}H_{25}NaO_4S$. In this study, 12 mm long polyvinyl alcohol (PVA) fibers were used to improve the crack control and mechanical integrity of geopolymer foam concrete. The technical properties of the PVA fibers are listed in Table 2.

Table 2. Technical properties of PVA fiber

Length (mm)	Diameter (μm)	Density (g/cm^3)	Young's modulus (GPa)	Tensile strength (MPa)	Elongation (%)
12	40	1.3	40	1500	6.5

2.2. Mix design

This study prepared nine different mixtures by varying the replacement level of blast furnace slag with MP at 0%, 20%, and 40% (by mass). PVA fibers were added at concentrations of 0%, 0.6%, and 1.2% (by volume) to the concrete. All mixtures maintained a constant total of 750 kg/m³ for BFS and MP, with water and sodium metasilicate kept constant at 300 and 150 kg/m³, respectively. The PVA fiber amounts of 0.6% and 1.2% by volume corresponded to 7.8 and 15.6 kg/m³, respectively. The expanded perlite content was adjusted to 67.3–70.9 kg/m³ to ensure volumetric balance. The detailed mixture compositions are listed in Table 3.

SLS was used as a foaming agent. The foaming solution was prepared by adding 5% SLS (50 g) to 1 L of water, and the resulting solution was foamed using a mechanical mixer. The wet density of the foam was approximately 120 g/L. To ensure comparability among the mixtures,

the foam quantity was kept constant across all series and added to the fresh mixture at a rate of 30 kg/m³.

Table 3. Mixing ratios and material amounts

Mix ID	Mix ratio (%)		Material amounts (kg/m³)						
	MP	PVA fiber	BFS	MP	Water	Sodium metasilicate	Expanded perlite	PVA fiber	Foam
MP0-F0	0	0	750	0	300	150	70.9	0.0	30
MP20-F0	20		600	150	300	150	70.2	0.0	30
MP40-F0	40		450	300	300	150	69.4	0.0	30
MP0-F0.6	0	0.6	750	0	300	150	70.2	7.8	30
MP20-F0.6	20		600	150	300	150	69.5	7.8	30
MP40-F0.6	40		450	300	300	150	68.4	7.8	30
MP0-F1.2	0	1.2	750	0	300	150	69.3	15.6	30
MP20-F1.2	20		600	150	300	150	68.1	15.6	30
MP40-F1.2	40		450	300	300	150	67.3	15.6	30

2.3. Mixing, Casting and Curing

To prepare the mixtures, BFS, MP, sodium metasilicate, and expanded perlite were mixed until a homogeneous distribution was achieved. Water was then added to the system, and mixing continued until the binder slurry attained a uniform consistency. In mixtures containing PVA fibers, the fibers were added to the mixture in stages to prevent clumping and ensure homogeneous distribution within the matrix.

Pre-prepared SLS-based foam with a wet density of approximately 120 g/L was used at 30 kg/m³ in all mixtures. To protect the pore structure of the foam and minimize air loss, it was added at the final stage of mixing and stirred at a low speed until evenly distributed. The fresh geopolymer foam concrete mixes were then poured into the test molds and smoothed on the surface. These specimens underwent thermal curing at 75 °C for 24h to accelerate geopolymerization. After curing, the specimens were demolded and stored in a laboratory setting until testing.

2.4. Test methods

The workability of the geopolymer foam concrete in its fresh state was determined using a spread-table test conducted in accordance with ASTM C1437, and the results were recorded as the flow diameter (mm). Apparent porosity and oven-dried density tests were conducted on 28-day-old cubic specimens measuring 50 mm × 50 mm × 50 mm. After drying the specimens at 50 °C for 3 days, their dry masses were determined. Subsequently, the masses of the specimens, both on the saturated surface and in water, were measured after they were saturated with water. The apparent porosity was calculated as the ratio of the volume of water-absorbing accessible voids to the total volume of the samples, and the results are expressed as percentages (%). The oven-dried density was calculated by dividing the dry sample mass by the solid volume and expressed in kg/m³.

The water absorption test was conducted on 28-day-old cubic specimens measuring 50 mm × 50 mm × 50 mm. The samples were dried at 50 °C for 3 days to determine their dry mass and then saturated with water. The water absorption rate was calculated as the difference between the saturated and dry masses divided by the dry mass and expressed as a percentage (%). The capillary water absorption test was conducted according to the TS EN 1015-18 standard. Only the bottom surfaces of the dried specimens were brought into contact with water, and the mass

increase at specific time intervals was recorded. The capillary water absorption behavior was determined based on the surface area in contact with water. The capillary water absorption of the specimens was determined after 24h. The physical parameters, such as water absorption, apparent porosity, and oven-dry density, were determined in accordance with the ASTM C642 standards. The thermal conductivity of the specimens was determined in accordance with ASTM C518 for 28-day-old specimens, whose size was 200 mm × 200 mm × 30 mm. Before performing the measurements, the specimens were dried in an oven at 50 $^{\circ}C$ for three days. The measurement was performed using a heat flux meter, and the results were obtained in W/(m.K).

Flexural and compressive strength tests were conducted on the specimens at 7 and 28 days. The flexural strength was measured on prismatic specimens measuring 40 × 40 × 160 mm in accordance with ASTM C348. Compressive strength tests were performed on the broken fragments from the flexural tests, in accordance with ASTM C349. The test results were reported in MPa.

High-temperature tests were performed on 28-day-old cubic specimens measuring 50 mm × 50 mm × 50 mm. The samples were heated in a laboratory muffle furnace at 10 °C/min to temperatures of 200, 400, and 600 °C. After the samples reached the target temperature, they were left to stand for 1 h and then allowed to cool inside the oven. Their masses were recorded before and after heating to assess weight loss, and the compressive strengths were measured post-exposure. The results were analyzed by comparing them with those of samples kept at the reference temperature.

3. Results and Discussions

3.1. Fresh properties

The spreading diameters of the mixtures ranged from 125 to 164 mm (Fig. 2). The spreading diameter of the reference mixture MP0-F0 was 149 mm, while in the fiber-free series, this value reached 156 mm (4.7% increase) and 164 mm (10.1% increase) by increasing the marble powder substitution to 20% and 40%, respectively. The maintenance of a similar increasing trend at both fiber levels indicates that marble powder improves the fluidity of the fresh mixture owing to its lower reactivity and physical effect of reducing friction between particles. The literature also reports that the spreading diameter increases with increasing marble powder content in BFS-marble waste-based alkali-activated systems [25].

In contrast, increasing the PVA fiber content significantly reduced the spreading diameter of the droplets. In the series without marble powder, 0.6% and 1.2% PVA reduced the spreading diameter by 5.4% and 16.1%, respectively, compared with that of the reference. The same trend was observed for the MP20 and MP40 series. This reduction can be explained by the hydrophilic PVA fibers with a high specific surface area retaining mixing water and by interfiber interactions that increase internal friction and limit the paste's free movement. Shah et al. reported that PVA fibers reduced the spreading of single-component alkali-activated mortars, depending on the fiber dosage [26]. Overall, marble powder partially offset the workability loss caused by PVA; however, the PVA fiber ratio was the determining parameter for the fresh-state behavior.

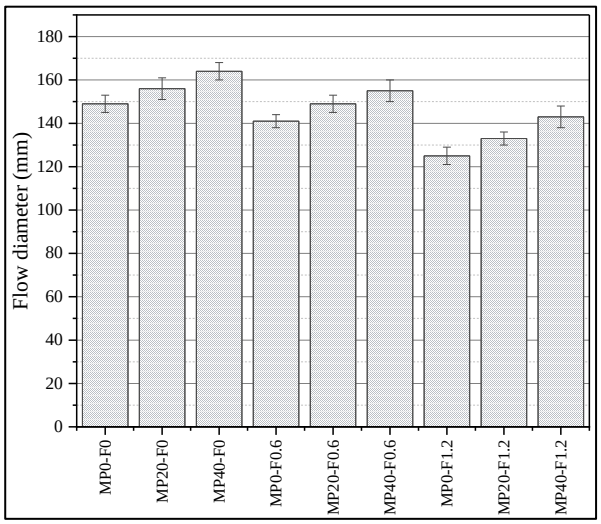

Fig. 2. Flow diameters of geopolymer foams

3.2. Physical Properties

The apparent porosities of the mixtures ranged from 16.43% to 41.43%, and their oven-dry densities ranged from 558 to 883 kg/m³ (Fig. 3). In the fiber-free series, increasing the marble powder ratio to 20% and 40% increased the apparent porosity by 16.7% and 41.8%, respectively, compared with the MP0-F0 reference, and decreased the oven-dry density by 4.7% and 7.4%. This trend can be explained by the dilution effect of the reduced reactivity of BFS at high marble powder ratios, the dominance of the filling effect of the marble powder, and a decrease in the volume of the binder gel that forms the pore walls. It has been reported that low marble powder ratios can improve the pore structure in alkali-activated slag systems; however, porosity and water absorption can increase again at ratios above 20% [18].

The effect of PVA fiber was particularly pronounced at 0.6% PVA fiber content. In the MP0-F0.6 mixture, the apparent porosity decreased by 43.8% to 16.43% compared to that of the reference, while the oven-dry density increased by 34.2% to 883 kg/m³. This suggests that an appropriate fiber ratio increases the cohesion of the fresh mixture, creating more compact pore walls and a less connected open-pore structure. However, increasing the fiber ratio to 1.2% increased the porosity of the same mixture to 25.62%, and the density decreased to 766 kg/m³. The irregular distribution of fibers, agglomeration, and formation of additional voids at the fiber-matrix interface may have contributed to this change at high fiber content. It has been previously reported that PVA fibers can increase pore connections in alkali-activated slag matrices, and that the fiber effect depends on the interface properties [27].

Generally, increasing the marble powder proportion at all fiber levels led to higher porosity and lower density. The lowest density recorded was 558 kg/m³ in MP40-F1.2, whereas the highest porosity was 41.43% in MP40-F0. However, because apparent porosity only measures open, water-accessible voids, a direct inverse correlation with density is not always expected for every mixture [27]. The water absorption values by immersion ranged from 14.56% to 37.65%, and the capillary water absorption values ranged from 11.35–23.46 kg/m² (Fig. 4). Increasing the proportion of marble powder in the fiber-free series negatively affected both properties of the samples. Compared to the reference MP0-F0, immersion and capillary water absorption increased by 32.2% and 12.5% in the MP20-F0 mixture and by 53.4% and 40.7% in the MP40-F0 mixture, respectively. This result can be attributed to the decrease in the amount of reactive BFS with marble powder substitution, weakening of the binder gel continuity, and increase in the associated open pore volume. It has been similarly reported that high proportions of marble

powder in alkali-activated slag systems can increase porosity and water absorption owing to the dilution effect [18].

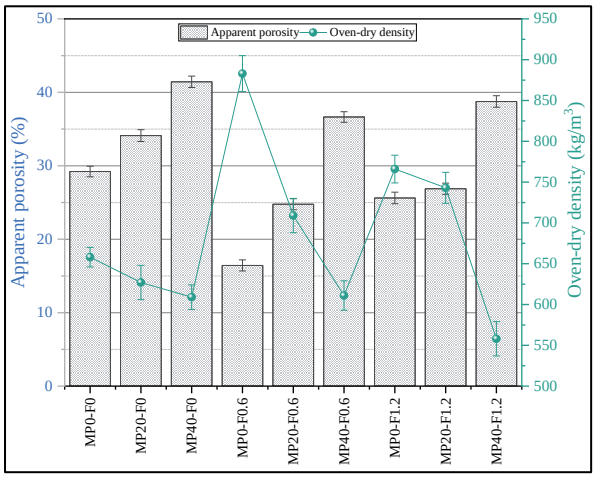

Fig. 3. Apparent porosity and oven-dry density of geopolymer foams

The most significant effect of PVA fibers was observed at a fiber volume ratio of 0.6% and in the MP0-F0.6 blend; immersion and capillary water absorption decreased by 40.7% and 31.9%, respectively, compared with the reference, reaching the lowest values among all the blends. Similarly, in the MP20 series, 0.6% PVA reduced water absorption and capillary water absorption by 31.8% and 10.6%, respectively, compared with those of the fiber-free counterpart. In the MP40 series, the reductions were 17.1% and 10.0%. This improvement can be explained by the appropriate fiber ratio, which enhances blend cohesion and foam stability, tightens pore walls, and limits associated capillary pathways.

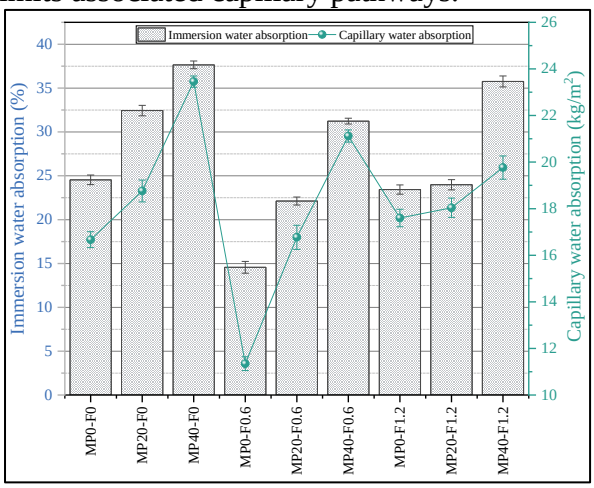

Fig. 4. Immersion and capillary water absorption

Increasing the fiber content to 1.2% did not provide the same level of improvement. In particular, the capillary water absorption of the MP0-F1.2 mixture was 5.6% higher than that of the reference. The decreased workability at high fiber contents, irregular fiber distribution, and connected passage paths formed at the fiber-matrix interfaces may have influenced this behavior. It has also been reported that PVA fibers can increase capillary pore connectivity in alkali-activated slag matrices [27]. In general, the results were consistent with the apparent porosity values, and the best water impermeability performance was obtained with the MP0-F0.6 mixture. In contrast, the worst performance was obtained with the MP40-F0 mixture.

3.3. Thermal performance

The thermal conductivities of the mixtures ranged from 0.143 to 0.229 W/(m·K). In the fiber-free series, adding 20% and 40% marble powder decreased the thermal conductivity by 6.1% and 9.2%, respectively, compared to that of MP0-F0 reference (Fig. 5). This decrease correlates with a reduction in the oven-dry density from 658 kg/m³ to 627 and 609 kg/m³, and an increase in the apparent porosity. The presence of air in the pores, combined with disrupted heat transfer pathways in the solid matrix, enhanced the insulation properties of the marble powder-containing mixtures. The literature also indicates that the thermal conductivity of geopolymer foams is heavily influenced by the pore amount, size, and distribution, as well as the overall density [28,29].

The effect of the PVA fibers was nonlinear. In the MP0-F0.6 mixture, the thermal conductivity increased by 40.5% relative to that of the reference, reaching a maximum of 0.229 W/(m·K). This result can be explained by the fact that 0.6% PVA stabilized the foam structure, reduced the apparent porosity, and increased the density to 883 kg/m³. Increasing the fiber ratio to 1.2% again decreased the density, reducing the thermal conductivity of the MP0-F1.2 mixture to 0.193 W/(m·K). However, the fiber effect is not solely dependent on fiber content; fiber distribution, foam stability, and pore interconnectivity are also important factors.

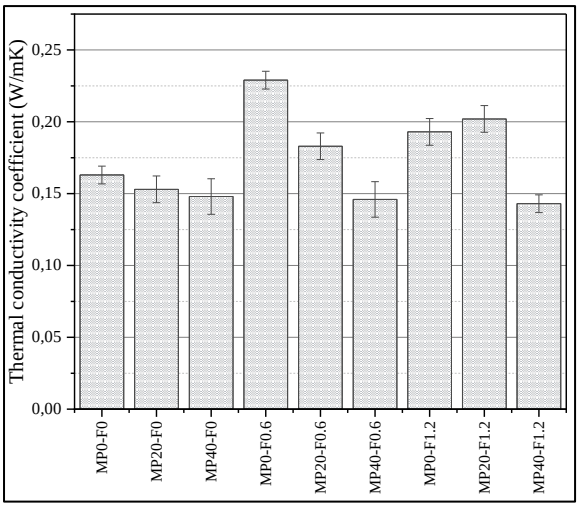

Fig. 5. Thermal performance of geopolymer foams

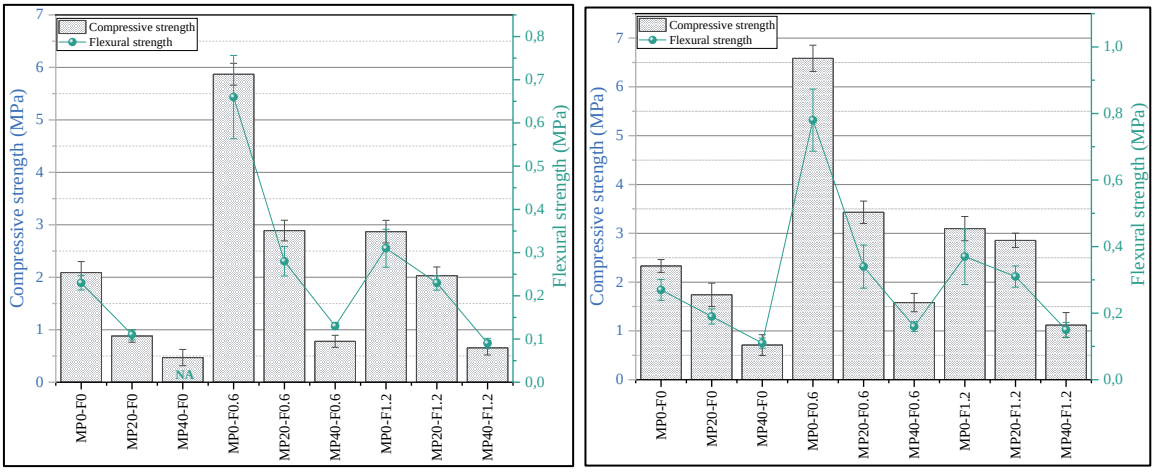

The lowest thermal conductivity, 0.143 W/(m·K), was observed for the MP40-F1.2 mixture. The combined evaluation of the data showed a strong positive correlation between thermal conductivity and oven-dry density and a strong negative correlation with apparent porosity. Therefore, in the system studied, the thermal performance was primarily determined by changes in the density and pore structure created by these components, rather than by the direct effects of PVA or marble powder.

3.4. Mechanical properties

In all mixtures, the 28-day strengths were found to be increased compared to the 7-day values (Fig. 6a). This increase indicates that the alkali activation reactions and binder gel formation continued even after 24h of heat curing at 75 °C. However, while the improvement between 7 and 28 days was more limited in strong and dense mixtures, the proportional increase was higher in mixtures containing marble powder; however, this increase could not compensate for the lower initial strengths. In the fiber-free series, substituting marble powder significantly reduced the mechanical performance. The 28-day compressive and flexural strengths of reference MP0-F0 were 2.33 and 0.27 MPa, respectively (Fig. 6b). In MP20-F0, these values

decreased by 25.3% and 29.6%, respectively, and in MP40-F0, by 69.5% and 59.3%, respectively. This behavior can be explained by the dilution effect from the reduced reactive slag as the marble powder ratio increases, the weakening of binder gel continuity, and the increased porosity observed in previous results. It has been reported that low marble powder ratios can provide a filling effect in alkali-activated slag systems. However, strength decreases at high substitution ratios owing to increased porosity and dilution of the slag [18,30].

The most significant effect of the PVA fibers was observed at a volumetric percentage of 0.6%. The 28-day compressive and flexural strengths of the MP0-F0.6 mixture were 6.585 and 0.78 MPa, respectively, representing increases of approximately 183% and 189% compared with the reference. This improvement is attributed to the 0.6% PVA bridging microcracks and maintaining the integrity of the foam walls, as well as the mixture's lowest apparent porosity and highest density. The literature also reports that PVA fibers can improve the compressive and, in particular, flexural performance of single-component alkali-activated systems [26].

(a) 7 days (b) 28 days

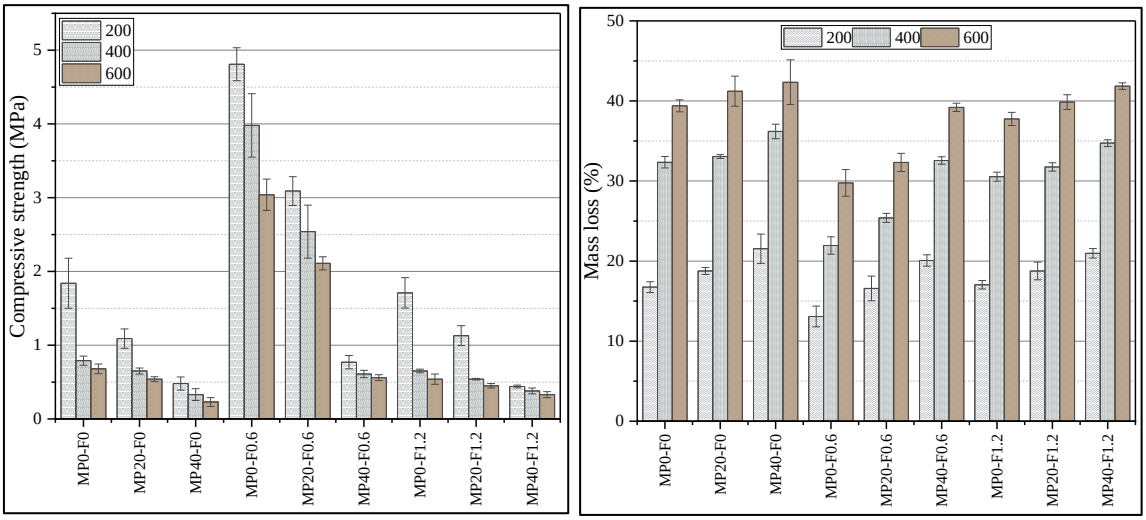

Fig. 6. Mechanical properties of geopolymer foams

Increasing the fiber content to 1.2% increased the strength compared to fiberless mixtures at all marble powder levels; however, it was not as effective as 0.6%-PVA. For example, the 28-day compressive strength of MP0-F1.2 was 3.10 MPa, and its flexural strength was 0.37 MPa. The reduction in flow diameter at high fiber contents, irregular distribution of fibers, and additional voids at the fiber-matrix interface may have limited the fiber-bridging effect. Overall, the highest mechanical performance was obtained with the MP0-F0.6 mixture, and the lowest 28-day performance was obtained with the MP40-F0 mixture. As the 7-day flexural strength of the MP40-F0 mixture could not be determined, this value was not included in the comparison.

3.5. High-temperature resistance

As the temperature increased from 200 to 600 °C, all mixtures showed a gradual decline in compressive strength, along with increasing mass loss (Fig. 7). This trend is attributed to the removal of free and bound water, the dehydration of alkali activation products, and the development of microcracks caused by thermal mismatch. In the series without fibers, a higher marble powder content led to a lower compressive strength. For instance, at 600 °C, the strengths of MP0-F0, MP20-F0, and MP40-F0 were 0.68, 0.54, and 0.23 MPa, respectively. Correspondingly, their mass loss increased from 39.39% to 42.34%. The initial porosity from high marble powder levels and limited BFS weakened the matrix at high temperatures. Additionally, the decomposition of some loosely crystallized carbonate phases at higher temperatures may have contributed to mass loss [31,32]. The most significant positive impact

of PVA fibers was observed at a volume concentration of 0.6 %. The MP0-F0.6 mixture exhibited the highest strengths at 200, 400, and 600 °C, with values of 4.81, 3.98, and 3.04 MPa, respectively. Conversely, the MP20-F0.6 mixture exhibited the greatest strength retention relative to its initial strength, maintaining about 90.1%, 74.1%, and 61.5% at those temperatures. The improved thermal performance is attributed to the more balanced pore structure created by the moderate marble powder and 0.6% PVA, along with its low thermal conductivity and fiber-bridging mechanism, which inhibited thermal damage progression.

(a) Compressive strength (b) Mass loss

Fig. 7. Mechanical and physical properties of geopolymer foams exposed to high temperatures.

Increasing the fiber ratio to 1.2% negatively affected the high-temperature performance of the asphalt mixture. PVA fibers melt or decompose at approximately 220 °C, creating voids and vapor release channels within the matrix. While these channels can reduce the risk of explosive spillage, they lead to the loss of the fiber bridging effect and an increase in porosity [27,33]. Therefore, significant strength losses were observed in mixtures containing 1.2% PVA, particularly after 400 and 600 °C. In general, 0.6% PVA was the optimum fiber ratio in terms of limiting mass loss and maintaining compressive strength, whereas increasing the marble powder content to 40% weakened the high-temperature performance at all fiber contents.

4. Conclusions

This study examined the influence of waste marble powder and PVA fibers on the performance of blast furnace slag-based geopolymer foam concretes. The key findings are summarized as follows:

- The substitution of marble powder increased the flow diameter, whereas the addition of PVA fibers reduced the workability of the mixtures. Marble powder partially compensated for the fluidity loss caused by the addition of fibers.
- Increasing the proportion of marble powder increased the apparent porosity and water absorption, while decreasing the density. The MP0-F0.6 mixture, which contained 0.6% PVA by volume, exhibited the highest density and lowest porosity and water absorption. Increasing the fiber ratio to 1.2% did not yield similar improvements.
- The thermal conductivity coefficients ranged from 0.143 to 0.229 W/(m·K) and were mainly influenced by the density and pore structure. The lowest value was observed for the MP40-F1.2 mixture.

- Although replacing marble powder reduced the mechanical strength, adding 0.6% PVA fiber significantly improved it. The 28-day compressive strength of the MP0-F0.6 mixture was 6.585 MPa, and its flexural strength was 0.78 MPa, which were approximately 183% and 189% higher than those of the reference, respectively.
- As the temperature increased, all the mixtures exhibited a decrease in compressive strength and an increase in mass loss. The MP0-F0.6 mixture exhibited the highest strengths, and MP20-F0.6 retained approximately 61.5% of its initial strength at 600 °C.

The 0.6% PVA fiber ratio was found to be optimal for the physical, mechanical, and high-temperature performance. MP0-F0.6 emerged as the best overall mixture, whereas MP20-F0.6 was ideal for applications requiring both waste utilization and high-temperature resistance.

Abstract. Cement is one of the most widely used materials in the world. In this context, efforts to reduce the carbon footprint in cement production have increased. Pozzolanic materials are actively used in the cement industry for this purpose. However, the frequent use of pozzolanic materials has raised the possibility of their depletion in the coming years. Industrial hemp is one type of bio-based product that has potential as a pozzolanic material. This study investigated the usability of powders obtained from two different hemp plant genders as a supplementary material for cement. The water-to-cement ratio of the cementitious mortars was adjusted to 0.3 and 0.7. Hemp powders were used in the mixture at three different ratios as, 1%, 3%, and 5%. The physical and mechanical properties of the cementitious composites were determined by spreading, unit weight, compressive, and flexural strength tests. It has been observed that as the amount of hemp powder products in cementitious mortars increases, the spread and unit weight values decrease. Similarly, as the amount of hemp powder products increases, the flexural and compressive strength of the mortars decreases. As a result, it has been determined that hemp powders can be used as an aggregate rather than as a binder in cementitious composites.

Keywords: Hemp powder; Cement; Mortar; Mechanical Properties.

1 Introduction

Previous studies have demonstrated the potential use of various waste-derived powders as binders or fillers in cement-based composites. A study [1] investigated the feasibility of incorporating agricultural waste ashes, including rice husk, hazelnut shell, sunflower, and corn ashes, as partial cement replacements at substitution levels of 2–10%. Among the investigated materials, hazelnut ash exhibited a flexural strength of 7 MPa and a compressive strength of 15 MPa, indicating its potential applicability in cement-based construction materials.

Tuyan investigated the production and performance of geopolymer paste, mortar, and concrete using various aluminosilicate materials, including natural pozzolans (zeolite and trass), waste brick powder, Class C fly ash, bottom ash, and Class F fly ash. The effects of alkali activator concentration, water-to-binder ratio, and curing conditions on the mechanical and durability properties of geopolymer mixtures were evaluated. Among the investigated binders, Class F fly ash-based mixtures exhibited the highest compressive strength, whereas zeolite-based mixtures showed the lowest. Binary binder systems incorporating Class F fly ash significantly improved the strength of mixtures containing waste brick powder, bottom ash, trass, or zeolite. In general, geopolymer concretes demonstrated higher bond strength with

reinforcement and lower drying shrinkage than conventional Portland cement concrete. The study also reported that increasing the Na_2O content and reducing the water-to-binder ratio enhanced compressive strength, while the influence of curing temperature and duration varied depending on the aluminosilicate source [2].

Mahmood investigated the use of waste polyvinyl chloride (PVC) fibers as reinforcement in cement mortars and evaluated their effects on fresh and hardened properties. PVC fibers were incorporated at volumetric contents of 0–3%, while silica fume and microsilica were used as partial cement replacements at replacement levels of 0–15%. The results showed that increasing the PVC fiber content reduced workability and fresh density while increasing porosity and water absorption. Although the addition of PVC fibers led to a reduction in compressive strength, higher fiber contents improved the ductility of the mortars by preventing sudden brittle failure. Mixtures containing silica fume exhibited lower water absorption and higher compressive and flexural strengths than both the control and microsilica-modified mixtures, with the highest compressive strength achieved in the mortar containing 15% silica fume without PVC fibers [3].

Malkoç investigated the influence of natural wollastonite as a partial cement replacement on the mechanical and durability properties of high-performance mortar. Wollastonite was incorporated at replacement levels of 3–15% while maintaining a constant water-to-binder ratio. Mechanical properties were evaluated through compressive strength, flexural strength, and ultrasonic pulse velocity tests, whereas durability was assessed using capillary water absorption and gas permeability tests. The results indicated that the incorporation of 3% wollastonite provided the greatest improvement in both strength and durability, while higher replacement levels resulted in a gradual reduction in performance, although 6% replacement still outperformed the control mixture. The enhanced performance was attributed to the needle-like morphology and high elastic modulus of wollastonite, which contributed to improved mechanical behavior and reduced capillary water permeability [4].

Mısır investigated the production of alkali-activated mortar using finely ground ferrochrome slag as the sole binder, eliminating the use of Portland cement. Marble powder (5–15%) and 0.5% glass fibers were incorporated as additives, while a combination of sodium hydroxide and sodium silicate ($NaOH/Na_2SiO_3$ = 1:2) served as the alkali activator at activator-to-binder ratios of 0.35–0.45. The mortars were evaluated for fresh, mechanical, durability, and microstructural properties. The results showed that the combined use of ferrochrome slag, marble powder, and glass fibers produced satisfactory performance, with the highest 28-day compressive strength of 21.09 MPa obtained for the mixture containing 10% marble powder at an activator-to-binder ratio of 0.35. The combined use of sodium hydroxide and sodium silicate was found to effectively enhance the binding performance of the alkali-activated mortar [5].

Bıçakcı investigated the durability performance of self-compacting concrete (SCC) containing limestone powder and fly ash as mineral admixtures. SCC mixtures were produced with constant cement and water contents while the mineral admixture content was varied, and their performance was compared with that of conventional concrete. Fresh properties and a comprehensive range of durability tests, including water absorption, chloride permeability, carbonation, electrical resistivity, freeze–thaw resistance, sulfate resistance, and water permeability, were evaluated. The results showed that increasing the mineral admixture content generally improved the durability of SCC. Fly ash mixtures exhibited superior durability compared with limestone powder mixtures in most tests, except for carbonation resistance.

Overall, SCC mixtures outperformed conventional concrete, demonstrating enhanced durability characteristics, particularly when fly ash was used as the mineral admixture [6].

Gülengül investigated the use of expanded glass as a partial replacement for natural sand in lightweight concrete at replacement levels of 0–20%. The effects of expanded glass on density, compressive strength, dynamic elastic modulus, thermal conductivity, and water absorption were evaluated. The results showed that increasing the expanded glass content reduced the density, compressive strength, elastic modulus, and thermal conductivity of the concrete, while maintaining the characteristics of structural lightweight concrete. The reduction in mechanical properties was attributed to the low density and strength of expanded glass aggregate. Nevertheless, the use of expanded glass provided significant benefits in terms of reducing structural dead load, improving thermal insulation, and promoting the recycling of waste glass, demonstrating its potential as a sustainable lightweight aggregate for concrete production [7].

Özdal investigated the effects of metakaolin, ground granulated blast furnace slag (GGBFS), and nano-sized TiO_2 on the mechanical properties of basalt aggregate concrete. Metakaolin and GGBFS were incorporated individually and in combination, while TiO_2 was used as a nano-filler. Compressive strength, flexural strength, and water absorption tests were conducted to evaluate concrete performance. The results indicated that the individual use of metakaolin or GGBFS provided better mechanical performance than their combined use. Furthermore, the incorporation of nano-TiO_2 enhanced the strength of the concrete, highlighting the potential of nano-materials to improve the performance of high-strength and durable cement-based composites [8].

Within the scope of this study, the use of powders obtained from the root and stalk parts of the hemp plant in cementitious composites was investigated. Hemp stalk and root materials were processed into powder and their potential use as binder or filler materials in cementitious composites was evaluated. In addition, the mechanical properties of the cementitious composites were investigated. Thus, the feasibility of using hemp-based products in cementitious composites in Türkiye was evaluated.

2 Material

CEM I 42.5 R type cement was used in the study. The chemical composition of the cement is presented in Table 1.

Table 1. Chemical composition of the cement.

Chemical composition	%
CaO	61.75
SiO_2	17.01
Al_2O_3	4.8
SO_3	3.75
Fe_2O_3	3.04
MgO	2.53
K_2O	1.23
Na_2O	0.249
LOI	4.86

In this study, crushed limestone sand with a particle size range of 0–5 mm, obtained from a crushed stone plant, was used. The specific gravity and water absorption of the limestone sand

were 2.6 and 1.95%, respectively. Polycarboxylate ether-based, high-range water-reducing/setting-accelerating superplasticizer (MasterGlenium 51) was used as a concrete admixture.

Hemp stalk and hemp root powders were used in mortar production. Within the scope of the study, two different gender of hemp plants, namely female and male plants, were used. Photographs of the hemp gender are presented in Figure 1.

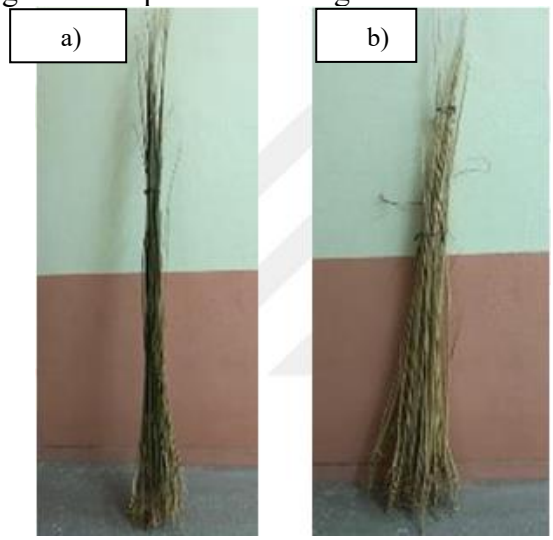

Fig. 1. a) Female hemp b) male hemp

The hemp stalk and hemp root were first cut into small pieces and subsequently ground into powder using a grinding machine. The powdered samples were sieved through a 0.063 mm sieve to obtain a fine particle size for the experimental study. The physical properties of the powdered samples are presented in Table 2.

Table 2. Physical Properties of the Hemp Powder Samples.

Hemp powder	Specific Gravity, kg/m^3	Water Absorption, %
Female root	1.43	242
Female stalk	1.02	225
Male root	1.15	258
Male stalk	0.96	276

Photograph of the hemp powder used in the study are shown in Figure 2.

Fig. 2. Hemp powder

Within the scope of the study, limestone sand mortars with water-to-cement (W/C) ratios of 0.3 and 0.7 were produced by replacing cement with hemp powder products at substitution rates of 1%, 3%, and 5%. The following examples are provided to explain the specimen designation used in the study.

DG3-1: A specimen in which female hemp stalk powder was substituted for cement at a rate of 1% in a mixture with a W/C ratio of 0.3.

EK7-3: A specimen in which male hemp root powder was substituted for cement at a rate of 3% in a mixture with a W/C ratio of 0.7.

The designations and quantities of the materials used in the study are presented in Table 3.

Table 3. Mortar mixture composition.

Specimen Code	Hemp Powder (g)	Cement (g)	Water (g)	Sand (g)	SP (g)
3K	-	450	135	1350	3.5

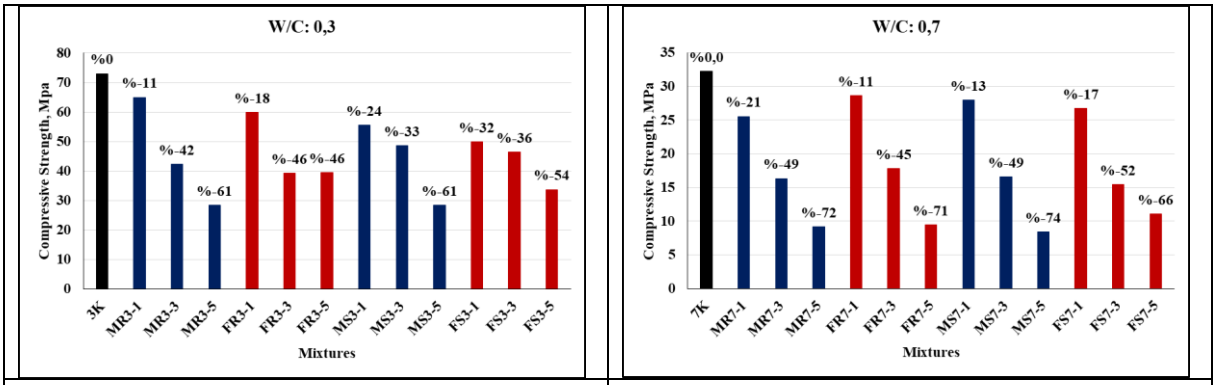
Within the scope of the study, a flow table test in accordance with TS EN 1015-3, a compressive strength test in accordance with TS EN 196-1, and flexural strength tests were

performed. Flexural strength tests were conducted on prismatic specimens with dimensions of 4 × 4 × 16 cm produced. The flexural strength tests were performed at a loading rate of 0.05 kN/s using three specimens from each mixture group. The test result was determined by taking the average of the results obtained from the three specimens.

Compressive strength tests were subsequently performed on the specimens obtained from the flexural strength tests. The compressive strength tests were conducted at a loading rate of 2.4 kN/s using a total of six specimens obtained by splitting the specimens into two pieces after the flexural strength test. The compressive strength was determined by taking the average of the results obtained from the six specimens.

3 Results

The graphs of the flow table test results are presented in Figure 3.



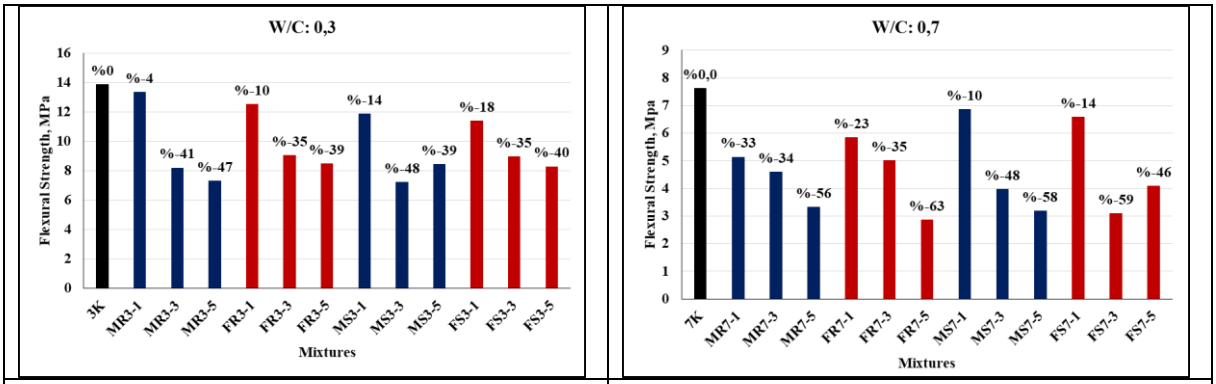
a) 0.3 W/C ratio b) 0.7 W/C ratio

Fig. 3. Spread test results.

For specimens with a W/C ratio of 0.3, the flow values of the mortars decreased as the volume of hemp powder increased. No significant difference was observed between the flow values of the reference specimen and those of the mixtures containing 1% hemp powder by volume. However, as the volume of hemp powder increased, a decrease in the flow values of the mixtures was observed. The results indicated that neither the female nor male hemp powder gender had a significant effect on the flow values. Similarly, no significant effect of hemp root or stalk powders on the flow values was observed. A chemical admixture was used to ensure adequate workability of the mixtures. The differences observed in the flow values are considered to be attributable to the use of the chemical admixture.

For specimens with a W/C ratio of 0.7, the flow values of the mixtures containing 5% hemp powder by volume decreased compared with the reference specimen. However, no change was observed in the flow values of the mixtures containing 1% and 3% hemp powder by volume. The results indicated that neither the female nor male hemp powder gender had a significant effect on the flow values. Similarly, no significant effect of hemp root or stalk powders on the flow values was observed.

The graphs of the compressive strength test results are presented in Figure 4.



a) 0.3 W/C ratio b) 0.7 W/C ratio

Fig. 4. Compressive strength test results.

For specimens with a W/C ratio of 0.3, the compressive strength values of the mixtures decreased as the volume of hemp powder increased. The compressive strength of the reference specimen was determined to be 73 MPa. The lowest reduction in compressive strength, 11%, was observed for the mixture coded MR3-1. No significant difference was observed between mixtures containing female and male hemp powders in terms of compressive strength. Similarly, neither hemp stalk nor hemp root powders were found to have a significant effect on compressive strength.

For specimens with a W/C ratio of 0.7, a decrease in the compressive strength of the mixtures was observed as the volume of hemp powder increased. The compressive strength of the reference specimen was determined to be 32.2 MPa. The compressive strength values of the hemp powder-containing mixtures were lower than that of the reference specimen. The lowest reduction in compressive strength, 11.2%, was observed for the mixture coded FR7-1. No significant effect of female and male hemp powders on the compressive strength was observed. Similarly, neither hemp stalk nor hemp root powders were found to have a significant effect on compressive strength.

The graphs of the flexural strength test results are presented in Figure 5.

a) 0.3 W/C ratio b) 0.7 W/C ratio

Fig. 5. Flexural strength test results.

For specimens with a W/C ratio of 0.3, the flexural strength values of the mixtures decreased as the volume of hemp powder increased. The flexural strength of the reference specimen was determined to be 13.85 MPa. In the mixtures containing 3% and 5% hemp powder, the flexural strength values decreased significantly compared with the reference specimen. The greatest reduction, 48%, was observed for the mixture coded MS3-3. No significant effect of female and male hemp powder on the flexural strength was observed. Similarly, neither hemp stalk nor hemp root powders were found to have a significant effect on flexural strength.

For specimens with a W/C ratio of 0.7, the flexural strength values of the mixtures decreased as the volume of hemp powder increased. The flexural strength of the reference specimen was determined to be 7.63 MPa. The flexural strength values of the hemp powder-containing mixtures were lower than that of the reference specimen. The greatest reduction, 62.7%, was observed for the mixture coded FR7-5. No significant effect of female and male hemp powders on the flexural strength was observed. Similarly, neither hemp stalk nor hemp root powders were found to have a significant effect on flexural strength.

4 Conclusion

The results obtained from the study are presented below.

As the volume of hemp powder products in the cementitious composites increased, a decrease in the flow values was observed. The greatest reduction in flow value, 13.3%, was observed in the mixtures containing 3% and 5% hemp powder. This decrease is considered to be attributable to the high water absorption capacity of the hemp powder products, which adversely affected the flowability of the mixtures.

As the volume of hemp powder products in the cementitious composites increased, a decrease in compressive strength was observed. The greatest reduction in compressive strength, 74%, was obtained in the mixtures containing 5% hemp powder and having a high W/C ratio.

As the volume of hemp powder products in the cementitious composites increased, a decrease in flexural strength was observed. The greatest reduction in flexural strength, 62.7%, was obtained in the mixtures containing 5% hemp powder and having a high W/C ratio.

In conclusion, the results indicate that hemp powders are not suitable for use as a partial replacement for the binder in cementitious composites. However, hemp powders may be considered for use as a partial replacement for aggregate in future studies. In addition, further research is recommended to determine the long-term performance of cementitious composites containing hemp powder.

Geopolymer concretes have been introduced as promising low-carbon alternatives to Ordinary Portland cement (OPC) due to their comparable mechanical performance and lower carbon dioxide (CO_2) emissions. However, the declining availability of conventional precursors such as fly ash and slag prompted the search for alternative materials. Stone wool kiln ash (SWKA), an industrial residue from mineral wool production, represents a potential alternative precursor due to its chemical similarity to traditional aluminosilicate materials. This study investigates the use of SWKA as a supplementary cementitious material in cement-based mixtures and as a substitute for ground granulated blast-furnace slag (GGBS) in geopolymer systems. Silica fume (SF) with a high content of amorphous silica was included in the mixture designs. Thus, cement was partially replaced with 30% SF, 30% SWKA, and 30% fly ash in cement-based mixtures. Geopolymer-based mixtures are composed of 60-100% GGBS, 0-10% SF, and 10-30% SWKA, and activated with sodium hydroxide (NaOH) at 15% by weight of the binder. Workability, setting time, compressive strength, and flexural strength tests were performed on fresh and hardened samples at 7 and 28 days. X-ray diffraction (XRD) was used to investigate the material characteristics. Results from cement-based mixtures indicated that SWKA exhibited pozzolanic activity. In geopolymer systems, 80% GGBS + 10% SF + 10% SWKA achieved the highest compressive strength (47.4 MPa) in 28 days, 18% higher than the 100% cement control mixture and 25% higher than 100% GGBS. SWKA content above the optimum level adversely affected the strength development.
Keywords: Geopolymer concrete, cement, silica fume, NaOH, stone wool kiln ash

1 Introduction

The continuous increase in CO_2 emissions has led to deteriorating environmental conditions and has significantly contributed to climate change by intensifying the greenhouse effect. Cement production accounts for about 7% of global CO_2 emissions [1], primarily due to clinker manufacturing and the calcination of limestone. Growing cities have led to the estimate that civil and architectural works would double, requiring a 25% increase in ordinary Portland cement (OPC) production by the 2030s [2]. Therefore, researchers have begun investigating sustainable, low-carbon construction materials, and geopolymers have emerged as a promising alternative.

Geopolymers utilize industrial by-products such as GGBS [3-5], silica fume [4-6], and fly ash [3-6], and may provide mechanical performance and durability comparable to that of ordinary cement. They are inorganic aluminosilicate materials from alumina- and silica-rich precursors activated by alkaline activators. Geopolymerization consists of three main stages: dissolution, reorientation, and finally polycondensation. Polycondensation leads to gel

formation (N-A-S-H, C-A-S-H) from dissolved species, resulting in a three-dimensional aluminosilicate network that depends on the precursor composition.

GGBS is one of the most widely used precursors in alkali-activated systems. Its high calcium content promotes the formation of dense reaction products due to its rapid reactivity under alkaline conditions, resulting in early strength development. However, primary steel production is gradually declining, and the increasing demand for GGBS has raised concerns regarding cost and long-term availability [7-8]. Thus, researchers have partially focused on alternative industrial by-products as supplementary materials to replace GGBS and maintain sustainable production in the future.

The large volume of stone wool waste requires proper storage; if stored in open areas, it may pollute the air, groundwater, soil, and plants. Stone wool kiln ash (SWKA) is a silica-rich by-product of stone wool insulation production [9]. Pavlin et al. [10] reported that the pozzolanic reactivity of mineral wool residues depends on their chemical composition, amorphous phase content, particle size distribution, and curing conditions. On the other hand, supplementary silica is used to enhance geopolymerization reactions. Silica fume (SF), a by-product of the production of silicon metal or ferrosilicon alloys, consists of almost amorphous silica. Earlier studies [4-6] reported that the high reactivity and extremely fine particle size of SF result in matrix densification, reduced porosity, and enhanced mechanical properties in alkali-activated binders.

Despite growing interest in alternative aluminosilicate precursors, the feasibility of using SWKA as a partial replacement for GGBS in geopolymer systems has not yet been systematically investigated. This study examines the fresh and mechanical properties of geopolymer-based mortars using GGBS as the primary binder, with SF replacing GGBS and varying levels of SWKA. The incorporation of SWKA was investigated with respect to workability, initial setting, flexural strength, and compressive strength. Geopolymer-based specimens were compared with cementitious mixtures to comprehend the feasibility of using SWKA as an alternative precursor to OPC.

2 Materials and Methods

2.1 Materials

In this study, two binder systems were investigated: OPC (CEM I) based mortars and alkali-activated geopolymer mortars. CEM I 42.5 R was selected for the cement-based mixtures, and GGBS served as the main precursor in geopolymer mixtures**.** SWKA was incorporated at different GGBS replacement levels. SF and SWKA were included as supplementary materials in both cement-based and geopolymer mortars. In addition, Class F fly ash (FA) was introduced as an additional series in the cement-based mixtures. NaOH pearls with 99% purity were used as the alkaline activator. Standard CEN sand conforming to TS EN196 was used as the fine aggregate in all the mixtures. The sand-to-binder ratio was kept constant. A polycarboxylate ether-based superplasticizer, Sika Visco Crete PC-61, was added to selected geopolymer mixtures to improve workability. For simplicity, Portland cement, GGBS, and SWKA will be abbreviated as C, G, and WA in the following mixture designs.

The mineralogical composition of the raw materials was determined by X-ray diffraction analysis and is presented in Figure 1. Fly ash exhibited crystalline phases corresponding to quartz (Q), mullite (M), hematite (H), and magnetite (Mag), as well as an amorphous aluminosilicate phase that contributes to long-term strength through pozzolanic activity. GGBS showed an amorphous hump at 20 $^{\circ}$-35 $^{\circ}$ 2θ, indicating a predominantly glassy structure. Alkaline activation of GGBS indicates high reactivity due to the presence of the amorphous

calcium aluminosilicate phase. The high amorphous content from calcium aluminosilicate indicated a potential for alkali activation. The XRD pattern of silica fume shows a broad, diffuse peak associated with amorphous SiO_2, confirming its amorphous nature. The absence of crystalline phases suggests high silica reactivity, which can promote matrix densification through pozzolanic activity and the filler effect. On the other hand, SWKA exhibited both crystalline and amorphous characteristics of calcium-magnesium aluminosilicate minerals; the main crystalline phases identified were gehlenite (G), akermanite (A), and merwinite (Me). The presence of calcium- and aluminosilicate-bearing phases suggests that SWKA may undergo partial dissolution, releasing Ca, Si, and Al species that actively contribute to alkaline reactions [11-12].

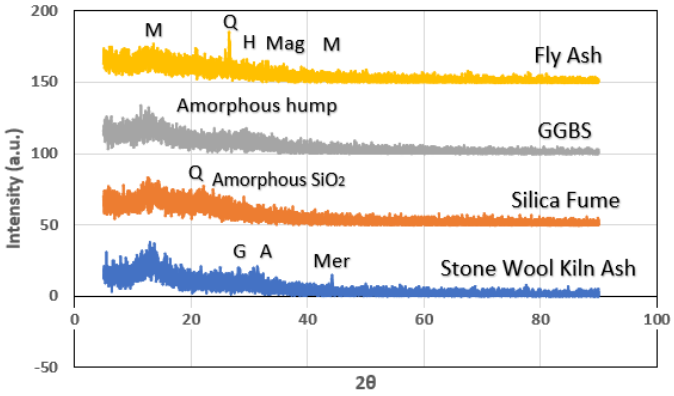

Fig. 1 XRD results of binding materials (M= Mullite, Q= Quartz, H= Hematite, Mag= Magnetite, G= Gehlenite, A= Akermenite, Mer= Merwinite)

2.2 Mix Proportions

Four cement-based mortars were produced: a control OPC mortar, and three mixtures in which 30% of OPC (135 g) was individually replaced by SF, SWKA, and FA, e.g., 70% C + 30% SF, 70%C+30% WA, 70%C+30%FA. The total binder was kept constant at 450 g, with a water-to-binder ratio (*w/b*) of 0.50 and a sand content of 1350 g. Superplasticizer (6 g) was used to improve workability only in 30%SF and 30%SWKA replacements.

For the geopolymer-based mortars, the total binding material was also kept constant at 450 g. GGBS was used as the main precursor and was activated using a 7 M NaOH solution prepared with 67.5 g NaOH and 225 g water, together with 1350 g of sand. GP_100%G, which is composed of 450 g of GGBS, was prepared as a control geopolymer mixture. For the other four mixes (GP_90%G+10%SF, 80%G+10%SF+10%WA, 70%G+10%SF+20%WA, 60%G+10%SF+30%WA), GGBS was progressively replaced by SWKA while keeping the SF content constant at 45 g. The dosage of the superplasticizer varied with the mixture composition. No superplasticizer was added to the control sample. 4.5 g of superplasticizer was used in GP_90%G+10%SF to improve the workability. 10 g of superplasticizer was incorporated into the other three geopolymer mixtures due to declining workability.

Table 1 Cement-based and geopolymer-based mixtures

Mixtures	Binding materials	Portland cement (OPC)	Ground gran. blast furnace slag (GGBS)	Silica fume	Stone wool kiln ash (SWKA)	Fly ash
		C	G	SF	WA	FA
Cement-based mixtures						
70%C+30%SF		315 g		135 g		
70%C+30%WA		315 g			135 g	
70%C+30%FA		315 g				135 g
Geopolymer mixtures						
GP_100%G	450 g		450 g			
GP_90%G+10%SF			405 g	45 g		
GP_80%G+10%SF+10%WA			360 g	45 g	45 g	
GP_70%G+10%SF+20%WA			315 g	45 g	90 g	
GP_60%G+10%SF+30%WA			270 g	45 g	135 g	

2.3 Mixing Procedure

The cement-based mortars were prepared in accordance with ASTM C305. The binding materials were first dry-mixed at low speed (140 rpm) for 30 s. Water was then added, and the mixture was mixed for an additional 30 s at low speed and 30 s at high speed (240 rpm). Afterward, the mixing bowl was taken out and scraped for 90 s. The mortar was then mixed again at a higher speed for 60 s.

The geopolymer-based mortars were first dry mixed at low speed for 30 s. When needed, the superplasticizer was dissolved in the mixing water. NaOH pearls were dissolved in water to ensure complete dissolution before being added to the dry precursor mixture, and the mixture was mixed for 30 s after the addition. Standard CEN sand was gradually added, and the mixture was mixed until a homogeneous mortar was obtained.

2.4 Test Methods

Workability was evaluated using a flow table in accordance with ASTM C1437. The setting behavior was assessed using a Vicat apparatus, and the initial setting time was determined by needle penetration. The tests were conducted at ambient conditions.

Fresh mortar mixtures were cast into molds and compacted to minimize the entrapped air. The specimens were cured at 30 ºC and 50% RH until testing at 7 and 28 days. Mechanical performance was evaluated using compressive strength tests on an electromechanical universal hydraulic testing machine (UTEST Material Testing equipment, Turkey). The flexural strength was determined by a three-point bending test.

3 Results and Discussion

3.1 Workability of designed geopolymer mortars

In the geopolymer-based series, as SWKA content increased, flowability decreased (Figure 2). Replacing GGBS's glassy morphology with SWKA, which has surface roughness and an angular particle shape, ultimately increased internal friction and water demand. SF addition also reduced the availability of free water due to its ultrafine particle size. The flow diameter of the cement-based samples ranged from 16.25 to 18.25 cm. The addition of FA yielded the highest value at 18.25 cm due to its spherical morphology and reduced internal friction [13].

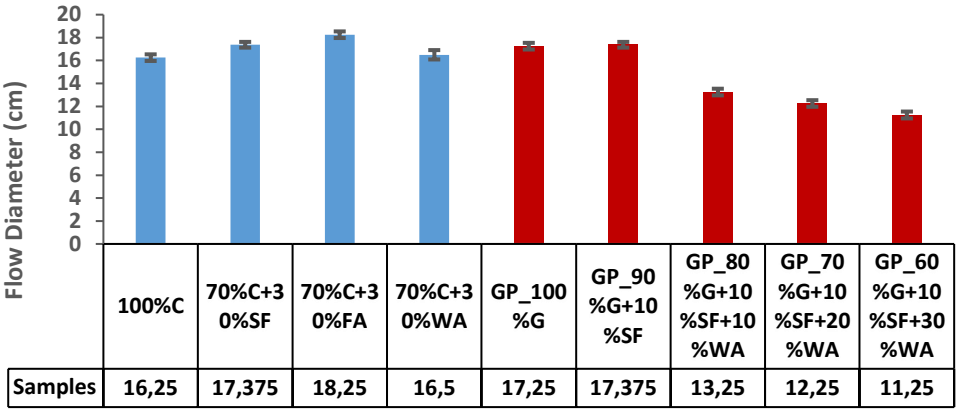

Fig. 2 Workability of mixtures (C=Cement, SF=Silica fume, WA=SWKA,Stone wool kiln ash, G=GGBS)

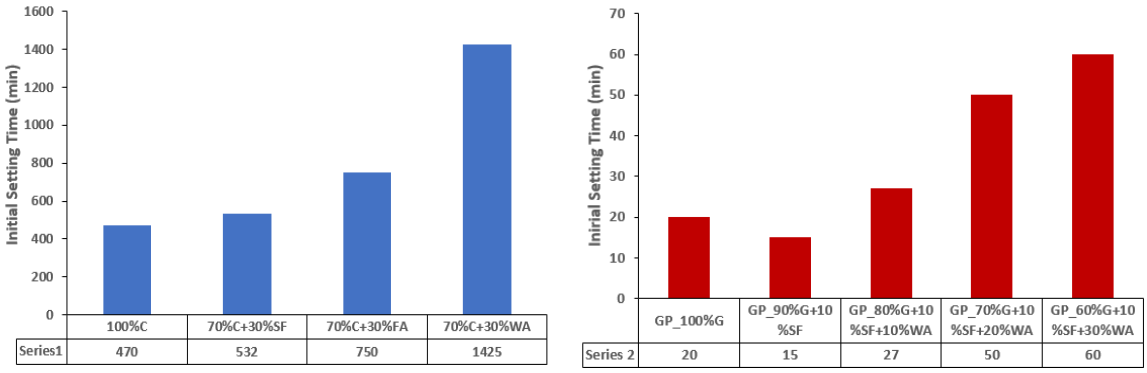
3.2 Initial setting time of geopolymer binders

The initial setting times of the cement and geopolymer-based pastes are presented in Figure 3. The cement-based pastes had significantly longer set times (470 min to 1425 min) than the geopolymer-based pastes (15 min to 60 min) due to differences in cement hydration and alkali activation. The 70%C+30%SF sample exhibited a longer setting time than the control 100%C. This phenomenon is attributed to the higher quantity of SF than of $Ca(OH)_2$, namely CH or portlandite, which binds to form C-S-H gel. Thus, SF acts as a filler rather than a chemical binder in the early hours. In the geopolymer-based series, there is rapid dissolution of Si-O-Si bonds due to a high-pH activator and the amorphous nature of SF, which has ultrafine particles. This behavior is likely due to SF combining with dissolved calcium and aluminum from the slag, thereby promoting the formation of C-A-S-H and N-A-S-H gels [14]. FA and SWKA prolonged the initial setting due to their relatively lower early-age reactivity compared to Portland cement. Based on XRD analysis, SWKA contains gehlenite, akermanite, and merwinite, whose relatively slow dissolution rates may contribute to delayed early-age reactions. Their slower dissolution may restrict the availability of Ca, Si, and Al at early ages, thereby limiting reaction product formation and delaying the densification of the reaction matrix [12]. In addition, an increasing amount of SWKA extended the initial setting time (27 to 60 min) due to the reduction in the highly reactive, amorphous GGBS.



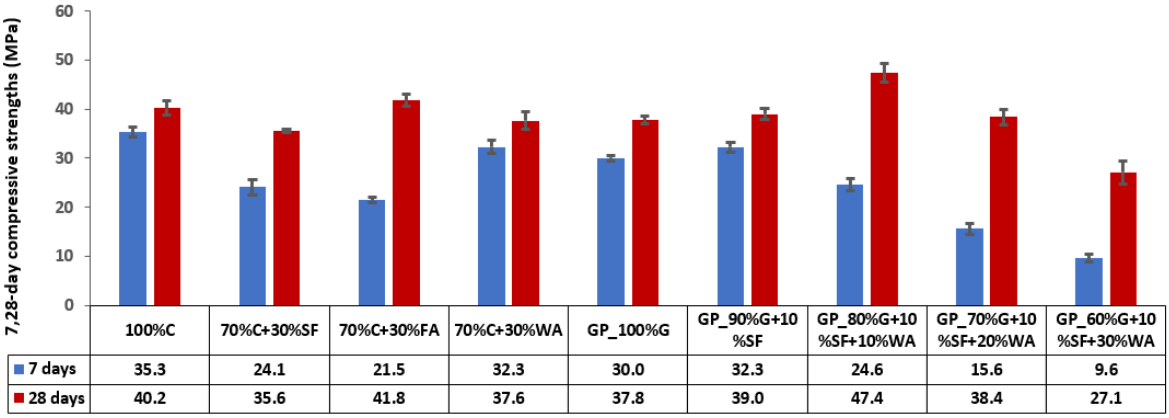


Fig. 3 Initial setting time of (a) cement-based pastes (b) geopolymer-based pastes

3.3 Compressive Strength

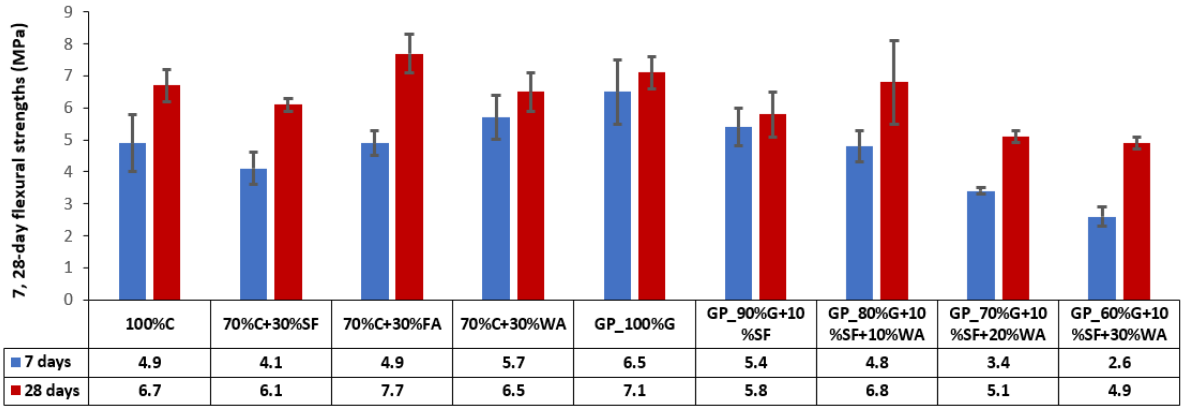
The highest 7-day compressive strength among the cement-based series was achieved for the 100%C, reaching 35.3 MPa due to its rapid hydration. The incorporation of supplementary materials reduced the 7-day strengths to 24.1 MPa, 21.5 MPa, and 32.3 MPa for 70%C+30%SF, 70%C+30%FA, and 70%C+30%WA, respectively. The strength reduction in the 30% SF mixture can be attributed to the high replacement level. Several studies [15-16] reported the optimal SF replacement range to be 10-22%. They noted a negative effect of higher replacement levels due to reduced cement content and a lack of CH to bind in the early-age period. Lower workability of the 70%C+30%SF mixture resulted in compaction problems that might have decreased compressive strength as well. These align with Khoso et al. [16], who noted a gradual decline in both strength and workability beyond 10% SF; in their study, the 7-day strength with a 30% SF replacement dropped by 52.9% compared to 100%C. A 30% FA incorporation had the lowest compressive strength (21.5 MPa). FA exhibits slow early-age pozzolanic reactivity and subsequently reacts with CH to form additional C-S-H gel. A higher compressive strength than that of the SF and FA mixtures was achieved with 30% SWKA (32.3 MPa). Early-age compressive strength suggests that SWKA may have enhanced the hydration process through filler and nucleation effects, likely promoting early hydration and improving particle packing.

For geopolymer samples, the highest 7-day compressive strength (32.2 MPa) was achieved with GP_90%G+10%SF. The incorporation of 10% SF slightly increased the compressive strength compared to GP_100%G (30 MPa). The filler effect of SF, due to its ultrafine particles, promoted the formation of a denser matrix. As SWKA replacement levels increased, early-age strengths gradually decreased with 10%SF+10%WA (24.6 MPa), 10%SF+20%WA (15.6 MPa), and 10%SF+30%WA (9.6 MPa). This reduction in strength might have been related to the lower reactivity of SWKA compared with GGBS, resulting in slower aluminosilicate dissolution and thus reduced formation of geopolymer gels. As the replacement levels of SWKA increase, the reduced availability of calcium due to lower GGBS content leads to a less dense microstructure, thereby lowering compressive strength.

	100%C	70%C+30%SF	70%C+30%FA	70%C+30%WA	GP_100%G	GP_90%G+10%SF	GP_80%G+10%SF+10%WA	GP_70%G+10%SF+20%WA	GP_60%G+10%SF+30%WA
7 days	35.3	24.1	21.5	32.3	30.0	32.3	24.6	15.6	9.6
28 days	40.2	35.6	41.8	37.6	37.8	39.0	47.4	38.4	27.1

Fig. 4 7, 28-day compressive strengths in cement-based and geopolymer-based mortar (C=Cement, SF=Silica fume, WA=SWKA, Stone wool kiln ash, G=GGBS)

Regarding the 28-day compressive strength, 30% SF yielded 35.6 MPa, a 47.7% increase. The difference between the 7-day and 28-day might be due to SF not reacting on its own and instead consuming CH from cement hydration to form C-S-H gels. At an early age, a 30% SF mixture may not have fully reacted until sufficient CH had accumulated. The 30% FA mixture, with the lowest strength (21.5 MPa) at 7 days, achieved the highest strength (41.8 MPa) at 28 days, with a 94.4% increment. FA reacts slowly at an early age, and continuous pozzolanic reactions with CH refine the pore structure and create C-S-H gels. 30% SWKA mixture reached



37.6 MPa at 28 days, with only a 16.4% increase after 7 days. The results of 30% SWKA indicate that it is a promising supplementary cementitious material for partial replacement of cement to achieve satisfactory mechanical performance.

The geopolymer-based control sample (GP_100%G) exhibited a 26.0% increase in compressive strength from the 7th day to the 28th day. GP_90%G+10%SF increased strength by 21% (39 MPa) due to ongoing geopolymerization and additional reaction products from the SF content. 80% GGBS with 10% SF and 10% SWKA attained the highest compressive strength (47.4 MPa). An optimized level of SWKA is likely associated with better particle packing while also providing an additional source of aluminosilicates. The effect of SWKA is strongly dependent on its replacement level. 10% SWKA was beneficial to later-age strength; the higher replacement levels could not compensate for the reduction in GGBS content. 20% SWKA reduced strength compared to 10% SWKA; however, the increment in 28-day strength relative to 7-day strength was 146.2%. 30% SWKA showed the highest relative strength gain, increasing from 9.6 to 27.1 MPa (+182.3%) between 7 and 28 days; however, the 28-day strength remained the lowest in comparison to the other geopolymer mixtures. This situation explains further that even though SWKA exhibited considerable later-age strength development, its excessive SWKA replacement limited the overall mechanical performance. Late reaction can also be correlated with phases such as akermanite, gehlenite, and merwinite, which possess high chemical stability and resist early rapid reactions [12], a trend that also correlates with Vicat test results.

3.4 Flexural Strength

For the 7-day early strength in cement-based mortars, the highest flexural strength was observed in 70% C + 30% SWKA at 5.7 MPa, followed by 100% C and 70% C + 30% FA at 4.9 MPa; 30% SF incorporation exhibited the lowest value (4.1 MPa) (Figure 5). 30% SF exceeds the optimum range by reducing the amount of cement available for early hydration. Lower workability and higher water demand due to the surface area of SF also negatively affected early-age flexural strength. 30% FA replacement achieved performance similar to 100% C; incorporating FA did not adversely affect early-age flexural strength, although the FA mixture exhibited better long-term strength due to its pozzolanic reaction. The highest strength (5.7 MPa) was observed in the 30% SWKA sample, exceeding 100%C by 16%. SWKA positively affected the early-age flexural strength in the cement-based series.

In the 7-day geopolymer series, the highest strength (6.5 MPa) was achieved in the 100% G control sample, with a gradual decline in the early strengths of the other mixtures. This phenomenon can be attributed to alkali-activated GGBS reacting rapidly and promoting the formation of calcium-aluminosilicate hydrates (C-A-S-H), thereby making the matrix cohesive and indicating superior performance at early ages. On the contrary, decreasing strength in 90%G+10%SF may be attributed to less calcium content and changes in reaction product chemistry, as silica fume modifies the silicate structures of C-S-H and aluminosilicate gels [17]. SF's fine particles and high specific surface area may increase the demand for alkaline activator liquid, thus reducing the water available to dissolve slag particles at early ages. The mixtures with 10%, 20%, and 30% SWKA undergo a slow alkaline dissolution due to their high crystalline stability. When GGBS is partially replaced by less reactive SWKA, the reduced GGBS may decrease the availability of calcium, aluminum, and silicon ions at early ages [18].

	100%C	70%C+30%SF	70%C+30%FA	70%C+30%WA	GP_100%G	GP_90%G+10 %SF	GP_80%G+10 %SF+10%WA	GP_70%G+10 %SF+20%WA	GP_60%G+10 %SF+30%WA
7 days	4.9	4.1	4.9	5.7	6.5	5.4	4.8	3.4	2.6
28 days	6.7	6.1	7.7	6.5	7.1	5.8	6.8	5.1	4.9

Fig. 5 7, 28-day flexural strengths in cement-based and geopolymer-based mortar

Regarding the 28-day cement-based series, the highest flexural strength (7.7 MPa) was achieved with a 30% FA replacement (a 57.1% increase compared to 7 days). The 30% SWKA mixture reached 6.5 MPa, exceeding the 30% SF mixture (6.1 MPa). At longer durations, hydraulic and pozzolanic reactivity increase its strength. However, compared with the FA mixture, SWKA's increase was moderate over the 28 days.

For the geopolymer-based series, the highest flexural strength (7.1 MPa) was attained in 100%G control samples; however, the strength gain (9.2%) was minimal. The highest flexural increment (50%) was observed in 10%SF+20%WA, following 10%SF+10%WA (41.7%) replacements. These results indicate that both FA and SWKA react mainly at a late age.

4 Conclusions

In this study, SWKA was investigated as an alternative aluminosilicate precursor in cement-based and alkali-activated geopolymers. The effects of replacing GGBS with SWKA in the presence of SF were evaluated for fresh properties, setting behavior, and mechanical performance in cement-based and alkali-activated geopolymers.

- In the cement-based series, 30% FA replacement achieved the highest compressive strength (41.8 MPa) at 28 days, exceeding the 100%C control (40.2 MPa). Pozzolanic reaction and filler effect of fly ash were observed at longer curing durations, which promoted a denser microstructure.
- The 70%C+30%SF sample exhibited a slightly lower compressive strength (35.6 MPa) than 100C, due to reduced workability and increased water demand from ultra-fine silica fume particles.
- An 80% GGBS + 10% SF + 10% SWKA mixture yielded the highest compressive strength (47.4 MPa) at 28 days. Compared to the 100% GGBS control sample, the 25% higher strength indicated a beneficial effect of optimal SWKA incorporation.
- 30% SWKA replacement for the geopolymer series adversely affected the mechanical characteristics. This suggests an excessive amount of SWKA, limiting the available calcium phases from GGBS and gel formation.
- The highest flexural strength (7.1 MPa) was achieved with the 100% GGBS control mixture. 10% SF + 10% SWKA replacement achieved the second-best performance, reaching 6.8 MPa at 28 days.

The results show that SWKA can be incorporated into GGBS-based geopolymers at optimal replacement levels. Using SWKA, this utilization of waste-derived by-products can reduce dependence on OPC while supporting sustainable, low-carbon construction materials. Further durability and microstructural investigations (e.g., SEM, pore-structure analysis) are

recommended to confirm the reaction mechanisms proposed here, based on the XRD and mechanical test results.

ACKNOWLEDGEMENTS

Abstract. This study investigates the use of recycled concrete powders as a cement substitute in mortar. The effect of using fly ash in combination with recycled concrete powders (RCP) in concrete powder mixtures was also examined. Four different RCPs with varying compositions were used in the study; three were prepared in the laboratory, while one was obtained from actual concrete. Crushed sand was incorporated at volumetric ratios of 0% (ARCP), 20% (ARCF20), and 40% (ARCF40) into the laboratory-prepared artificial concrete waste whilst the aggregate content of the actual concrete waste powder (RCF) was unknown. The materials produced in the laboratory were milled after ninety days of curing. For comparison, reference mortar containing CEM I, CEM II mortar, and mixtures with fly ash replacing 20% cement were prepared. The specific gravity and blaine fineness of RCPs varied from 2.3 to 2.57 g/cm³ and from 4300 to 4750 cm²/g, respectively. A total of 12 mixtures were prepared according to ASTM C311. In fresh state, unit weight and flow tests; and in the hardened state, 2, 7, and 28 days compressive and flexural tests were applied. Based on the results, it can be concluded that mixtures containing recycled concrete powder when used alone, increase the water demand, therefore their use in combination with fly ash is appropriate. Compressive strength activity of 20FA, 10ARCF2010FA, 10ARCF4010FA and 10RCF10FA mixtures provided 75% that of the reference mixture and can be used as pozzolan in concrete applications.

Keywords: Recycled concrete powder; cement replacement; strength activity index; alternative cementitious materials.

1 Introduction

The production of Portland cement is closely related to both natural resource consumption and carbon dioxide emissions. Consequently, the use of supplementary cementitious materials (SCMs) or alternative mineral admixtures that can substitute for cement offers the possibility of directly reducing the clinker ratio. The development of cement-based materials has also become an important element for more sustainable cement production. However, the availability of SCMs can vary depending on the source and production processes. This situation increases the need for studies related to the search for SCMs. Construction and demolition waste (CDW) constitutes a potential secondary resource for the cement and construction industries. Concrete waste contains both mineral aggregates and cementitious phases. By processing this waste and incorporating it into cement production, it is possible to produce fine materials containing hydrated cement paste. These fine materials are generally referred to as recycled concrete dust. Studies in the literature have shown the potential for recovering and using fractions containing hydrated cement recovered from demolished concrete [1-4]. The use of such materials is consistent with a circular approach because it involves recovering material from concrete waste and reintroducing it into the production chain [5]

Despite this potential, the behavior of using recycled concrete powder in place of cement is largely dependent on the material's composition and processing history. RCP may contain hydrated cement paste and fine aggregate. Composition dependent differences can affect its physical, chemical and mineralogical properties. This different aggregate content provides the opportunity to provide insight into the effect of the concrete powder source and composition. Previous research has highlighted the importance of determining and characterizing the composition to understand the effect of using recycled concrete powders in cement-based materials on performance [6-8].

The substitution of recycled concrete powders for cement in the mortar phase can affect fresh state and mechanical properties. Recycled concrete powders differ from Portland cement in terms of fineness, specific gravity and surface properties. Therefore, the water demands necessary to achieve a certain workability may vary. Changes in water demands can affect the pore structure and mechanical performance in the hardened state. Furthermore, the reduction in clinker content due to the hydrated phases and aggregate content in the material substituted for Portland cement will cause a decrease in the amount of clinker. Therefore, reductions in strength may occur in mixtures with a high percentage of recycled concrete powder substitution. Due to these effects, it can be said that the performance of recycled concrete powder depends not only on the substitution percentage but also on the properties of the material [8-10]. Fly ash (FA) can be a suitable complementary cementitious material to be considered together with recycled concrete powder.

The aim of this study is to compare the physical, chemical and mineralogical properties of materials and performances of twelve different mortar compositions, including CEM I Portland cement, CEM II limestone cement, a mixture with 20% fly ash replacement for Portland cement, four 20% replacement recycled concrete powder mixtures, four 10% recycled concrete powder and 10% fly ash hybrid mixtures, and finally a 20% recycled concrete powder and 10% fly ash hybrid mixture, as well as four different types of recycled concrete powder, on their fresh and hardened state performance. Furthermore, the strength activity index (SAI) specified in the ASTM C311 (Standard Test Methods for Sampling and Testing Fly Ash or Natural Pozzolans for Use in Portland-Cement Concrete) standard was used as a reference in determining the strength activity of pozzolanic materials substituted for cement. According to this standard, the material(s) replacing 20% of the cement must provide at least 75% of the 28-day strength of the reference Portland cement mixture. In addition, the water demand associated with each type of recycled concrete powder, the effect of the type of recycled concrete powder

on 28 days compressive and flexural strength and the effect of replacing half of the recycled concrete powder with fly ash and replacing it entirely with recycled concrete powder were investigated. The main contribution of the study is to establish a link between hybrid systems containing only recycled concrete powder and those containing both recycled concrete powder and fly ash at a consistent replacement ratio.

2 Materials and Methods

The experiment utilized recycled concrete powder with four different compositions. ARCP represents hydrated cement paste. ARCF20 and ARCF40 contain 20% and 40% crushed sand, respectively. These three materials were produced in a laboratory setting and represent recycled concrete powders with different compositions that can be obtained from real demolition waste through a specific process. RCF was obtained from real concrete waste and represents the powder of demolished concrete obtained from real demolition waste. All four RCPs were selected to compare their effects on mortar performance. In the experiments, CEM I Portland cement was used as the main reference binder material. CEM II was also present in the experimental setup as a different reference. Fly ash was used alone as a 20% substitute in one series, while in other hybrid mixtures, fly ash was used as a 10% substitute alongside the concrete powder to replace cement.

Table 1. Chemical and physical analysis.

Chemical Components (%)	**ARCP**	**ARCF20**	**ARCF40**	**RCF**	**PC**
CaO	53.1	54.3	54.0	17.0	65.9
SiO_2	16.1	12.0	9.1	50.5	21.0
Al_2O_3	3.7	2.5	1.8	9.5	5.2
Fe_2O_3	2.9	2.0	1.3	4.2	3.8
MgO	0.9	0.8	0.7	2.2	0.8
Na_2O	0.2	0.2	0.2	1.8	0.2
K_2O	0.3	0.2	0.2	1.4	0.5
Cr_2O_3	0.1	-	-	-	-
SO_3	3.1	2.1	1.4	0.5	0.4
Mn_2O_3	0.1	-	-	0.1	-
F	0.1	0.1	0.1	0.2	-
P_2O_5	0.2	0.1	0.1	0.1	-
LOI	20.5	26.2	32.1	11.9	2.1
Total	100.7	100.2	100.8	99.0	99.9
Specific Gravity (g/cm^3)	2.30	2.40	2.50	2.57	3.12
Fineness (cm^2/g)	4750	4500	4500	4300	3700

Before mortar production began, the physical, chemical, and mineralogical properties of the recycled concrete powders to be used were determined. Specific gravity and blaine specific

surface area tests were performed for physical characterization. The chemical composition was determined by X-ray fluorescence (XRF) in Table 1. The mineralogical composition was determined by X-ray diffraction (XRD) in Table 2.

Table 2. Mineralogical analysis results with the rietveld method.

Phases (%)	ARCP	ARCF20	ARCF40	RCF
Tobermorit (CSH)	80.4	63.4	51.2	14.3
Portlandit (CH)	15.1	16.7	12.3	-
Calcium Carbonate	3.9	18.8	36.0	20.0
Kuzelite	0.6	0.5	-	-
Ettringite	-	0.5	0.3	0.3
Calcium Carboaluminate	-	0.1	0.1	-
Quartz	-	-	-	33.3
Albite	-	-	-	29.1

The specific gravities of RCPs ranged from 2.30 to 2.57. This value is smaller than the specific gravity of Portland cement used in the experiments. ARCP showed the lowest specific gravity while shows the highest blaine fineness. RCF, on the other hand, showed the highest specific gravity while exhibiting the lowest blaine fineness (Table 1). These values affect the water demand in the mixtures where the materials are used. XRF results clearly show a significant difference between artificial RCPs and RCF. ARCP, ARCF20, and ARCF40 have a CaO content exceeding 50%. This is due to their richness in hydrated cement paste. In contrast, RCF contains a high amount of aggregate based silica sources, resulting in a SiO_2 content exceeding 50%. It yielded a result close to 17% in terms of CaO content. When the loss on ignition values were examined, the reason for the higher number of RCPs containing 20% and 40% crushed sand by volume is the use of limestone-based sand in their composition (Table 1).

XRD with the rietveld method results show that the RCPs have different compositions. ARCP, since it contains only hydrated cement paste, contains 80.4% tobermorite or calcium silicate hydrate (CSH) and 15.1% portlandite according to the XRD Rietveld analysis results. With increasing limestone-based crushed sand content, the CSH ratios decreased to 63.4% and 51.2% in ARCF20 and ARCF40, respectively. Calcium carbonate phase contents, on the other hand, increased from 3.9% to 18.8% and 36% in artificial RCPs. RCF has different mineralogical properties from artificial materials. While the CSH content is limited to 14.3%, it contains quartz and other components. This difference in composition is related to the high aggregate ratio in RCF (Table 2).

The experimental study was designed and tested in accordance with the general approach of ASTM C311 for alternative cement substitutes. Twelve different mortar mixtures were designed with a constant sand content of 1375 grams according to the ASTM C311 standard (Table 3). Reference CEM I, CEM II, 20% substitute, and 10% binary hybrid mixtures were prepared according to the standard with a binder content of 500 grams. Importantly, the water content was not kept constant as required by the standard. Instead, it was adjusted to remain 5 mm below or above the flow value provided by the CEM I potland cement mixture with 242 grams of water in its fresh state. This ASTM C311 SAI approach allows for an assessment of the fresh water requirement of each substituted material. Consequently, differences in mechanical performance are not solely dependent on chemical reaction and substitution ratio but should also be evaluated according to the water/binder (w/b) ratio of the mixture, the

properties of the RCP used in the mixture, and the structure of the binder phase (Table 3). The mixture codes were designed according to the mass percentages of the constituent materials. In the coding system, the numerical value indicates the mass percentage of the corresponding material, while the letters identify the material type. For instance, 100CEMI and 100CEMII mean that these cements are used 100% in these mixtures. In others, they represent the percentage of cement substitution. For example, 10ARCP10FA means that a total of 20% cement is replaced by a hybrid mixture of 10% recycled concrete powder and 10% fly ash.

Table 3. Mix_proportions.

Mixture Code	Cement (g)	Water (g)	Sand (g)	Fly Ash (g)	RCP (g)	W/B
100CEM I	500	242	1375	0	0	0.48

The flow diameter and unit weight measurements were taken in the prepared mortars. Flow diameter was done to evaluate the workability obtained after adjusting the water content of the mixture. Unit weight indicated the effect of recycled concrete powder and fly ash on mortar density. The set mortars were subjected to flexural and compressive tests after 2, 7 and 28 days.

3 Findings

All twelve mixtures were produced according to a fixed nominal binder quantity. The water content was adjusted to achieve the target consistency. Therefore, the water/binder (w/b) ratios are related to the binder phase content. Mixtures containing recycled concrete powder generally required more water than the reference mixture (Fig. 1).

The CEM I reference mixture required the lowest water demand. Mixtures containing RCP showed higher water demands. This difference is significant because increased water demand can increase the void ratio in the hardened state and reduce the density of the matrix. Consequently, it can decrease mechanical performance. When comparing the strengths of mixtures containing RCP, not only the percentage of substitution but also the w/b ratio should be considered (Fig. 1).

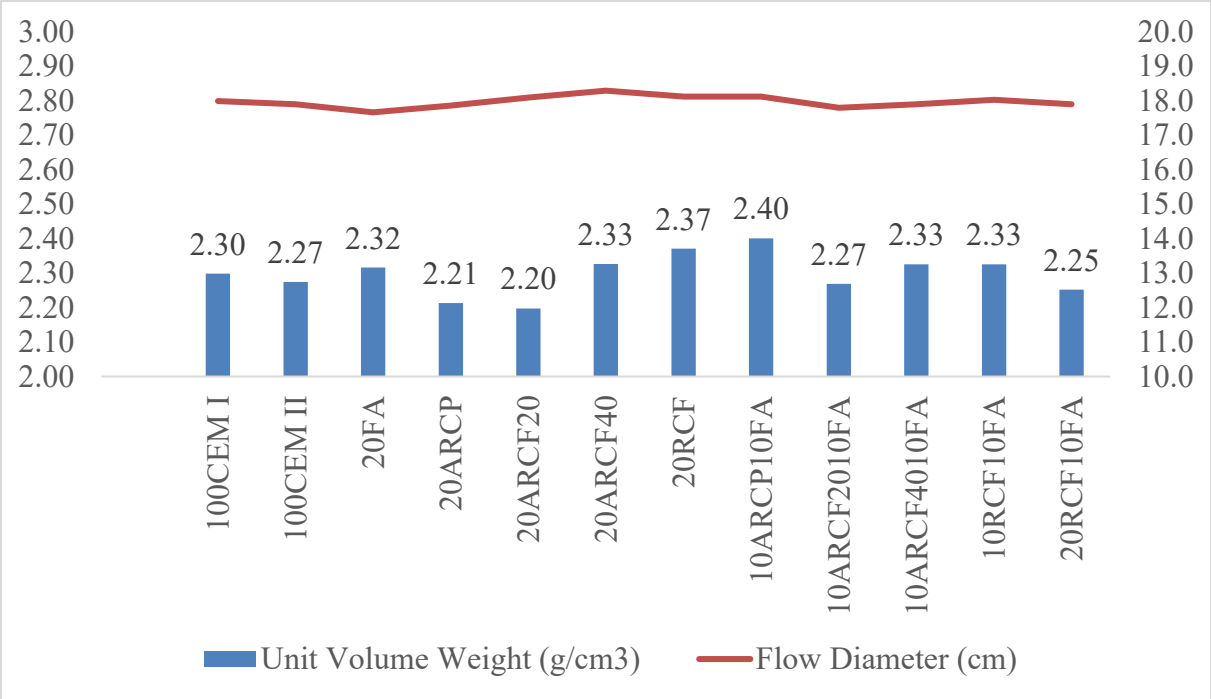

Fig. 1. Unit volume weight and flow diamater results of mixtures.

The reference CEM I mixture of compressive strength reached 31.8 MPa in 2 days, 58.1 MPa in 7 days, and 67.9 MPa after 28 days. The reference CEM II mixture reached 58 MPa in 28 days. The mixture with 20% fly ash substitution showed slower early age development, reaching 24.3 MPa in 2 days, 43.4 MPa in 7 days and 51.2 MPa in 28 days. Mixtures containing only 20% RCP substitution showed lower strength performance compared to the reference. The 20ARCP, 20ARCF20, 20ARCF40, and 20RCF mixtures reached strengths of 40.8 MPa, 45.1 MPa, 44.3 MPa, and 29.3 MPa, respectively. Among the RCP containing mixtures, the 20RCF mixture showed the largest decrease in strength (Fig. 2).

Hybrid mixtures containing fly ash and recycled concrete powder yielded different results. 10ARCP10FA reached 47.2 MPa at 28 days, 10ARCF2010FA 51.7 MPa, 10ARCF4010FA 54.3 MPa, and 10RCF10FA 52.5 MPa. Therefore, hybrid mixtures showed improved strength performance because they also reduced water requirements in the presence of fly ash (Fig. 2).

When flexural strengths were evaluated, the CEM I reference reached 10.2 MPa at 28 days, while the CEM II mixture reached 8.7 MPa. The 20% fly ash mixture reached 8.9 MPa. In systems containing only RCP, 20ARCF20 showed the highest 28-day flexural strength at 8.8 MPa, while 20RCF showed the lowest value at 6.5 MPa. Various RCP types in hybrid mixtures showed different performances. 10ARCF2010FA and 10ARCF4010FA reached values of 8.5 and 8.6 MPa, respectively after 28 days. These results show that the positive effect of hybridization is not limited to compression alone and can also be observed in bending response; however, the hybrid mixtures did not exceed the CEM I reference value after 28 days (Fig. 3).

Strength increases between 7 and 28 days are a significant indicator of pozzolanic behavior. The CEM I reference mixture showed a 16.8% increase, while the CEM II mixture showed a 9.2% increase. The 20% fly ash mixture showed a 18% increase. For mixtures containing only RCP, the increases were 35.2% for 20ARCP, 39.7% for 20ARCF20, 43.5% for 20ARCF40, and decrease were -11.8% for 20RCF. Hybrid mixtures showed increases of 26.4%, 30.9%, 31.0%, and 14.3%, respectively. Particularly noteworthy strength improvements were observed in hybrid ARCF systems. Their final 28 days strengths showed higher compressive and flexural strengths compared to mixtures containing only RCP. This suggests that fly ash containing mixtures provided more favorable strength development (Fig. 2 and Fig. 3).

A direct comparison between systems containing 20% RCP and those containing 10% RCP along with 10% fly ash is one of the most important findings of the experiment. For ARCP, increase was from 40.8 to 47.2 MPa or 6.4MPa, for ARCF20, the corresponding increase was from 45.1 to 51.7 MPa, or 6.6 MPa. For ARCF40, the increase was from 44.3 to 54.3 MPa or 10 MPa. For RCF, the increase was from 29.3 to 52.5 MPa, or 23.2MPa. The amount of improvement in strength with the use of fly ash was least in the RCP type ARCP and best in the RCF because the 20RCF mixture had the lowest 28 days strength among the four different RCP substitutions. Therefore, it can be said that the addition of fly ash appears to be more beneficial in systems with weaker RCF (Fig. 2).

A similar trend was observed in flexural strengths. Hybrid mixtures improved the 28 days flexural strength for ARCP, ARCF40, and RCF compared to their counterparts containing only RCP, while the ARCF20 pair showed only a small difference. It can be said that hybrid systems can improve the overall mechanical performance (Fig. 3).

The results show significant variability depending on the source of the material used in the mixture. Therefore, there are strength differences among four different RCP mixtures substituted with the same 20%. When the characterization results provided for RCPs are evaluated against mechanical results, differences in specific gravity, fineness, chemical composition, and mineralogical structure can affect the water requirement and the contribution of RCPs to the binder phase in mixtures produced with these materials (Fig. 2 and Fig. 3).
